THE JOURNAL OF

The Institution of Electrical Engineers

VOL. 62.

INAUGURAL ADDRESS

By Dr. ALEXANDER RUSSELL, President.

(Address delivered before THE INSTITUTION, *18th October,* 1923.)

In this address a few comments are first made on the work of this Institution. A very brief survey is then given of the progress of electrical engineering since the War. Finally one or two scientific and engineering subjects in which I am specially interested are discussed.

THE INSTITUTION OF ELECTRICAL ENGINEERS.

We naturally take pride in our connection with this Institution and, through it, with the many electricians who have advanced our knowledge and applied electrical science so successfully to ameliorate the conditions of human life. Special mention must be made of Lord Kelvin and Alexander Graham Bell. Both made many inventions and founded new industries, and both are universally regarded as benefactors of humanity.

Concurrently with the phenomenal increase in our numbers we have kept in close touch with all parts of the kingdom by means of our Local Centres and Sub-Centres. Through the *Journal* our overseas members learn of the progress that we make and of the difficulties that we encounter. The Institution unites the workers in all branches of the electrical industry for mutual help and encouragement. It has always taken a leading part in the vanguard of electrical research. It takes a special interest in engineering education, recognizing that a thorough understanding of physical principles and a sound knowledge of the latest engineering developments are essential to progress.

As in duty bound, it honours all the great electricians. Its library contains many very valuable pamphlets and books which are at the disposal of engineers of every nationality. In addition to its functions as a storehouse of knowledge it does its utmost, by means of its Benevolent Fund, to assist to be self-supporting those who have fallen on evil times.

It has always been our policy to keep in close touch with our sister Institutions. Recently an advisory body founded by the Institutions of Civil, Mechanical and Electrical Engineers, and by the Naval Architects, has been formed. It is called the Engineering Joint Council. So far as we are concerned it takes the place of the Conjoint Board of Scientific Societies which has now been disbanded. It is hoped that this organization will be a help in advancing our joint interests.

Forty years ago this Institution co-operated with the Royal Meteorological Society, the Royal Institution of British Architects and the Physical Society of London in investigating the methods of protecting against damage by lightning. This Lightning Rod Conference published a valuable report in 1882. Sir Oliver Lodge, in a paper read before this Institution in 1889, showed that advances in our knowledge made it essential to alter several of the recommendations made by the Conference. Recent advances in meteorology have again revived interest in the matter. Some of the problems in connection with it are discussed later.

We are making arrangements for closer co-operation with the American Physical Society and with the Physical Society of London in producing the Physics Section of *Science Abstracts*. From every point of view this co-operation is highly desirable and we welcome it.

TRANSATLANTIC RADIO-TELEPHONY.

During last year satisfactory progress has been made in the development of transatlantic radio-telephony. It has been proved experimentally that under favourable weather conditions telephony between New York and London is perfectly satisfactory. The results published show that there are very large daily variations in the audibility and also very large seasonal variations. The assumption that the daily variation is due to the difference in the absorbing qualities of the atmosphere in daytime and night-time leads to results which agree well with the experiments. The latest results indicate that it will be necessary to use a wave-length greater

than 5 000 metres if the best voice transmission is to be obtained.

Broadcasting.

In the United States there were no fewer than 581 licensed broadcasting stations on July 2nd. But of this number about 25 per cent had ceased to operate. The reasons for their stoppage are mainly financial. In very few cases has the service been discontinued owing to a lack of appreciation by the public. In this country we have only one organization for broadcasting and it has made good progress during the past year. It is certain that, in the future, broadcasting will have an important effect on national development.

The Electric Lighting Industry.

Since the termination of the War in 1918 the section of the industry which deals with the supply of electrical energy has been very active and real progress has been made. Although during the War years, power stations had to be extended hurriedly so as to cope with the normal growth of the load, yet many of them were prohibited from getting the necessary new plant. They had therefore to run under overload conditions. Only repairs which were absolutely necessary were made. The result of this was that in the beginning of 1919 many schemes were under consideration either for the overhaul of existing or for the purchase of new plant.

During 1920 and 1922 the prices of engineering materials were very high. This naturally hindered development. Now that prices are falling to values approaching pre-War level, a large amount of generating machinery is being installed in all parts of the country. In 1920 official sanction was given for the installation of generating plant aggregating 500 000 kilowatts. In 1921, for the reasons stated above, this figure fell, but in 1922 it nearly reached the same value. Since the War several very large generating stations have been built and several others are in course of erection.

Boiler house.—In the boiler house radical developments are taking place. The possibilities of pulverized fuel are being thoroughly investigated both in this country and in America. The changes which have been made and which it is proposed to make in the working pressure of the steam would seem incredible to the older generation of engineers. The working steam pressure was gradually raised from 160 to 250 lb. per square inch. Now steam pressures of 350, 450 and even 500 lb. per square inch are not uncommon. The new station * of the Edison Electric Illuminating Co. of Boston will have boilers supplying steam at a pressure of 1 200 lb. per square inch to a 2 500-kW high back-pressure turbo-generator. The exhaust steam is reheated to 700° F. and then enters a second turbine which is of ordinary construction.

We know that as the temperature in a boiler rises the density of the water in it diminishes and the density of the steam in it increases owing to the increased pressure. When the critical temperature of 705° F. is attained the steam and water have the same density and are indistinguishable from one another. At this temperature the pressure is roughly 3 200 lb. per square inch. The water also, having no latent heat, passes quietly into the gaseous state. The English Electric Co., in association with the Benson Engineering Company of London, are making experiments at the present time * to generate steam at about 3 200 lb. pressure per square inch which, after being throttled to 1 500 lb. per square inch by means of a reducing valve and its temperature raised to about 700° F., will be used to drive a specially constructed 350-kW turbine. After being expanded in this turbine the steam will be reheated and passed at a pressure of 250 lb. per square inch to a low-pressure turbine which will be of ordinary make. That difficulties will be encountered in the manufacture of these very high-pressure turbines is certain. That economies would result from their use is equally certain. Increasing the steam pressure will secure a higher thermodynamic efficiency. It will also have the advantage of reducing the size of the steam pipes. The pioneers of the method are to be congratulated on their courage and their foresight.

Engine room.—In the turbine room the size of generating plant continues to increase. In 1918 a 6 000-kW set was considered a large unit. To-day a standard size is 15 000 kW. Several sets of 25 000 kW are in operation and in a London station now being built 35 000-kW sets are being installed. Messrs. C. A. Parsons & Co. of Newcastle are constructing a 40 000-kW set for the Commonwealth Company of Chicago, and a 60 000-kW set is being built in America.

The use of these larger sets, with the corresponding increase in the total capacity of the modern power house, has led to great improvements in switchgear. As such switchgear under modern conditions may be called on to break over a million kilowatts and under such circumstances is subjected to enormous mechanical and electrical stresses, much still remains to be done in safeguarding it from damage. The British Electrical Research Association has the problem in hand and is carrying out a series of tests on switchgear which are likely to yield important results.

Since 1918 the thermal efficiency in large power stations has almost doubled. Five years ago the ratio of the heat equivalent of the kilowatts generated to the heat equivalent of the fuel consumed, that is, the thermal efficiency, was commonly only about 10 per cent. To-day there are power stations in different parts of the country with a thermal efficiency of 18 per cent. An efficiency of 25 per cent may be attained in the not very distant future.

Power transmission.—For the transmission of electrical energy over considerable distances the use of pressures of 6 000 and 11 000 has given place to pressures of 33 000 and 66 000 volts. The cable makers of this country are to be congratulated on their successful solution of the problem of making underground cables suitable for 66 000 volts. The number of overhead lines for transmission over long distances and for transmitting energy over scattered rural districts is rapidly increasing. There are, however, indications that for power transmission in country districts cheaper systems of underground cables using 11 000 and 22 000

* *Journal of the American Institute of Electrical Engineers*, 1923, vol. 42, p. 799.

* *English Electric Journal*, vol. 2, p. 229.

volts respectively will become common. Where a single-phase system of supply is used these methods will compare favourably as regards cost with overhead lines.

Polycore cables.—The use of polycore cables for a working pressure of 33 000 volts is becoming general in large industrial areas and in cities. At a few stations, where the loads justify it, higher working pressures are used or are on the point of being used. When polyphase systems are employed there is still, unfortunately, a difference of opinion as to whether it is more advantageous to use a polycore cable or single-core cables. The leading cable manufacturers are prepared to guarantee three-core cables up to 66 000 volts, and there are already a few of these cables in use.

The supply authorities in this country favour three-core cable as it is easy to handle. In Paris a three-phase system of 60 000 volts is in operation using single-core cables. No unexpected difficulties have arisen. A very real advantage of the Paris system is that all faults are faults to earth. Hence by putting a suitable impedance coil in the earth connection it is possible to restrict the fault current to a definite value. Hence an accidental fault gives no harmful shock to the supply system.

In the United States and Canada, where electricity is in more general use than in this country, there is a demand in the great industrial cities for cables which will withstand working pressures of at least 100 000 volts. Manufacturers are seriously considering the construction of short feeders for 100 000 volts as a commercial experiment. In a few years' time the question of using these very high pressures will have become one of great urgency in this country owing to the rapid increase in the load. Should, however, the supply engineers decide on their immediate use it will be necessary to use single-core cables.

Throughout Holland 50 000 volts has been adopted as the standard pressure for primary power transmission. Overhead transmission in conjunction with underground cables is in general use. It is interesting to notice that in several cases both three-core and single-core cables are used simultaneously. Data which will enable a practical comparison of their relative merits to be made will therefore soon be available. The three-core cables are of British and the single-core cables are of German manufacture.

Broadly speaking, we may say that the delay in the adoption of higher working pressures in this country and the delay consequently in securing the economies associated with them are due mainly to the absence of an effective national policy which would secure the harmonious working of the various supply stations so as to obtain the maximum economy. The Electricity Commission is doing everything in its power to obtain this desirable end. The developments that have taken place since the war, and their resulting economies, are reflected in the gradual lowering of the price of electricity to the consumer.

British Electrical Manufacturing Industry.

The closing of the mid-European and Russian markets to British products has been a severe handicap to the manufacturing industry. It has, however, been lessened by the increased demand from the overseas portions of the British Empire. It is satisfactory to notice that the exports of electrical machinery to British Dominions have increased and are continuing to increase. Judging from the steady improvement which has taken place during the past five years, there is every reason to regard hopefully the future position of the British electrical manufacturing industry.

The British Empire Exhibition.

The section of the British Empire Exhibition devoted to electrical manufactures embraces the most representative and impressive examples of electrical machinery and apparatus ever shown in this or any other country. Arrangements have been made for demonstrations of long- and short-distance radio-transmission, the very latest appliances being shown in operation. The plant of the power station, the value of which is £150 000, has been lent by the members of the British Electrical and Allied Manufacturers' Association (the B.E.A.M.A.) to the Exhibition for only a small fraction of its value. The Electrical Development Association is giving a very interesting exhibit which will show visitors the advantages of the domestic and small power applications of electricity.

World Power Conference.

In co-operation with our Institution, and with other scientific and technical Institutions, the B.E.A.M.A. is promoting a World Power Conference. The advantages of such a Conference are many, and keen interest is being taken in it by practically every civilized country. Committees have been formed representing the Dominion of Canada, the United States, America, France, Belgium, Italy, Norway, Sweden, Holland, Denmark, Greece and Czecho-Slovakia.

The Electrical Installation Industry.

The electrical installation industry to-day is prosperous. The quality of the materials used has never been better and the standard attained has never been higher. This is due to the good work done by the Institution in the production and continual revision of its Wiring Rules, and to the activities of the Electrical Contractors' Association. The British Engineering Standards Association by standardizing materials has helped to stabilize the industry. The National Industrial Councils also have done excellent work in fostering the good feeling which exists between employers and employed at the present time.

The Lamp-making Industry.

Immediately after the War the lamp makers embarked on a broad policy of extension and co-ordinated research work. The benefits of this policy are already seen in the great improvements that have been made in the manufacture of incandescent lamps. An immense amount of research work has been expended on the gas-filled lamp. Its universal adoption will greatly raise the standard of illumination. In the factory this

will lower the risk of accident, increase very appreciably the output and do much to prevent industrial fatigue.

Not many years ago the number of electric lamps used per head of the population of this country was the same as the corresponding number in the United States. Now the latter number is more than four times the former. I am glad, therefore, that the lamp industry is bringing the numerous advantages of a higher standard of illumination to the notice of the public.

Post Office Automatic Telephony.

The British Post Office, having had experience of the successful and economical working of 17 automatic exchanges in public service in this country, has decided that in the future this type of equipment shall be adopted in all important areas. Several of these exchanges are being constructed in the provinces, and contracts have been placed for others.

The difficult problems suggested by automatic working in the largest cities which have been under consideration for a lengthy period have now been solved. Arrangements have been made for the introduction of automatic switching in London. It is anticipated that the installation of several important automatic exchanges in the Central District will be commenced in 1925.

Long-distance Communication.

On 17th March, 1921, Sir William Noble outlined the use of light-gauge coil-loaded cables with thermionic repeaters. Great progress has since been made in their adoption. Cable routes have been completed between London, Derby and Manchester, London and Brighton, and London, Portsmouth and Southampton. Others which are approaching completion are London to Bristol, Bristol to Birmingham, Birmingham to Manchester, and Leeds to Hull. Several important extensions of existing routes are well in hand and several additional routes will shortly be commenced.

The rapid expansion of traffic between Great Britain and the Continent has rendered it necessary to consider the adoption of a type of submarine cable capable of carrying a larger number of channels than those at present in use. The manufacture for the Anglo-Dutch telephone service has therefore been commenced of a paper-core, lead-covered and continuously loaded cable.

Developments in Radio-Telegraphy in the Post Office.

The main trend of recent progress in radio-telegraphy has been in the direction of improvements in methods of transmission by the elimination of harmonics and impurities, and development work in connection with high-power radio transmitters using silica valves and water-cooled metal valves.

As the result of successful experiments on the use of a coupled circuit on an arc transmitter at the Northolt station, a similar circuit is now being installed at the Leafield station supplementary to the 250-kW arc installation. Very marked improvement has been effected in the suppression of harmonics and other undesirable emissions by the introduction of these circuits.

Valve transmitting sets producing 40 kW in the aerial have been assembled and operated using both silica valves and water-cooled metal valves. The most powerful valve which has proved commercially satisfactory is capable of producing 14 kW of high-frequency power in an oscillatory circuit. As the result of experimental work, valve transmitters are to be used in the new high-power station now in course of erection at Rugby. This station rated at 1 000 kW is designed to deliver 500 kW to the aerial circuit. The height of the masts for this station is to be 820 feet. Eight are now being erected and the site is so arranged that extensions up to twice that number can be carried out.

Railway Electrification.

The problem of railway electrification presented many almost insuperable difficulties in the past. The necessity for costly experiments and the difficulty of getting the requisite capital made engineers proceed cautiously. It has to be remembered also that steam railways were built with an eye always to the needs of the locomotive. It was only when railway engineers saw that it was the best way of overcoming the difficulties connected with urban and suburban traffic or of long tunnels or steep gradients that they adopted electric traction. The outlook at the present time is much more promising. Large orders for the extension of the electrification of railways in New Zealand, Australia, South Africa, Brazil and Japan have been received in this country and are very welcome to manufacturers. Electric traction engineers and manufacturers are looking forward to a busy future. With the high pressures now available for transmission and the use of automatic substations there is no technical reason why the whole of our railway systems should not be electrified. One benefit will be the diminished inroads on the limited stores of coal in our mines on which posterity has some claim. Mr. Roger T. Smith * has calculated that if the railways of this country were electrified there would be a saving effected of about 50 per cent in the quantity of coal consumed.

Research.

Combined research has much to place to its credit. The British Electrical and Allied Industries Research Association has broken much new ground and obtained interesting and important results. The opening of the Research Laboratories of the General Electric Co. at North Wembley is an excellent augury that the importance of scientific and commercial co-operation will soon be recognized by every leader of industry.

I should like to emphasize that our progress depends very largely on the work of the rank and file in the industry. It especially depends on those who make new inventions or perfect old methods. Our late President, W. Duddell, used to say that we could advantageously do much more than we are doing to encourage those who have made small inventions or discoveries. In particular he advocated that we should publish, in our *Journal*, accounts of any advances that

* Presidential Address to the British Section of the *Société Des Ingénieurs Civils de France*, 10th October, 1923.

had been made, no matter how short the paper was in which they are described. Some improvements may seem trifling to many and some may appear almost self-obvious. As, however, they may cheapen the cost of production and improve the quality and efficiency of our manufactures, they are of the highest value from the point of view of our national prosperity.

Kelvin Centenary.

On the 26th of June next we shall be celebrating the centenary of the birth of the greatest of our Past-Presidents, Lord Kelvin. It is only 16 years ago since some of us attended his funeral in Westminster Abbey, where he was buried with all the honours due to a prince of science. The greatest of natural philosophers since Isaac Newton, he had the power, rare amongst scientists, of completely realizing his conceptions in practice. We honour him specially for what he did to advance electrical knowledge. From the time when he was a student at Cambridge calculating the attractions between electrified spheres, down to the speculations he made about electrons in the latest years of his life, he was ever looking with eager eye to discover Nature's secrets.

Relativity.

A teacher is asked many questions about the theory of relativity. I am afraid that however much he has tried to understand this theory his answers will give little satisfaction. The Michelson-Morley experiment appears to show that the velocity of light is independent of the velocity of the earth. This is a very hard and a very disturbing statement. Luckily Fitzgerald showed us a way out. We are forced to conclude that the measuring rod has contracted by the two-hundred millionth part of its length in the direction in which the earth is travelling. A possible explanation of this is that the atoms forming the rod contain electrons. These electrons move with the rod and therefore act like electric currents. Theory shows that the mutual action of these currents would shorten the rod in exact accordance with the observed law.

We must remember that when Copernicus stated that the sun was stationary and the earth moved round it, he was derided by the upholders of the fixed earth theory. It is necessary therefore to be careful not to belittle Einstein's theory. It has nothing whatever to do with the mathematical suggestion of four dimensions in space for the existence of which not the slighest evidence has ever been advanced. Einstein discovered that our conceptions of the framework of space and time were at fault as we had neglected the fact that we were on a moving globe. The four dimensions in his theory are the three in space and one in time, and his results show that these four dimensions are not independent. The theory has been applied in astronomy and is also used in atomic theory. Unless, however, an engineering student has exceptional mathematical abilities he can employ himself more profitably by studying theories more directly applicable to our everyday life.

Atomic Theory.

On 15th January, 1891, Sir William Crookes gave an epoch-making Presidential Address to this Institution. It was entitled "Electricity in Transitu; from Plenum to Vacuum." He showed electric discharges in tubes exhausted to a high vacuum by powerful air pumps. He pointed out that the discharges acted as if they consisted of streams of negatively charged particles. A few years later Sir Joseph Thomson proved that these negatively charged particles were exactly the same from whatever gas they were obtained. They were in fact the atoms of which a negative charge of electricity is made up.

There is strong evidence that these electrons form part of every atom of matter. Sir Ernest Rutherford * recently described to us his theory that the atom consists of a nucleus surrounded by planetary electrons. The nucleus contains sufficient positive electricity to neutralize exactly the sum of the charges on the negative electrons. The atomic number of an element, which has introduced great simplifications in theory, is simply the resultant charge on the nucleus. The atomic numbers range from 1 to 92, so that we can infer that there are 92 different kinds of atom which could be distinguished by their chemical reactions. There are, however, only two different kinds of electrical atoms, the positive one which is the nucleus of the hydrogen atom, often called the proton, and the negative one called the electron. The assumption is made that all the different kinds of atoms are built up of protons and electrons. If these electrical atoms had been known to the scientists of 60 years ago, electrical progress in several directions would have been much accelerated.

Thunderstorms.

A remarkable thunderstorm visited London on the night of July 9–10, 1923. The storm appeared on the south coast and progressed W.N.W. at a speed of about 25 miles an hour, travelling through London, Bedford and Hull. The main rainfall, which was torrential in places, extended over a belt about 30 or 40 miles wide. The lightning flashes in some places occurred with only a few seconds' interval for hours at a time. The discharges were mainly from cloud to cloud or from a cloud to the upper air, and so the damage done was not serious.

It will be useful to consider the physics of the problem. In a Royal Institution lecture on 18th May, 1860, Kelvin† reminded his audience that many years previously Beccaria with very insensitive instruments had made many records of atmospheric electricity. He suggested that now that accurate instruments are available careful records should be made. He wanted to know in particular how electricity was distributed in fine weather in the strata of the atmosphere up to a distance of 6 miles. He pointed out that this could easily be done by means of balloon observations. He wanted to know also whether the particles of rain, hail and snow possessed charges of electricity.

To picture what happens more clearly I shall

* *Journal I.E.E.*, 1922, vol. 60, p. 613.
† See "Reprint," p. 268.

describe some of the additions made to our knowledge during the last 25 years by meteorological science. From data published by the Meteorological Office we find that in the south-east of England if the temperature of the air at the earth level be 10° C., then as we go vertically upwards it falls uniformly for a distance of 6 miles where the temperature is only about − 53° C. After this altitude is attained the temperature, curiously enough, remains almost practically constant up to the greatest height reached by pilot balloons, which is about 12 miles. The layer of the atmosphere up to 6 miles high is called the troposphere. Above this is the isothermal layer called the stratosphere. Clouds only appear in the troposphere. There is very little moisture in the stratosphere. For example, practically no snow falls on the top of Mount Everest; the snow on it is blown up from lower down the mountain.

On a calm day as we go upwards the electric potential gradient diminishes. In midsummer a usual ground value is of the order of 100 volts per foot. In mid-winter the average ground value is at least twice as high. In foggy weather it is sometimes greater than 500 volts per foot. In fine weather the potential difference between the ground and the top of the troposphere is of the order of a million volts, and above this the potential gradient is practically zero, and so the isothermal layer is also an equipotential layer. This voltage between the earth and the equipotential layer is, however, much too small to produce a lightning flash. That requires at least thousands of millions of volts.

The surface of the earth is generally at negative potential but it sometimes has a small positive potential. Owing to the vertical potential gradient, the electrons from the earth are always moving skywards and act like a vertical earth-air current. Sir Francis Ronalds,* one of the early members of this Institution, made observations at Kew Observatory for the British Association. He found that the intensity of the atmospheric electrification had a maximum value every morning and another maximum value in the afternoon. Chree† has shown that these maxima values are usually greatest in cold weather. Possibly, therefore, they may be due to smoke or other impurities in the atmosphere.

The following table may be taken as roughly typical of the temperature, pressure and electric strength of the atmosphere at various heights above the ground up to 12 miles. The ground temperature and pressure are supposed to be 15° C. and 760 mm of mercury respectively.

Height in miles	Temp., Cent.	Pressure in mm	Electric strength in kV per cm‡
0	15	760	28
3	− 15	412	17
6	− 50	206	10
9	− 50	96	4·6
12	− 50	44	2·1

The table shows that at a height of 3 miles the temperature is below the freezing-point and the electric strength of the air is only about half what it is at the surface of the earth. At a height of 24 miles the barometric pressure would only be about 2·4 mm and the electric strength would only be of the order of some hundreds of volts per centimetre. At some height, probably about 30 miles vertically up, the electric strength would attain a minimum value. At greater heights it would begin to increase very rapidly and soon become at least 30 times greater than the electric strength of air at ground-level.

J. L. R. Hayden* placed two 1-cm spheres in a kenotron bulb at a distance of 0·3 cm apart. At atmospheric pressure the disruptive potential gradient was 47 kV per cm, but with an excellent vacuum a gradient of 1 235 kV per cm was required to break down the gap. A good vacuum therefore has an electric strength at least 26 times the strength of air at ordinary pressures.

In a recent paper† F. W. Peek has shown that a much higher impulsive voltage, that is, a voltage similar to that which causes Lodge's B flash, is required to spark over a given distance than a voltage at ordinary working frequencies. He also shows that some substances which act as conductors at working frequencies can be punctured by impulsive voltages. For instance, he found that an impulsive voltage of 149 kilovolts broke down the gap between two 1-in. spheres, immersed in water, at a distance of 1 inch apart. The conducting water therefore acted as if it were a dielectric having an electric strength between three and four times that of air.

It is easy to get a discharge from an electrode to the surface of water. The author remembers once being in a small boat on the sea on a perfectly calm day during a thunderstorm. Where the lightning struck the sea a narrow column of spray, or more probably steam, seemed to rise suddenly not unlike the splash made by a gannet when diving. Possibly when a flash of lightning strikes sandy soil and forms a fulgurite, vapour or smoke might be observed.

When it is considered that two million volts will only bridge a few feet in air, the voltage of a lightning flash to earth must be exceedingly high. We can conclude from laboratory experiments that the electric resistance of fog or mist is greater than that of clear air, but that its electric strength is much the same.

Let us now consider very briefly the mechanism of a thunderstorm. Owing to the small potential differences produced by the ordinary earth-air electric current, and consequently the minute amount of electrostatic energy stored in the field, we are justified in assuming that the most important function of this current is in assisting to start the storm. A thunderstorm usually travels over considerable distances and keeps on generating prodigious quantities of electrical energy. It functions like an electrostatic machine

* Cf. W. Snow Harris: "Rudimentary Electricity," 1848.
† *Philosophical Transactions*, vol. 206, p. 299.
‡ By the electric strength of air we mean the maximum electric stress it would withstand between two very large spheres at an appreciable distance apart. The numbers given at the greater heights are only roughly approximate.

* *Journal of the American Institute of Electrical Engineers*, 1922, vol. 41, p. 853.
† *Ibid.*, 1923, vol. 42, p. 623.

driven by a very powerful motor. We have to consider what produces the energy which the lightning flash converts into heat, light, sound and radio waves. Aviators and balloonists report that the air in the centre of a thundercloud is practically always moving upwards with considerable velocity. In the upper layers of the troposphere, owing to ionization, there are sometimes many free electrons. If the humidity of the upward current of air be high enough the vapour condenses round the electrons and so the air is full of minute globules of water. Some of these coalesce together forming larger drops. If the vertical velocity of the air be greater than 8 metres per second (17 miles per hour) the large drops as they are blown upwards often break into smaller drops. Experiment shows that the charge on the smaller drops is generally negative and on the larger drops positive. As the larger drops are often kept oscillating in the higher and very cold strata of the atmosphere owing to fluctuations in the velocity of the air currents, they keep melting and freezing again, producing ordinary hailstones. As the gusts vary we have the large drops and hailstones positively charged descending downwards. Electrical energy, due partly to the work done by gravity on the descending drops and by the air currents on the ascending drops, is stored in the atmosphere. On the upper part of the cloud we have a negatively charged layer and on the lower part a positively charged layer. The falling drops keep increasing the potential difference until it gets so high that a disruptive discharge ensues.

I have imagined the cloud to be bipolar. Several kinds of electric discharge can therefore ensue. We may have brush discharges between the upper layer and the better conducting layers higher up. Some kinds of sheet lightning could be caused in this way. On a summer evening it is not very unusual to see sheet lightning in broad flashes coming from a cloud and ending in the upper air. An ordinary flash also has sometimes been observed to end in clear air. If another cloud drifts up we may have a flash between the upper layer and this cloud. We may have flash discharges between the lower layer and the earth or another cloud. Possibly also we may have a flash-over between the two poles of the thundercloud when they are not too far apart. C. T. R. Wilson* describes this phenomenon by saying that the cloud may be short-circuited.

Operations of this nature happen during a thunderstorm. The separation of the charged drops due to the difference in their velocities produces high potential differences. There is plenty of energy available. The work done by an inch of rain falling a mile is 27 500 ft.-lb., or the one-hundredth part of a kilowatt-hour, per square foot of the earth's surface. It has recently been shown that in general the purer† the raindrops the greater are the electric charges they assume on pulverization. In particular any contamination of a raindrop with sodium chloride diminishes the charges produced when it breaks in air. This possibly has the effect of diminishing the intensity of thunderstorms at seaside towns. It has been suggested that the introduction of ammonia into the upper layers of the atmosphere would hinder the development of a thunderstorm. To utilize this practically, however, could rarely be attempted, as a thunderstorm usually covers a large area.

What we as engineers are specially interested in is how to protect buildings and apparatus and power and communication lines from damage due directly or indirectly to lightning flashes or to the gradual accumulation of electric charges. I think that there is no need to call a second Lightning Rod Conference. The principles laid down by Sir Oliver Lodge* in this Institution in 1889 still hold good. They have been adopted by the Lightning Research Committee of the Royal Institute of British Architects.† In practice they are found quite satisfactory.

We now know that a lightning discharge is unidirectional although it may be rapidly pulsatory. But even a unidirectional discharge gives rise to an alternating current in line wires, and may give rise to alternating currents in lightning conductors. The wires in insulated conductors have been found broken into small pieces by a lightning discharge. This seems to point to rapidly alternating currents. Lodge's A and B flashes of lightning are known to all students of electrical engineering. The B flash, which is the dangerous one, is also referred to as an impulsive discharge. I think that possibly too much stress is laid on the importance of having a low resistance to earth of a lightning rod. About 25 years ago I measured the resistance to earth of the conductor of a large chimney stack. It came to 70 ohms. As the end of the conductor was buried in coke I had it dug up to examine the earth plate. This was found to be a brick placed there 20 years previously by the workman who erected it. I was told that the conductor had several times been struck by lightning and acted quite satisfactorily. I have noticed that workmen before the test is made sometimes pour a pail of water on the spot where the conductor enters the ground. Possibly they think that a high earth resistance is a reflection on the way they perform their duties.

Difficult problems sometimes arise. I remember once considering how to protect a very large iron water tank supported by iron pillars on the summit of a hill and naturally making an excellent earth through the water pipes at its centre. As the outside iron pillars were embedded in concrete it was throught advisable to connect them directly to earth by means of earth plates.

I think it highly desirable that records of curious lightning phenomena should be kept. In the eighteenth century this was done; the *Philosophical Transactions* of the Royal Society before 1800 contain very many interesting records. If we knew exactly the mechanism of thunderstorms the need for recording unusual phenomena would not be so urgent. Faraday was very doubtful about the existence of globular lightning. In his "Experimental Researches," vol. 2, p. 525, he says: "It is more than doubtful that they have anything to do with atmospheric electricity or lightning."

* "Atmospheric Electricity," Glazebrook's D.A.P., vol. 3.
† T. T. Nolan and H. V. Gill, *Philosophical Magazine*, 1923, vol 46, p. 226.

* *Journal I.E.E.* 1889, vol. 18, p. 386; or Lodge's "Lightning Conductor and Lightning Guards."
† *Journal of the Royal Institute of British Architects*, 1904, vol. 12, p. 405.

Even W. J. Humphreys in his recent excellent book on the "Physics of the Air" says: "Doubtless many reported cases of ball lightning, probably the great majority, are entirely spurious, being either fixed or wandering brush discharges or else nothing other than optical illusions due presumably to persistence of vision." After these weighty statements I now give my own experience.

Many years ago when I was on the coast of Ayrshire on the west side of Scotland, I saw what I consider to be globular lightning. Although the visibility was very fair there was a curious haze higher up. The ground potential gradient was probably high. Suddenly two spheres of incandescent gas of a dull reddish colour about 20 or 30 feet up moved slowly in from the sea. They were each about a foot in diameter. One of these hit the wall of a building but did no apparent damage although it made a loud report and considerably startled the inhabitants. The other drifted away.

I consider that the evidence in favour of globular lightning is overwhelming. Witnesses testify to seeing it, to hearing it burst, to finding small metal objects melted by it and even to seeing people killed by it. I shall confine myself to describing two typical cases. The first case I take from the *Philosophical Transactions* of the Royal Society for 1781, p. 42. At Eastbourne the tenant of a large three-story house facing the sea was standing and looking through the window at an ominous black cloud. He saw several balls of fire drop successively out of the cloud into the sea. Suddenly he was violently thrown backwards by what he described as a flash of fire. Many people outside the house at that instant saw something which in form and flame they all agreed was like an immense "sky rocket" strike the house. The tenant's clothes were torn and pieces of metal he had about him were melted. Every pane of glass in the room was completely smashed. On the ground floor the coachman and a footman were killed and on the top floor a lady and her maid were rendered insensible. All the bell wires in the house were deflagrated.

The second case is similar to many others.* It is described by a sergeant† of H.M. 96th Regiment which was stationed at Dum-Dum near Calcutta in 1879, where the phenomenon occurred. The ball of globular lightning first passed over a bathing tank in which seven men were bathing. It went right through the first floor of one barracks, making one man insensible. Going out of a window it passed down the wall, moved over the end of the barrack square and then climbed up to the roof of the next barracks, knocking off a projecting rain-water pipe. Finally it went down a zinc ventilating pipe where it burst with a loud report, killing a soldier who was sitting on his bed directly underneath. A current passed down the punkah wire, setting the punkah on fire. Much damage was done to the victim's rifle, parts of it being melted. Three of the men bathing were rendered temporarily deaf. Many other very similar instances could be given, the undesigned coincidences in which, as Paley would say, are very convincing.

* "Phénomènes Électriques de l'Atmosphère": Gaston Planté, 1888.
† *The Builder*, Oct. 26, 1896, p. 359.

Globular lightning seems to be a brush discharge taking place at the end of a column of air of higher conductivity than the neighbouring air. The difficulty in accepting this explanation, however, is in seeing how the conducting column can go through rooms and yet provide sufficient energy to the globe a considerable distance away to do serious damage. In certain cases, however, it may possibly get its energy from the atmosphere by another path when it bursts.

A Clear Atmosphere.

Engineers are accustomed to think of light waves and Hertzian waves as travelling in straight lines. They were therefore surprised when it was found that Hertzian waves travel round the earth. This is generally explained by supposing that the radio waves are successively reflected by certain conducting layers of the upper atmosphere and by the surface of the earth or sea. Since light waves only differ from radio waves in wave-length we should expect, when the atmosphere is exceptionally still and clear, to be able to see round the curvature of the earth. An interesting case where the spectators could see over 400 miles occurred on the 2nd of May last. Colonel Neame, V.C., and Mr. F. S. Smythe, an electrical engineer, were climbing the Finsteraarhorn in the Bernese Oberland. The weather was perfect and the visibility extremely good. On a rock ridge at an altitude of 13 800 feet they could see the Black Forest 150 miles to the north and the snow-capped peaks of Italy over 100 miles to the south. What they next saw I shall tell in Colonel Neame's own words taken from a letter to *The Times*.

"Suddenly at 11.55 a.m., the image of a ship appeared in the sky just to the east of the Eiger Peak, floating in a blue shimmer just beyond the visble horizon. This lasted for a minute or so and then vanished. Very soon after a line of five ships appeared further east, funnels and masts clearly distinguishable. This image lasted for some 15 minutes and varied in its clearness from time to time. The ships of course appeared greatly exaggerated in size and were the right way up and not inverted. The nearest sea in this direction was the English Channel 400 miles away."

As, at the height they were, the visible horizon was only some 140 miles away, the light must have been bent round the curvature of the earth. A mirage seen over this distance must be a very rare phenomenon. It was probably caused by the refraction of the light rays by the strata of the atmosphere and these strata must have been very sharply defined. As radio and light waves only differ from one another in wave-length we can infer with certainty that radio waves can be refracted in the troposphere so as to bend round the earth. In certain cases also they can be reflected by damp earth, the sea or the dividing surface between two strata. In addition to reflection and refraction, however, the radio waves are scattered at the dividing surface between two strata, and this scattering must play an important part in radio transmission. The assumption that there is a definite stratum of the atmosphere that always reflects radio waves seems unnecessary.

Mathematical Theorems.

In conclusion a few mathematical theorems are given which are of theoretical interest and may be of practical value. Brief discussions of them are given in the Appendix. The first theorem shows that the inductance coefficient per unit length of the current in one cylinder with the current in a second parallel cylinder, is not equal to the inductance coefficient of the current in the second cylinder with the current in the first cylinder except in the case when the two cylinders are equal to one another. For example, when we have two infinite parallel cylinders we cannot assume that they have a "mutual" inductance coefficient. In the case of a concentric main there is a mutual inductance coefficient between the outer and inner conductors when their axes are coincident. If the axes of the outer and inner conductor are parallel but not coincident there is no mutual coefficient. In these cases, however, it is proved that the effective self-inductance of the concentric main is independent of the distance between the axes. The values found for the inductance coefficients can be at once applied to find the effective inductance of a concentric main in which the inner or outer or both of the conductors are made up of individual wires.

The second theorem discussed is to find the position of the site of a power station when the feeding points are given so that the amount of copper required for the feeding mains may be a minimum for the given power loss in them. It is shown that if the current required at or near one of the feeding points is equal to or greater than the sum of the currents required at the other feeding points, then this is the site which makes the copper required for the mains a minimum. It will be noticed that this site is not the centre of gravity of the load.

The third problem discussed is that of the specification of wave shape for alternators. The deviation and harmonic factor methods are examined and found unsuitable. An easy method is suggested for finding graphically the effective value and the first and third harmonics of an alternating current wave from its oscillogram. If the effective value of the wave comes out equal to the amplitude of the first harmonic within the limits of the errors of observation and the ratio of the amplitude of the third to the first harmonic be sufficiently small, and if, in addition there is no obvious ripple on the wave, then it may be considered to be satisfactory. If there is obviously a ripple, the frequency of which can be measured, its amplitude can be readily found by applying a formula first given by Silvanus Thompson. Instead of finding the harmonics graphically from the oscillogram, in many cases it would be more convenient to find them experimentally by a resonance method.

The final problem discussed is that of specifying the power factor of a polyphase load. In single-phase working the numerical value of the load in watts, the value of the power factor and whether it is lagging or leading are sufficient to specify the load. In polyphase work, however, not only have we to consider the load and the power factor, but it is necessary to introduce another factor to measure the balance or the want of balance of the currents taken from the mains. For the same total load and average power factor we can have all kinds of loads more or less desirable. But if a balance factor is given in addition, then the nature of the load is specified much more definitely. A first attempt has been made to specify an unbalanced polyphase load. The author hopes that others will follow up and improve his suggestions.

APPENDIX.

1. The Inductance Coefficients of Cylindrical Conductors.

When electric circuits are completely separated from one another the ordinary definitions of self and mutual inductance apply. When, however, the electric currents have paths in common, as for instance the three mains of a three-phase system or the inner and outer conductor of a concentric main, there may be no "mutual" inductance coefficient between two of the conductors. That is, the inductance coefficient per unit length of one of the mains on the other may have a different value from the corresponding coefficient of the latter on the former.

We shall first consider the coefficients for two infinitely long, parallel, hollow cylindrical conductors (Fig. 1). Let the inner and outer radii of the cylinders

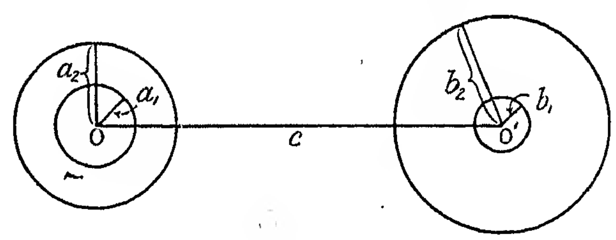

Fig. 1.

be a_1, a_2 and b_1, b_2 respectively. Let c be the distance oo' between their axes. Then if i_1 and i_2 be the currents in the conductors the linkages per unit length of the flux due to i_1 between the axis of the current i_1 and a concentric cylinder of radius $c + b_2$ may be written $L_{11}i_1^2$. If $i_1 + i_2 = 0$, the cylinders of the flux due to i_1 having a greater radius than $c + b_2$, being linked with $i_1 + i_2$, will add nothing to the total linkages. Similarly we can write the linkages of the flux due to the current i_1 with i_2 in the form $L_{12}i_1i_2$, neglecting the cylinders of flux the radii of which are greater than $c + b_2$. Proceeding as in Russell's "Alternating Currents" (vol. 1, p. 86), we find that

$$L_{11} = \frac{a_2^2 - 3a_1^2}{2(a_2^2 - a_1^2)} + \frac{2a_1^4 \log (a_2/a_1)}{(a_2^2 - a_1^2)^2} + 2 \log \frac{c + b_2}{a_2} \quad (1)$$

and $$L_{12} = 2 \log \frac{c + b_2}{c} \quad . \quad . \quad . \quad . \quad (2)$$

Similarly, when $i_1 + i_2 = 0$, we get by symmetry:—

$$L_{22} = \frac{b_2^2 - 3b_1^2}{2(b_2^2 - b_1^2)} + \frac{2b_1^4 \log (b_2/b_1)}{(b_2^2 - b_1^2)^2} + 2 \log \frac{c + a_2}{b_2} \quad (3)$$

and $$L_{21} = 2 \log \frac{c + a_2}{c} \quad . \quad . \quad . \quad . \quad (4)$$

Comparing (2) with (4) we see that $L_{21} = L_{12}$ only when $a_2 = b_2$.

The effective inductance, L, per unit length of the circuit formed by the two conductors is given by:—

$$L = L_{11} + L_{22} - L_{12} - L_{21}$$

On substituting and simplifying we get Maxwell's formula.*

In the case of solid wires, $a_1 = 0$, $a_2 = a$, $b_1 = 0$ and $b_2 = b$, and we get

$$\left.\begin{aligned} L_{11} &= \tfrac{1}{2} + 2 \log \frac{c+b}{a}, \quad L_{22} = \tfrac{1}{2} + 2 \log \frac{c+a}{b} \\ L_{12} &= 2 \log \frac{c+b}{c}, \qquad L_{21} = 2 \log \frac{c+a}{c} \end{aligned}\right\} \quad (5)$$

and $$L = 1 + 2 \log \frac{c^2}{ab}$$

As an example of the use of formula (5) let us find an expression for the electromagnetic energy stored up per unit length in three parallel cylindrical conductors, 1, 2 and 3 (Fig. 2), the radii of the conductors being r_1, r_2 and r_3 and the distance between their axes being a_{12}, a_{23} and a_{31}. We shall suppose that

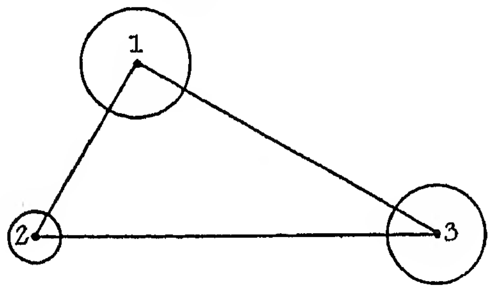

FIG. 2.

$i_1 + i_2 + i_3 = 0$. Then the energy stored in the field arising from the flux linkages due to i_1 is, if a_{13}, a_{23} and a_{12} are in descending order of magnitude, given by:—

$$\left\{ \tfrac{1}{2} + 2 \log \frac{a_{13} + r_3}{r_1} \right\} i_1^2 + 2 \log \frac{a_{13} + r_3}{a_{12}} i_1 i_2 + 2 \log \frac{a_{13} + r_3}{a_{13}} i_1 i_3$$

Writing down the other two components, adding them all together and noticing that

$$i_1^2 + i_2^2 + i_3^2 = -2(i_1 i_2 + i_2 i_3 + i_3 i_1)$$

we see that the energy W_m is given by

$$\begin{aligned} W_m = &\left\{ \tfrac{1}{2} + 2 \log \frac{a_{12} a_{13}}{a_{23} r_1} \right\} i_1^2 \\ &+ \left\{ \tfrac{1}{2} + 2 \log \frac{a_{23} a_{21}}{a_{31} r_2} \right\} i_2^2 \\ &+ \left\{ \tfrac{1}{2} + 2 \log \frac{a_{31} a_{32}}{a_{12} r_3} \right\} i_3^2 \end{aligned} \quad (6)$$

* CLERK MAXWELL, "Electricity and Magnetism," vol. 2.

This is true whatever are the relative values of the sides of the triangle.

In the ordinary balanced three-phase case we can write

$$a_{12} = a_{23} = a_{31} = a, \quad r_1 = r_2 = r_3 = r.$$
$$i_1 = I \sin \omega t, \quad i_2 = I \sin [\omega t - (2\pi/3)]$$

and $$i_3 = I \sin [\omega t - (4\pi/3)]$$

Hence $$W_m = \tfrac{3}{4}\left(1 + 4 \log \frac{a}{r}\right) I^2$$

which is an absolute constant independent of the time. Similarly if k_{11}, k_{12}, . . . be Maxwell's capacity coefficients and $e_1 = E \sin \omega t$, etc., we get

$$W_e = \tfrac{3}{4}(k_{11} - k_{12}) E^2$$

where W_e is the electrostatic energy. Hence on a balanced load $W_e + W_m$ has the same value at every instant. It is not easy to compute the value of $k_{11} - k_{12}$. As it equals double the capacity between any two of the mains it can, however, be very easily measured.

Let us now consider a hollow cylinder (Fig. 3) sur-

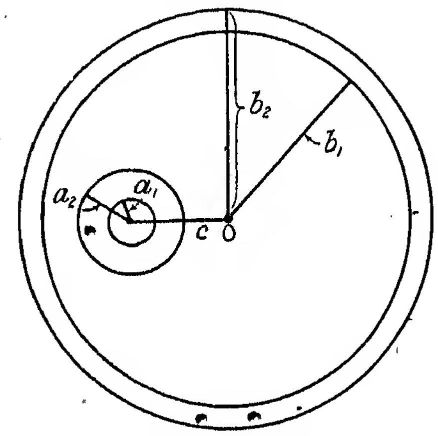

FIG. 3.

rounding another hollow cylinder, their axes being parallel but at a distance, c, apart. If the inner and outer radii of the inner cylinder be a_1 and a_2, and for the outer cylinder b_1 and b_2, $c + a_2$ being less than b_1, we get the result, assuming that $i_1 + i_2 = 0$ and proceeding as in Russell's "Alternating Currents" (vol. 1, p. 86), that

$$L_{11} = \frac{a_2^2 - 3a_1^2}{2(a_2^2 - a_1^2)} + \frac{2a_1^4 \log (a_2/a_1)}{(a_2^2 - a_1^2)^2} + 2 \log \frac{b_2 + c}{a_2} \quad . \quad . \quad (7)$$

$$L_{12} = 1 - \frac{2b_1^2}{b_2^2 - b_1^2} \log \frac{b_2}{b_1} + 2 \log \frac{b_2 + c}{b_2} \quad . \quad . \quad . \quad . \quad (8)$$

$$L_{21} = 1 - \frac{2b_1^2}{b_2^2 - b_1^2} \log \frac{b_2}{b_1} \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad (9)$$

and

$$L_{22} = \frac{b_2^2 - 3b_1^2}{2(b_2^2 - b_1^2)} + \frac{2b_1^4 \log (b_2/b_1)}{(b_2^2 - b_1^2)^2} \quad . \quad . \quad . \quad . \quad . \quad . \quad (10)$$

To get the effective self inductance, L, we have

$$L = L_{11} + L_{22} - L_{12} - L_{21}$$

On substituting the values of the coefficients and simplifying we get Rayleigh's formula * for the effective self inductance of two coaxial cylinders. We have thus proved the important result that the inductance of a circuit formed by two hollow, parallel cylinders one inside the other is independent of the distance between their axes. It is to be noticed that L_{12} is only equal to L_{21} in the case when the cylinders are coaxial. The value of L_{11} depends on c but the value of L_{22} is independent of c.

When the inner cylinder is solid, $a_1 = 0$, $a_2 = a$, and so $L_{11} = \frac{1}{2} + 2 \log \frac{b_2 + c}{a}$, the other coefficients remaining the same. Formulæ (1) to (4) and (7) to (10) enable us to write down the formulæ for polycore cables very simply, without the necessity of using formulæ for geometrical mean distances. Consider, for instance, an n-core cable (Fig. 4) the radius of

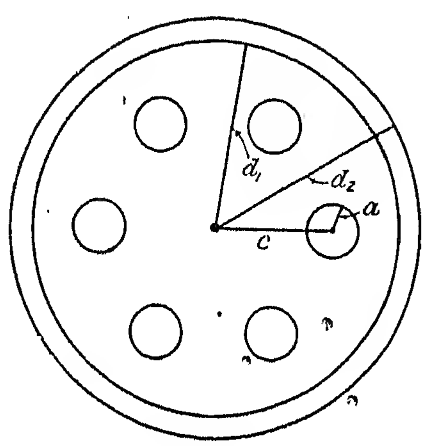

FIG. 4.

each core being a and the axis of each core being at a distance c from the axis of a hollow cylinder, of radii d_1 and d_2, by which we suppose the current returns. Let the current in each core be i, and let I be the current in the return cylinder, so that $ni + I = 0$. If a_{pq} denote the distance between the axes of the pth and qth core, we get by De Moivre's property of the circle:—

$$a_{12} \times a_{13} \ldots a_{1n} = nc^{n-1}$$

and, writing W for the electromagnetic energy,

$$\begin{aligned} 2W &= ni^2 \left\{ \frac{1}{2} + 2 \log \frac{d_2 + c}{a} \right\} + 2ni^2 \log \frac{(d_2 + c)^{n-1}}{nc^{n-1}} \\ &+ niI \left\{ 1 - \frac{2d_1^2}{d_2^2 - d_1^2} \log \frac{d_2}{d_1} + 2 \log \frac{d_2 + c}{d_2} \right\} \\ &+ niI \left\{ 1 - \frac{2d_1^2}{d_2^2 - d_1^2} \log \frac{d_2}{d_1} \right\} \\ &+ I^2 \left\{ \frac{d_2^2 - 3d_1^2}{2(d_2^2 - d_1^2)} + \frac{2d_1^4 \log (d_2/d_1)}{(d_2^2 - d_1^2)^2} \right\} \\ &= LI^2 \end{aligned}$$

where L is the effective self inductance of the whole circuit, and thus

$$L = \frac{1}{2n} + \frac{2}{n} \log \frac{c}{na} + 2 \log \frac{d_1}{c} - \frac{3d_2^2 - d_1^2}{2(d_2^2 - d_1^2)} + \frac{2d_2^4}{(d_2^2 - d_1^2)^2} \log \frac{d_2}{d_1} \quad . \quad (11)$$

We see that the effective self inductance is only independent of c when n is unity. When we can take $d_1 = d_2 = d$, the formula simplifies to

$$L = \frac{1}{2n} + \frac{2}{n} \log \frac{d^n}{nac^{n-1}}$$

In the case of a concentric main where the thickness of the outer conductor is very small compared with either of its radii, and $n = 1$, we have:

$$L = \frac{1}{2} + 2 \log \frac{d}{a}$$

and L is independent of c.

When $n = 6$, we have:—

$$L = \frac{1}{12} + \frac{1}{3} \log \frac{d^6}{6ac^5}$$

$$= -0 \cdot 5139 + 2 \log \frac{d}{c} + \frac{1}{3} \log \frac{c}{a}$$

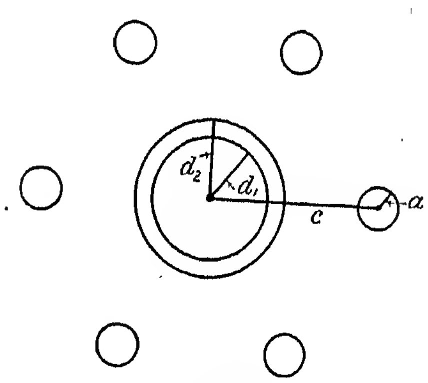

FIG. 5.

Similarly (Fig. 5) when the small cylinders are arranged symmetrically round the large one, we find that

$$L = \frac{d_2^2 - 3d_1^2}{2(d_2^2 - d_1^2)} + \frac{2d_1^4 \log (d_2/d_1)}{(d_2^2 - d_1^2)^2} + \frac{1}{2n} + \frac{2}{n} \log \frac{c}{na} + 2 \log \frac{c}{d_2} \quad . \quad (12)$$

where a is now the radius of the small cylinders and d_1, d_2 are the radii of the large inner cylinder. If $d_1 = 0$ and $d_2 = d$ we get

$$L = \frac{1}{2} + \frac{1}{2n} + \frac{2}{n} \log \frac{c}{na} + 2 \log \frac{c}{d} \qquad (13)$$

When n is unity, $L = 1 + 2 \log \frac{c^2}{ad}$, and, when n is very large, $L = \frac{1}{2} + 2 \log \frac{c}{d}$.

As a numerical example, put $c = 2$, $d = 1$, $a = \frac{1}{2}$, and

* Philosophical Magazine, 1886, vol. 21, p. 385, or RUSSELL'S "Alternating Currents," vol. 1, p. 84.

$n = 6$. Then the effective inductance of 10 metres of this cable would be given by :—

$$L = 1\,000\left\{\tfrac{1}{2} + \tfrac{1}{12} + \tfrac{1}{3}\log\tfrac{2}{3} + 2\log 2\right\}$$
$$= 1\cdot 8344 \text{ microhenrys.*}$$

It has to be remembered that all the logarithms given in this paper are Napierian.

If K be the electrostatic capacity between all the small cylinders connected in parallel (Fig. 4) and the outer sheath, then by putting $d_2 = d_1 = d$ and supposing that the small cylinders are hollow, we see that when c/d and a/c are small, we have, approximately :—

$$K = \frac{n}{2\log\dfrac{d^n}{nac^{n-1}}} \quad . \quad . \quad . \quad . \quad . \quad (14)$$

A more accurate value of K got by the method of electrical images is given in Russell's "Cables and Networks," p. 294.

Similarly for the cable shown in Fig. 5 we get :—

$$K = \frac{n}{2\log\dfrac{c^{n+1}}{nad^n}} \text{ (approximately)}$$

The problems of bimetallic wires can also be readily solved by the formulæ given above. Consider two equal non-magnetic bimetallic parallel cylinders. Let c be the distance between their axes, (o, a_1) the radii of the inner metal cylinder of resistivity ρ_1, and (a_1, a_2) the radii of the outer metal cylinder of resistivity ρ_2. Then if i_1 be the current in the inner metal and i_2 be the current in the outer metal,

$$\frac{i_1}{i_2} = \frac{\rho_2 a_1^2}{\rho_1(a_2^2 - a_1^2)}$$

and if the energy be given by $\frac{1}{2}L(i_1 + i_2)^2$ we get :—

$$L = 1 + 4\log\frac{c}{a_2} + \frac{4(\rho_2 - \rho_1)^2 a_1^4}{\left\{\rho_2 a_1^2 + \rho_1(a_2^2 - a_1^2)\right\}^2}\log(a_2/a_1)$$
$$+ \frac{2\rho_1(\rho_2 - \rho_1)a_1^2(a_2^2 - a_1^2)}{\left\{\rho_2 a_1^2 + \rho_1(a_2^2 - a_1^2)\right\}^2} \quad . \quad (15)$$

Putting $\rho_2 = \rho_1$ in (14) we get the value of L for parallel cylinders each of radius a_2. Putting $\rho_2 = 0$ or $\rho_1 =$ infinity, we find that

$$L = 1 + 4\log\frac{c}{a_2} + \frac{4a_1^4}{(a_2^2 - a_1^2)^2}\log\frac{a_2}{a_1} - \frac{2a_1^2}{a_2^2 - a_1^2}$$

which gives the value of L for two parallel hollow tubes.†

We shall conclude this section by discussing the problem of a thin conducting cylindrical shell (Fig. 6) of radius d, containing two parallel cylindrical cores of radii a and b respectively. The axes of the three cylinders are supposed to lie in one plane, the axis of the shell being at an equal distance $\frac{1}{2}c$ from the other two. If we put $a = b$, we get the case of a twin concentric main. Suppose that i_1 and i_2 are the currents in the cores and that i_3 is the current in the shell. Then by the formulæ given above we find that, if $i_1 + i_2 + i_3 = 0$, the electromagnetic energy, W, is given by :—

$$W = \tfrac{1}{2}\left(\tfrac{1}{2} + 2\log\frac{d}{a}\right)i_1^2 + \tfrac{1}{2}\left(\tfrac{1}{2} + 2\log\frac{d}{b}\right)i_2^2 + 2i_1 i_2\log\frac{d}{c} \quad . \quad (16)$$

In this case

$$L_{11} = \tfrac{1}{2} + 2\log\frac{d + c/2}{a}; \quad L_{22} = \tfrac{1}{2} + 2\log\frac{d + c/2}{b}$$
$$L_{12} = L_{21} = 2\log\frac{d + c/2}{c}; \quad L_{13} = L_{23} = 2\log\frac{d + c/2}{d}$$
$$L_{31} = L_{32} = L_{33} = 0$$

It will be seen that the values of the self and inductance coefficients all depend on the value of d, except when i_3 is zero. Since i_1 and i_2 in (16) can have any values, we can deduce that the force, F, between the two cores is given by :—

$$F = \frac{\partial W}{\partial c} = -\frac{2i_1 i_2}{c} \quad . \quad . \quad . \quad . \quad (17)$$

Hence if i_1 and i_2 are flowing in the same direction so that they attract one another and c diminishes, we

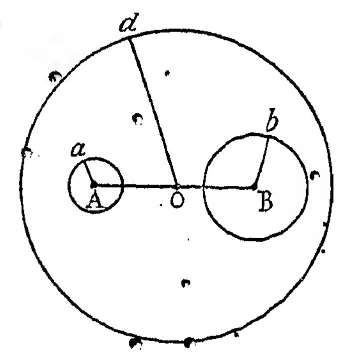

FIG. 6.

see by (17) that W increases. The work done by F in moving the wires to a smaller distance c_1 apart is equal to $2i_1 i_2\log(c/c_1)$, and this, by (16), is equal to the concurrent increase in the value of the energy W stored in the field. This is a particular case of Kelvin's theorem.

With alternating currents the mean value of F is $(2A_1A_2\cos\phi)/c$, where ϕ is the phase difference between i_1 and i_2, and A_1 and A_2 are their effective values. The force is attractive when ϕ lies between 90° and − 90°, and repulsive in other cases.

In the preceding problems we have supposed that the current is uniformly distributed over the cross-sections of the cylinders. With high-frequency currents this, however, is not the case. With very high-frequency currents, the currents are practically confined to the surfaces of the cylinders. Approximate values† for the coefficients can be found in this case.

II. THE BEST SITE FOR A POWER STATION.

In considering the best site for a power station it is helpful to know the position of the site for which

* Cf. C. E. GUYE, *Comptes Rendus*, 1894, vol. 118, p. 1329, and E. B. ROSA, *Bulletin of the Bureau of Standards*, 1907–1908, vol. 4, p. 333.
† Cf. RUSSELL'S "Alternating Currents," vol. 1, p. 88.

* RUSSELL, "Alternating Currents," vol. 1, p. 41.
† RUSSELL, *Proceedings of the Physical Society*, 1918–1919, vol. 31, p. 111.

the copper required for the feeder mains would be a minimum. In many cases the most suitable site is determined by local conditions. We have to take into account, for instance, the cost of the site, the facilities for obtaining fuel, the available supply of condensing water, whether "wayleaves" can be obtained and at what price, and many other considerations. A discussion of the simplified problem, however, leads to interesting results which are of practical value.

Formerly the only case considered was when the fractional loss of the energy was the same for every feeder. In this case it follows almost at once that the site of the power station which makes the volume of the copper used in the feeder mains a minimum, is the centre of gravity of the load. To get, however, the minimum volume of copper required for a given total power loss, it can be shown that the fractional heating loss in the feeders must be proportional to the length of the feeders.*

Let us first assume any site B and let l_n and S_n be the length and cross-section of the feeder from B to the nth distributing station A_n. Let the current taken by this station have a fixed value, I_n, and let P be the sum of the power losses in all the feeders. Then for a given value of P the requisite volume of the copper has its minimum value V, when †

$$\frac{I_1}{S_1} = \frac{I_2}{S_2} = \ldots = \frac{P}{2\rho(l_1 I_1 + l_2 I_2 + \ldots)} \quad . \quad (18)$$

where ρ is the volume resistivity of copper. It readily follows that

$$V = \frac{4\rho}{P}(l_1 I_1 + l_2 I_2 + \ldots)^2 \quad . \quad . \quad . \quad (19)$$

We see that for *any* given site the cost of the copper is reduced to a minimum when the current densities in the feeders are all equal and are given by the Equations (18). If this value of the current density be too high, then the maximum permissible value of the current density should be used. This is a useful theorem.

We now suppose that the position of the site of the power station is varied, P, I_1, I_2, etc., always having the same values. In this case we see from (19) that V depends on the square of the value of the expression $l_1 I_1 + l_2 I_2 + \ldots$ It is therefore of importance to keep this expression as small as possible. Mr. Carrothers ‡ has suggested a simple mechanical method of finding the point or points where ΣlI has a minimum value. A few general rules, however, can be given which enable this site to be found at once in special cases.

Let us first suppose that there are only two distributing centres, A_1 and A_3 (Fig. 7), and that $I_1 = I_3$. In this case $\Sigma lI = (l_1 + l_3)I_1$. Hence V has its absolute minimum value $V_{min.}$ at every point on the line A_1A_3. A considerable latitude is therefore allowed to the electrical engineer in this case. So long as the power station is not far from the line A_1A_3 the expense for the necessary copper will be near its minimum value.

* *Journal I.E.E.*, 1921, vol. 59, p. 123.
† *Ibid.*, loc. cit.
‡ *Ibid.*, 1921, vol. 59, p. 97.

Let us now suppose that $I_2 = I_4$ and that A_2A_4 intersects A_1A_3 in B. Then B is obviously the required site. The position of B is independent of the distances of A_1 and A_3 from it, so long as their loads are equal and they are on opposite sides of B. Similarly the positions of A_2 and A_4 are immaterial. It follows in the limiting case, when the lengths of BA_1 and BA_2 are zero, that B is still the most economical centre. Hence if we have three distributing stations and the load at one of them is equal to or greater than the sum of the loads at the other two, the station taking the heaviest load is the most economical site.

Similarly if there are n stations and the load at one of them equals or is greater than the sum of the loads at the others, the station taking the heaviest load gives to V its absolute minimum value $V_{min.}$.

If the power station is already erected, then, by properly choosing new distributing stations, the copper required for the mains for a given power loss in them can be made a minimum. A much greater latitude is permitted than if we were bound by the rule of choosing

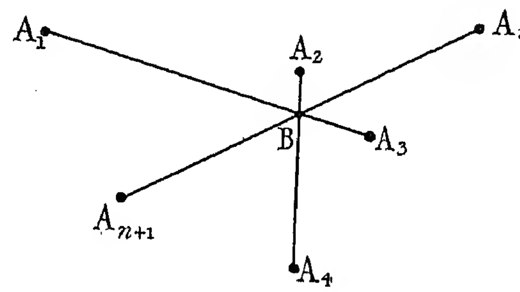

FIG. 7.

the centre of gravity of the load as the generating centre.

In any given case we first choose the site so that ΣlI is as small as practicable. We then apply Kelvin's theorem as follows. Let us suppose that the mains are loaded for H hours per annum, that the price of generating energy is q pence per kilowatt-hour, that the cost of a cubic centimetre of copper is r pence, and that interest plus depreciation is to be taken as 10 per cent. If M denote the total annual cost of the energy expended in heating the mains, together with the annual interest plus depreciation on the initial cost of the mains, we have by (19) :—

$$M = \frac{qHP}{1\,000} + \frac{r}{10} \times \frac{4\rho(l_1 I_1 + l_2 I_2 + \ldots)^2}{P}$$

If we now vary P, M has its minimum value when

$$P^2 = 400(l_1 I_1 + l_2 I_2 + \ldots)^2 \frac{\rho r}{qH}$$

Substituting this value for P in (18) we get :—

$$S_1 = \frac{I_1}{10}\left(\frac{qH\rho}{r}\right)^{\frac{1}{2}}; \quad S_2 = \frac{I_2}{10}\left(\frac{qH\rho}{r}\right)^{\frac{1}{2}} \qquad (20)$$

and the current density in all the mains is $10(r/qH\rho)^{\frac{1}{2}}$.

III. THE SPECIFICATION OF WAVE-SHAPE.

In connection with dangers from resonance, and the trouble that may be caused by interference with neighbouring telephone circuits, it is desirable to have alter-

nators which give sine-shaped waves of E.M.F. under all conditions of load. Failing this it is desirable that, at least on open circuit, they should give sine-shaped waves. We have therefore to test the purity of the wave. The physical method of doing this is to determine the amplitudes of the harmonics in the given wave by resonance methods similar to those used by Armagnat and Pupin.* I think it would be easy to standardize a method of this kind. Many manufacturers, however, think that it would be better to apply some graphical method to the oscillogram of the E.M.F. wave in order to test its departure from sine shape. In this note, therefore, the author will only discuss graphical methods.

The correct basis to determine whether a given wave approximates with sufficient accuracy to sine shape or not is to know whether the ratios of the amplitudes of the third and higher harmonics to the amplitude of the first harmonic are less than certain specified fractions. In many cases one or two simple measurements will serve to reject the wave. As some of the methods in use seem unsuitable it will be helpful to give a brief *résumé* of them and suggest more promising methods. Alternating waves only will be considered, that is, waves for which

$$y = f(x) = -f(x + \lambda/2) = f(x + \lambda)$$

where λ is the wave-length of the complete alternating-current wave. It can be shown that

$$y = a_1 \cos \frac{2\pi}{\lambda}x + a_3 \cos 3\frac{2\pi}{\lambda}x + \dots$$
$$+ b_1 \sin \frac{2\pi}{\lambda}x + b_3 \sin 3\frac{2\pi}{\lambda}x + \dots \quad (21)$$

The amplitude of the $(2n+1)$th harmonic is $(a_{2n+1}^2 + b_{2n+1}^2)^{\frac{1}{2}}$ and its phase lag [see (26)] is given by $\tan \alpha_{2n+1} = a_{2n+1}/b_{2n+1}$. In (21) the standard practice is to write the coefficients a for the cosine terms and the coefficients b for the sine terms.

During the past 100 years several mathematicians have suggested that if we neglect all terms of order greater than $2n+1$ in (21) and take the values of y corresponding to $2n$ different values of x, we get $2n$ equations from which the $2n$ constants $a_1, a_3 \dots a_{2n+1}$ and $b_1, b_3, \dots b_{2n+1}$ can be found. Obviously for high values of n the method is laborious, but several ingenious schedules have been devised which reduce the labour to a minimum.

It is evident that we can only be sure that the results found in this way are correct when the harmonics higher than the $(2n+1)$th are not present in the wave. What is done is to find the curve of the form (21), where a_{2n+1} and b_{2n+1} are the highest terms on the right-hand side, which passes through the extremities of the ordinates $y_1, y_2 \dots y_{2n}$, and then assume that the values of $a_1, a_2 \dots b_1, b_2 \dots$ give the required Fourier coefficients. Gauss† showed that this method can be used for interpolation, and applied it to astronomical problems. It may be useful for this purpose, but for the practical determination of the harmonics it is not suitable as it is laborious and theoretically inaccurate.

* RUSSELL, "Alternating Currents," vol. 2, chap. iv.
† C. F. GAUSS, "Werke," band 3, p. 265.

The method the author adopts is to take the Fourier solutions for a_n and b_n which are given in the form of integrals, and use methods of evaluating them which are well known to mathematicians and actuaries.

Fourier showed that

$$a_n = \frac{2}{\lambda}\int_0^\lambda f(x) \cos n\left(\frac{2\pi x}{\lambda}\right)\partial x \quad (22)$$

and

$$b_n = \frac{2}{\lambda}\int_0^\lambda f(x) \sin n\left(\frac{2\pi x}{\lambda}\right)\partial x \quad (23)$$

Now since $\int_0^\lambda y\partial x$ is simply the area enclosed between a curve and the axis of x, we see that a_n and b_n are equal to the areas enclosed by the curves,

$$y = f(x) \cos n\left(\frac{2\pi x}{\lambda}\right) \quad \dots \dots \quad (24)$$

and

$$y = f(x) \sin n\left(\frac{2\pi x}{\lambda}\right) \quad \dots \dots \quad (25)$$

from 0 to λ multiplied by $2/\lambda$.

The problem is therefore reduced to that of finding the area enclosed by a curve. If we use the planimeter,

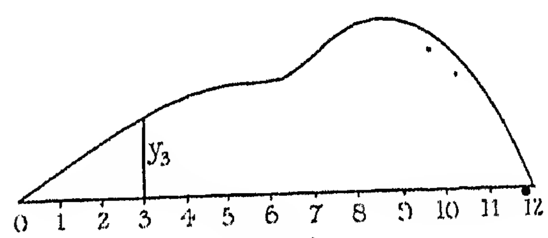

FIG. 8.

however, it would be necessary to draw the graphs of (24) and (25), and this would be laborious. We therefore use the methods of graphical quadrature and draw ordinates.* By drawing a sufficient number of ordinates we can find, theoretically at least, the values of a_n and b_n to any required degree of accuracy.

In practice the accurate measurement of the lengths of 11 ordinates of the given wave is about all that we could reasonably demand from an engineer. We suppose that the base of the positive half of the wave (Fig. 8) is divided into 12 equal parts and that ordinates $y_0, y_1, y_2, \dots y_{12}$ are erected at the extremities of these parts. In practice $y_0 = y_{12} = 0$.

With eleven ordinates we can calculate with sufficient accuracy the value of the first harmonic, the third harmonic and the effective, or root-mean-square, value of the wave by means of the formulæ given below. These values are often sufficient to enable us to judge the wave. In alternating-current notation we suppose that the wave is given by

$$e = E_1 \sin(\omega t - \alpha_1) + E_3 \sin(3\omega t - \alpha_3) + \dots \quad (26)$$

* RUSSELL, "Alternating Currents," vol. 2, p. 132.

Then simplifying the formulæ given in Russell's "Alternating Currents" (vol. 2, p. 132) we get:—

$$E_1 \sin \alpha_1 = \tfrac{1}{40}\{2(y_0 - y_{12}) + y_4 - y_8\} + \frac{\sqrt{3}}{40}(y_2 - y_{10}) + \frac{3\sqrt{2}}{20}(y_3 - y_9) + 0{\cdot}241(y_1 - y_{11}) + 0{\cdot}065(y_5 - y_7) \quad . \quad . \quad . \quad . \quad . \quad (27)$$

and

$$E_1 \cos \alpha_1 = \tfrac{1}{40}(y_2 + 4y_6 + y_{10}) + \frac{\sqrt{3}}{40}(y_4 + y_8) + \frac{3\sqrt{2}}{20}(y_3 + y_9) + 0{\cdot}241(y_5 + y_7) + 0{\cdot}065(y_1 + y_{11}) \quad . \quad . \quad . \quad . \quad . \quad (28)$$

Squaring and adding the values of $E_1 \sin \alpha_1$ and $E_1 \cos \alpha_1$ given by these equations, we find E_1^2 and thus we can find E_1.

Similarly, we have:—

$$E_3 \sin \alpha_3 = \tfrac{1}{20}(y_0 - y_4 + y_8 - y_{12}) + \frac{\sqrt{2}}{8}(y_1 + y_7 - y_5 - y_{11}) + \frac{3\sqrt{2}}{20}(y_9 - y_3) \quad . \quad (29)$$

and

$$E_3 \cos \alpha_3 = \tfrac{1}{20}(y_2 + y_{10} - 2y_6) + \frac{\sqrt{2}}{8}(y_1 + y_{11} - y_5 - y_7) + \frac{3\sqrt{2}}{20}(y_3 + y_9) \quad . \quad (30)$$

Hence E_3 is easily determined from these two equations. If V be the effective value of e, we get by a double application of Weddle's rule for finding areas:—

$$V^2 = \tfrac{1}{40}\{y_0^2 + y_2^2 + y_4^2 + 2y_6^2 + y_8^2 + y_{10}^2 + y_{12}^2\} + \tfrac{1}{8}(y_1^2 + y_5^2 + y_7^2 + y_{11}^2) + \tfrac{3}{20}(y_3^2 + y_9^2) \quad . \quad . \quad (31)$$

Table 1 has been computed by means of (28), (30) and (31). All the waves being symmetrical, α_1 and α_3 are zero.

TABLE 1.

Shape	$y_{max.}$	V	E_1	E_3
Rectangular ..	1	1	1·273	0·424
Circular	1	0·816	1·134	0·188
Parabolic	1	0·730	1·032	0·038
Sine	1	0·707	1·000	0·000
*Circular topped ..	1	0·707	0·999	−0·013
Triangular ..	1	0·577	0·811	−0·090

As we always have

$$2V^2 = E_1^2 + E_3^2 + E_5^2 + \ldots \quad . \quad . \quad . \quad . \quad (32)$$

this suggests that the harmonic factor † which equals

$$\frac{\{2V^2 - E_1^2\}^{\frac{1}{2}}}{E_1} \quad \text{or} \quad \frac{\{E_3^2 + E_5^2 + \ldots\}^{\frac{1}{2}}}{E_1}$$

might be taken as a criterion for sine shape. From the table given above we see that for a rectangular wave the harmonic factor is 0·48; for a circular wave 0·19; for a parabolic wave 0·04; and for a triangular wave 0·12. Unfortunately, for waves which are very approximately sine-shaped, V and E_1 have to be determined with an accuracy much exceeding the probable accuracy of the measurements of the ordinates in order to get an accurate value for the harmonic factor. It is therefore of little use for the end we have in view.

Another factor that is often used is the "deviation factor." This factor * is defined as follows: "The deviation factor of a wave is the ratio of the maximum difference between corresponding ordinates of the wave and of the equivalent sine wave of equal length to the maximum ordinate of the equivalent sine wave when the waves are superposed in such a way as to make this maximum difference as small as possible."

To examine this definition, let us consider those waves for which e has a large maximum value when ωt in (26) is 90° and for which $\alpha_1 = \alpha_3 = \ldots = 0$.

In this case the deviation factor is

$$\frac{(E_1^2 + E_3^2 + \ldots)^{\frac{1}{2}} - E_1 + E_3 - E_5 + \ldots}{(E_1^2 + E_3^2 + \ldots)^{\frac{1}{2}}}$$

This fraction is a complicated function of the amplitudes of the harmonics, and there is no mathematical reason why we should adopt it. By considering special cases also it can be shown that the value of the deviation factor varies with the time-lags of the various harmonics. There seems to be no justification for using such a definition.

As formula (31) is new some may hesitate to accept it. As we have so many ordinates, however, the ordinary formulæ for V^2, namely,

$$12V^2 = \frac{y_0^2 + y_{12}^2}{2} + y_1^2 + y_2^2 + \ldots + y_{11}^2 \quad . \quad (A)$$

or better, $\quad 12V^2 = Y_1^2 + Y_2^2 + \ldots + Y_{12}^2 \quad . \quad . \quad . \quad (B)$

where Y_1, Y_2, are the ordinates at the midpoints of the portions into which the base is divided, may be used. Table 2 shows the errors introduced by these formulæ when applied to find V^2.

TABLE 2.

Shape	Error using (A)	Error using (B)
	Per cent	Per cent
Rectangular	Correct	Correct
Circular	0·7 high	0·3 low
Parabolic	0·005 low	0·004 high
Sine	Correct	Correct
Circular topped	Correct	Correct
Triangular	1·4 high	0·7 low

It is curious to notice that if we divide the base of a sine wave into n equal parts and use formulæ similar to (A) and (B) we always get the correct answer in both cases. The result given by formula (31) gives the exact answer in all the cases considered above.

* The top part of this curve is the quadrant of a circle of radius unity. The tangents at the ends of the quadrant form the rest of the wave. They are inclined to the axis at an angle of 45°.

† BEDELL, *Transactions of the American Institute of Electrical Engineers*, 1915, vol. 34, p. 1135.

* Standards of the American Institute of Electrical Engineers, Def. 3274, 1921.

It is not difficult to find a case where using (31) would introduce an error. Take, for example, a symmetrical trapezoidal wave the top part of which is a line parallel to the base and equal to one-third of it. If the maximum height of the wave is unity, we have :—

by (A), $V^2 = \frac{5}{9}(1 + \frac{1}{80})$.
by (B), $V^2 = \frac{5}{9}(1 - \frac{1}{160})$
and by (31), $V^2 = \frac{5}{9}(1 - \frac{1}{64})$

The true value of V^2 is $\frac{5}{9}$, so in this case (31) actually gives the greatest error, V determined in this way being nearly $0 \cdot 8$ of one per cent too small. The reason of this is that there are two points of mathematical discontinuity in the wave, and (31) has been obtained on the assumptions that *smooth* curves have been drawn through the extremities of the ordinates y_0, $y_1, \ldots y_6$ and through $y_6, y_7, \ldots y_{12}$. As points of discontinuity do not occur on practical waves, (31) is the safest formula to use. By the use of similar formulæ actuaries check "tables of mortality" which are obviously governed by no simple law. A serious objection to using (B) is that it entails the labour of measuring the lengths of the 12 new ordinates Y_1, Y_2, $\ldots Y_{12}$.

Four additional formulæ,* which are useful when judging wave shape, can be written down at once from (26). We get

$$E_1 \sin a_1 + E_3 \sin a_3 + E_5 \sin a_5 + \ldots = y_0 \quad . \quad (33)$$

$$E_1 \cos a_1 - E_3 \cos a_3 + E_5 \cos a_5 - \ldots = y_6 \quad . \quad (34)$$

$$E_3 \sin a_3 + E_9 \sin a_9 + E_{15} \sin a_{15} + \ldots = \tfrac{1}{3}(y_0 - y_4 + y_8) \quad . \quad (35)$$

$$E_3 \cos a_3 - E_9 \cos a_9 + E_{15} \cos a_{15} - \ldots = \tfrac{1}{3}(y_2 - y_6 + y_{10}) \quad . \quad (36)$$

No new measurements have to be made as we are using the same ordinates as those we used for determining $E_1 \sin a_1$, $E_1 \cos a_1$, $E_3 \sin a_3$ and $E_3 \cos a_3$. If $y_0 - E_1 \sin a_1$ is not very small compared with E_1, then by (33) some of the higher harmonics are appreciable and the wave could be rejected. Similarly by (34) $y_6 - E_1 \cos a_1$ must be very small compared with E_1. Two other similar conditions are got from (35) and (36). If any of these four conditions is not satisfied the wave can be rejected. It does not necessarily follow that if they are satisfied the wave is approximately sine-shaped. But if $\sqrt{2}V - E_1$ is equal to zero within the limits of errors of measurement, if also E_3/E_1 is a very small fraction and the four conditions stated above are satisfied, the curve might be accepted, provided there were no obvious ripples on it.

If there is a ripple on the wave the frequency of which shows that it is a harmonic of frequency m, its amplitude could be accurately determined by the following equations :—

$$E_m \sin a_m = \frac{1}{2m}\left\{ y_0 - y_{\frac{\lambda}{2m}} + y_{\frac{2\lambda}{2m}} - \ldots - y_{\frac{(2m-1)\lambda}{2m}} \right\} \quad . \quad (37)$$

$$E_m \cos a_m = \frac{1}{2m}\left\{ y_{\frac{\lambda}{4m}} - y_{\frac{3\lambda}{4m}} + y_{\frac{5\lambda}{4m}} - \ldots - y_{\frac{(4m-1)\lambda}{4m}} \right\} \quad . \quad (38)$$

where λ is the wave-length of the complete alternating wave.

As an example, consider a rectangular wave of height unity. In this case $\sqrt{2}V - E_1 = 0 \cdot 141$ and $E_3/E_1 = 0 \cdot 333$. Neither of the first two conditions would be admissible. Formulæ (33) and (35) are satisfied, but (34) and (36) give $-0 \cdot 273$ and $-0 \cdot 091$, neither of which would be admissible.

As another example consider a semi-circular wave of height unity. In this case $\sqrt{2}V - E_1 = 0 \cdot 021$, $E_3/E_1 = 0 \cdot 166$ and (34) and (36) give $-0 \cdot 134$ and $0 \cdot 070$. Remembering that E_1 is $1 \cdot 134$ we see that any of these four would reject the wave.

This section may be summed up as follows. Neither the harmonic factor nor the deviation factor is of much use in determining whether a wave is approximately sine-shaped or not. At present it does not seem feasible to measure graphically with sufficient accuracy the high harmonics of a wave. We can, however, measure without much labour the values of the amplitudes of the first and third harmonics, and the effective value of the wave, with sufficient accuracy for practical purposes by only measuring eleven ordinates. From these values we deduce critical formulæ which enable us to rule out certain waves. Visual comparison of the so-called equivalent sine wave with the wave being inspected might be used. But unless the two curves are practically coincident the methods described above are preferable. A method of finding the accurate value of the amplitude of a harmonic ripple on the wave is given.

If this graphical method or an improved graphical method on similar lines be not acceptable, we shall have to fall back on experimental methods of finding the amplitudes of the harmonics. The wave can only be judged when we know its harmonics or superior limits to their values or to the sum of their values.

IV. The Power and Balance Factor of a Polyphase Load.

The author has previously discussed * whether it is possible to define the power factor of a polyphase load in such a way that a knowledge of its value will be of assistance to an engineer in judging the desirability or otherwise of a given unbalanced load. It was proved that if the power factor were defined in a certain way and if, in addition, a quantity called the "balance factor" were defined, then a knowledge of their values would be a help to the engineer. It will be useful, therefore, to give these definitions and to give also a *résumé* of the theorems on which they are founded.

Let us first consider a three-phase case where the voltages between the lines are all equal and their phase

* Cf. Silvanus Thompson, *Proceedings of the Physical Society*, 1910–1911, vol. 23, p. 334, or Russell's "Alternating Currents," vol. 2, p. 128.

* *Faraday House Journal*, 1922, vol. 9, p. 73. See also the many instructive papers on polyphase power factor which were read at the Annual Convention of the American Institute of Electrical Engineers held at White Sulphur Springs on June 29, 1920.

differences, consequently are also equal. If w denote the instantaneous value of the power supplied to the load, we have, with the usual notation:—

$$w = e_1 i_1 + e_2 i_2 + e_3 i_3$$

Assuming that $e_1 = E \sin \omega t$, $e_2 = E \sin (\omega t - 120^\circ)$ and $e_3 = E \sin (\omega t - 240^\circ)$, and writing V for the effective value of e, and A_1, A_2 and A_3 for the effective values of i_1, i_2 and i_3 respectively, we get, if ϕ_1 denote the phase difference between e_1 and i_1:—

$$\begin{aligned} w = {} & VA_1 \{ \cos \phi_1 - \cos (2\omega t - \phi_1) \} \\ & + VA_2 \{ \cos \phi_2 - \cos (2\omega t - \phi_2 - 240^\circ) \} \\ & + VA_3 \{ \cos \phi_3 - \cos (2\omega t - \phi_3 - 120^\circ) \} \\ = {} & R \cos \phi - Q' \cos (2\omega t - \gamma) \quad . \quad . \quad . \quad . \quad . \quad . \quad (39) \end{aligned}$$

where

$$R \cos \phi = VA_1 \cos \phi_1 + VA_2 \cos \phi_2 + VA_3 \cos \phi_3 \quad (40)$$

$$Q'^2 = V^2[\Sigma A_1^2 + 2\Sigma A_1 A_2 \cos \{\phi_1 - \phi_2 + 120^\circ\}]$$

and $\tan \gamma$

$$= \frac{A_1 \sin \phi_1 + A_2 \sin (\phi_2 + 240^\circ) + A_3 \sin (\phi_3 + 120^\circ)}{A_1 \cos \phi_1 + A_2 \cos (\phi_2 + 240^\circ) + A_3 \cos (\phi_3 + 120^\circ)}$$

Since $i_1 + i_2 + i_3 = 0$, we easily deduce that

$$0 = \Sigma A_1^2 + 2\Sigma A_1 A_2 \cos (\phi_1 - \phi_2 - 120^\circ)$$

Hence

$$Q'^2 = 2V^2 \{ \Sigma A_1^2 - \Sigma A_1 A_2 \cos (\phi_1 - \phi_2) \} \quad (41)$$

The quantity Q' is measured in volt-amperes and gives the amplitude of the double frequency component of the instantaneous power. We see from (41) that it does not vanish when $\phi_1 = \phi_2 = \phi_3 = \phi$ unless we have also $A_1 = A_2 = A_3$.

This shows that to specify a given load usefully we must know not only how the phase differences are balanced but also how the currents are balanced. The first term on the right-hand side of (39) gives the average total power taken by the consumer. From analogy with the single-phase case we have denoted this by $R \cos \phi$. R has the dimensions of volt-amperes but we have not yet defined R and ϕ.

In order to fix our ideas and see the nature of the problem more clearly we shall have recourse to geometry. We shall make the theorems more general by removing the restrictions about the amplitudes and shapes of the E.M.F. waves. To simplify them, however, we shall only consider the three-phase case.

By means of three ordinary wattmeters we can read the power taken at the terminals 1, 2 and 3. Let the readings be $V_1 A_1 \cos \phi_1$, $V_2 A_2 \cos \phi_2$ and $V_3 A_3 \cos \phi_3$ respectively. From analogy with (40) we write:—

$$R \cos \phi = \Sigma V_1 A_1 \cos \phi_1 \quad . \quad . \quad . \quad . \quad (42)$$

Similarly by a meter for the wattless current we find $V_1 A_1 \sin \phi_1$, $V_2 A_2 \sin \phi_2$ and $V_3 A_3 \sin \phi_3$. It has to be remembered that any of the meters may run backwards. If the wattmeter connected with the first main run backwards then ϕ_1 must be greater than $\frac{1}{2}\pi$ or less than $-\frac{1}{2}\pi$.

We now fix the values of R and ϕ by assuming that they are connected by the additional equation

$$R \sin \phi = \Sigma V_1 A_1 \sin \phi_1 \quad . \quad . \quad . \quad . \quad (43)$$

Equations (42) and (43) show that if we draw forces $V_1 A_1$, $V_2 A_2$ and $V_3 A_3$ inclined to the axis of x at angles ϕ_1, ϕ_2 and ϕ_3, then R gives the magnitude of their resultant and makes an angle ϕ with the axis.

In Fig. 9, let $OQ_1 = V_1 A_1$, $OQ_2 = V_2 A_2$ and $OQ_3 = V_3 A_3$. Let also the angles Q_1OX, Q_2OX and Q_3OX equal ϕ_1, ϕ_2 and ϕ_3 respectively. This diagram pictures the volt-amperes taken by the consumer and the phase angles at which they are taken, but otherwise it has no physical signification. The quantity R is the resultant of OQ_1, OQ_2 and OQ_3. If G be the centre of gravity of the triangle $Q_1Q_2Q_3$, by a well-known theorem in statics, $R = 3 \cdot OG$, and the angle GOX equals ϕ. R and ϕ are therefore the same wherever Q_1, Q_2 and Q_3 are, provided that the centre of gravity of the triangle formed by them is at G. Of the loads that have the same R and ϕ, some are obviously more desirable

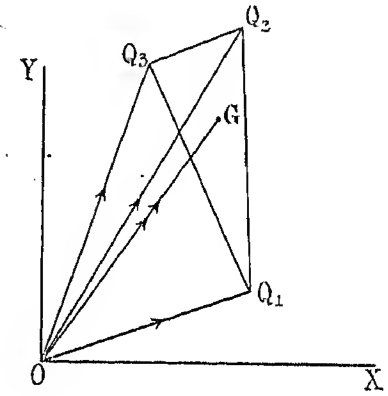

FIG. 9.

from the supply point of view than others. A knowledge of R and ϕ gives us no information about the lack of balance of the currents. We have therefore to find an expression which measures in some way the want of balance of the volt-amperes.

Let $OQ_1 = R_1$, $OQ_2 = R_2$ and $OQ_3 = R_3$ (Fig. 9). By algebra we have

$$3(R_1^2 + R_2^2 + R_3^2) = (R_1 + R_2 + R_3)^2 + (R_1 - R_2)^2 + (R_2 - R_3)^2 + (R_3 - R_1)^2$$

Hence we see that, for a given aggregate value of the volt-amperes, $R_1 + R_2 + R_3$, $\sqrt{3}(R_1^2 + R_2^2 + R_3^2)^{\frac{1}{2}}$ has its minimum value, $R_1 + R_2 + R_3$, when $R_1 = R_2 = R_3$, i.e. when the volt-amperes are balanced. From Fig. 9 we see that when $R_1 + R_2 + R_3$ is fixed, R has its maximum value $R_1 + R_2 + R_3$ when $\phi_1 = \phi_2 = \phi_3$. Hence for a given aggregate value of the volt-amperes, R is less than $\sqrt{3}(R_1^2 + R_2^2 + R_3^2)^{\frac{1}{2}}$, except when both $R_1 = R_2 = R_3$ and $\phi_1 = \phi_2 = \phi_3$. This suggests the following definition of the balance factor, b:—

$$b^2 = \frac{R^2}{3(R_1^2 + R_2^2 + R_3^2)} \quad . \quad . \quad . \quad . \quad (44)$$

It will be seen that the greater the value of b the better the balance of the load, and that when b is unity the load is perfectly balanced.

It may be objected that (44) is a purely artificial definition. That it has some physical as well as geometrical significance will appear if we introduce the definition of the lack of balance, or "unbalance" factor u of the load. We define this quantity by the equation

$$u^2 = \frac{Q^2}{3(R_1^2 + R_2^2 + R_3^2)} \quad . \quad . \quad . \quad . \quad (45)$$

where $Q^2 = Q_1Q_2^2 + Q_2Q_3^2 + Q_3Q_1^2 =$ the sum of the squares of the sides of the triangle $Q_1Q_2Q_3$ (Fig. 9). The value of u is zero when the load is balanced, and it has its maximum value of unity when R is zero and G coincides with O.

By considering the moments of inertia of three equal particles placed at Q_1, Q_2 and Q_3 respectively (Fig. 9) about axes at O and G perpendicular to the plane of the paper, we get at once that

$$R_1^2 + R_2^2 + R_3^2 = 3 \,.\, OG^2 + GQ_1^2 + GQ_2^2 + GQ_3^2$$

Hence

$$3(R_1^2 + R_2^2 + R_3^2) = R^2 + 3(GQ_1^2 + GQ_2^2 + GQ_3^2)$$
$$= R^2 + Q^2 \quad . \quad (46)$$

It follows that $\qquad b^2 + u^2 = 1 \quad . \quad . \quad . \quad . \quad . \quad . \quad (47)$

It is to be noticed on our assumptions that Q_1Q_2 is the vector difference between R_1 and R_2, Q_2Q_3 is the vector difference between R_2 and R_3, and Q_3Q_1 is the vector difference between R_3 and R_1. Hence Q is the vector sum of these unbalanced volt-amperes supposed to act at right angles to one another.

If we rotate the triangle $Q_1Q_2Q_3$ (Fig. 9) about its centre of gravity, G, we get different simultaneous values of R_1, R_2 and R_3, all of which have the same R, Q, ϕ, b and u as the original load. Every triangle $Q_1Q_2Q_3$, the sum of the squares of the sides of which is Q^2 and the centre of gravity of which is at G, will give values to R_1, R_2, R_3, ϕ_1, ϕ_2 and ϕ_3 which will give the same values to R, u and ϕ, or to R, b and ϕ. None of the members of the group of loads which are specified by R, b and ϕ seems to be appreciably more or less attractive to the supply engineer than the others. We therefore suggest that for a rough specification of the magnitude and character of a given load it is sufficient to specify values for R, b and ϕ respectively.

We see that R is the value of the aggregate volt-amperes when $\phi_1 = \phi_2 = \phi_3 = \phi$. It may therefore be called the "equal phase volt-amperes" of the given load.

From Fig. 9 we see that

$$Q^2 = Q_1Q_2^2 + Q_2Q_3^2 + Q_3Q_1^2$$

and when $V_1 = V_2 = V_3 = V$, we get

$$Q^2 = 2V^2[\Sigma A_1^2 - \Sigma A_1A_2 \cos(\phi_1 - \phi_2)]$$
$$= Q'^2$$

Thus for sine waves and balanced voltages

$$w = R\cos\phi - Q\cos(2\omega t - \gamma) \quad . \quad . \quad (48)$$

Q in this case has a definite physical meaning. It is the amplitude of the double frequency component of the instantaneous value of the power. Hence b and u have physical meanings. In general, R and Q are connected with the volt-amperes by the simple relation (46).

It may be asked why do we not take Q/R as the measure of the unbalance of the load. The objection to this is that Q/R can have any value between zero and infinity. In my opinion it is better to use a balance or an unbalance factor which cannot be greater than unity.

Let us now consider how the quantities R, b and ϕ can be measured. We can easily measure the power and the wattless volt-amperes taken at the three feeding points, by means of a wattmeter and a meter for the wattless volt-amperes. Denoting these readings by $R_1\cos\phi_1$, $R_2\cos\phi_2$, $R_3\cos\phi_3$, $R_1\sin\phi_1$, $R_2\sin\phi_2$ and $R_3\sin\phi_3$ respectively, we get:—

$$R\cos\phi = R_1\cos\phi_1 + R_2\cos\phi_2 + R_3\cos\phi_3 = a$$
and $$R\sin\phi = R_1\sin\phi_1 + R_2\sin\phi_2 + R_3\sin\phi_3 = b$$

Thus $R = (a^2 + b^2)^{\frac{1}{2}}$ and $\tan\phi = b/a$. We determine $\tan\phi_1$ and therefore ϕ_1 by dividing the reading of the wattless meter by the reading of the wattmeter. Hence we find $\cos\phi_1$ and, dividing the reading of the wattmeter by $\cos\phi_1$, we get R_1. Similarly we get R_2 and R_3. We then find b easily by (44).

This procedure seems lengthy at first sight, but it must be remembered that a three-phase consumer can take a given amount of power in an infinite variety of ways, some of which would be very objectionable to the supply engineer. Doubtless simpler methods of determining P, b and ϕ will be discovered. Instruments also may be devised for determining these quantities at once.

WESTERN CENTRE: CHAIRMAN'S ADDRESS

By C. T. Allan, Member.

(Abstract *of Address delivered at* Cardiff, 15*th October*, 1923.)

I wish to deal to-night with a subject that has been in my mind for a long time past, namely, the training and, more particularly, the status of the engineer, especially the electrical engineer.

First of all a few words about the training of young engineers—the youths whose capabilities will in the near future determine the position which Great Britain is to occupy among the engineering nations of the world.

I sometimes ask myself if we are not too intent upon producing craftsmen—skilled manual workers—and too often forgetful of the demand for thinkers, men of brains with creative ideas and higher technical knowledge. The latter species must always be rarer than the man with clever fingers; but that is all the more reason for seeking him out and cultivating him.

Take two average young men who desire to be engineers and whose fathers, with average family expenses, can only afford to pay for two or three years' training.

Assume that one of the young men apprentices himself, is taught craftsmanship, and attends evening classes (if he is near them). At the end of his training he is at best an average craftsman or draughtsman—if indeed he has not been left in a groove as a turner or a fitter, or specialized in some particular work for which his foreman thought he showed an aptitude.

Assume that the other young man takes a course at a technical college and takes his diploma or degree after he has been trained to use his brain. His hands will probably have been fairly well trained in the college workshops and during the vacation courses at the neighbouring works.

Both young fellows then begin seeking further advancement. After many vicissitudes they will advance, but when they reach the age of thirty, one of them will be holding a more important job than the other; I am sure that that one will be the one with the trained brain. He will more quickly be able to grasp and solve problems. He will understand more intelligently the meaning and use of the practical appliances that surround him. Both men at the start may have to take jobs as labourers to keep themselves alive, but I know which one will take most advantage of every step that leads to the top. They may neither of them continue to earn their living as engineers, but still the acceleration of the man with the trained brain will be the faster. I am not speaking of freaks, or what I term "brains on legs," but of average level-headed men.

I think that the fetish of manual training is often overdone, because the present-day machine and mass-production methods may often leave an apprentice with little knowledge beyond that of operating one or two machines. I am not decrying manual training in reason, but I remember that the late war showed that an intensive course quickly made raw material into specialized craftsmen. I expect that some of you saw lawyers working lathes, women welding joints, insurance agents as colliers, and publicans firing boilers, as though to the manner born. (Moreover, a civil engineer does not take any part of his training at a bench, and a marine engineer to obtain his certificate must, in addition to his practical work, also have his brain trained.)

Some of the Continental nations do not allow an engineer to practise until he has taken his degree, and it is from these nations that we have to expect fiercer and still fiercer competition in the coming commercial war. We must be prepared to go one better and make an even better product than they to keep our place at the head. Did not the engineers' war, as it was termed, prove that after the men of the British Empire got into their stride they were supreme on the sea and under it, on the land and over it?

When the coming commercial war arrives we must be already in our stride, by preparing the brains of those who are to succeed the young fellows who gave their lives for their country. I believe that this advanced training should be within the reach of all, even free of cost if possible, and the money spent for such a purpose would be returned a hundredfold, nay a thousandfold.

Doctors cannot practice until they have taken their degree; the same is true of clergymen; marine engineers must have a certificate. The trained mind and the trained mind alone can enter into the professions and the higher branches of business.

Our own Institution is leading the way to the production of a technical engineer by its Associate Membership Examination. This is a step in the right direction, but much remains to be done. It has too long been an accepted belief that the technical man can have no proper grasp of business methods and finance. We might be poets and dreamers for all the faith that is displayed by some people in our knowledge of economics. And so we see big undertakings which are essentially engineering concerns under the charge of actuaries, accountants and other specialists in "business methods." On engineering matters these people may be even more ignorant than we are of the niceties of advanced accounting, and they must rely on the advice of their technical staff.

Still, it is undeniable that money talks—and so our young men must have sound training on the management of that eloquent commodity. So far as I can find, none of the technical colleges teaches the art of

economically spending money. Yet an engineer has been described as a man who knows how to do a job for one pound that anyone else could not do for two. Why not encourage him to learn how to do it for ten shillings, by discovering as a student what an invoice is, what happens after he has made out a requisition, what a cost-sheet looks like and what it is for, what accounts for the margin between profit (success) and loss (failure) ?

If the commercial side were added to the training of an engineer, then we might see engineers at the head of more of our industries. In my own company our engineer trainees, by the willing co-operation of the accountants' department, obtain an intensive training in the costing, invoicing, wages and purchasing sections. I heard of two Canadian power company engineers who were looking for a taxi to take them on an inspection. One taxi driver offered his services for considerably less than the other drivers; when asked how he could underbid the others, he said: "I am now a shareholder in your company and am interested in its success. I am making only a little more than my expenses on this trip, but it will come back to me in dividend." Needless to say this taxi driver is getting all the business that the power company can give him. My point is, that if the taxi driver understands what costs and dividends mean, even more so should a young engineer know.

At that I must for the time being leave this question of training, but I sincerely hope that the members of our Institution will give earnest consideration to the points I have raised—the necessity of making the majority of recruits to our profession trained thinkers and brain-workers; and the equally urgent necessity of extending the scope of their technical education so that they may acquire that knowledge of business methods and that capacity for organization which are necessary in the higher appointments. To the young engineer I therefore say: Have confidence, for—

"If you think you're outclassed you are,
You've got to think high to rise,
You've got to be sure of yourself before
You ever can win a prize.
Life's battles don't always go
To the stronger or faster man
But soon or late the man who wins
Is the fellow who thinks he can."

Now let us for a few minutes examine the present status of the already qualified engineer. Why is it that the engineering Institutions have had such an uphill job in establishing the status of the engineer ? Why is he so little understood and appreciated ? Why are his works made ridiculous by a blundering general Press ? Why do non-engineer officials try to thrust him into a back seat ? Why is it we so seldom find his name on his masterpieces ?

The artist takes care to sign his pictures, the eminent actor insists that his name shall appear in large type on the play-bills; even the clerk to the parish council has his name emblazoned on a public notice board, but the engineer's name is seldom to be found.

Members have doubtless seen on the commemoration stones of large public works or buildings the names of the mayor, the aldermen, the councillors, the clerk to the council and perhaps—perhaps, I say—in a corner at the bottom and in small letters the name of the engineer who really did the job.

Upon a prospectus of an engineering venture we find the names of the directors and their titles in full, the stockbroker, the secretary, the solicitor, but seldom or never the name of the man who is going to build the concern and make it run—the engineer. If it does appear he is accused of advertising.

That brings me at once to the bed-rock of the whole question—publicity. Let us dismiss from our minds at once any suspicion that I am asking engineers to advertise in newspapers or handbills. The Institution to which we belong has laid down very proper rules as to professional conduct, and we gladly uphold those rules. Yet the present position is very unsatisfactory; the engineer is isolated.

The doctor comes into frequent contact with all his patients; the actor appears before big audiences; the artist, novelist and dramatist are interviewed and newspapers make them famous.

The minister of religion preaches to whole congregations, and the people know his voice and manner. Even the great soldier, the great sailor, the great lawyer are known to large bodies of men.

The engineer, usually serving boards of directors and corporations without body or soul, is known only to his own staff; beyond them he is a mystery. He might be a hermit for all the public know.

On the films we see the airman, the musician, the traveller, the soldier, the artist, the actor, the sculptor, kings, queens, bishops, Members of Parliament. But did we ever see an engineer on the films ? What is he like ? How would we know him ? Would he be armed with sword or a soldering iron ?

Some may think that this does not matter; but I believe that it matters very much. For better or for worse, the age of publicity has dawned. The rewards of modern life are in proportion to merit and publicity judiciously mingled. Make no mistake, however, pure unadulterated merit has only a dog's life to expect. Unfortunately, publicity can do almost anything. We may put up pure chalk as a tooth powder, and all that we have to do is to spend enough on publicity and it will go like wildfire.

I believe that electrical engineers have the best commodity in the world to sell, and that hitherto we have not known how to sell it. Sometimes the engineer affects to despise publicity, maintaining that it is not of his world. To him it matters not a jot. His duty is to his employers; to laymen he has nothing whatever to say. He is wrong; he is utterly wrong, and the British engineer in particular is wrong. Not only has he personally suffered from his own isolation; the progress of engineering in general has suffered because we are uncommunicative.

In Chicago there is a demand of no less than 800 kWh per annum for every man, woman and child. The average in this country—80—is considered to be quite a respectable figure. Why this astonishing contrast ?

Some of it may be due to cheap English gas. Some of it is due to the American consumer being more willing to try a new thing; but when all is said and done, quite a lot of the difference is due to the fact that the American electric supply interests understand publicity and that ours do not.

We are now being taught and we all admire the good work of the British Electrical Development Association, who are, however, working under a handicap, namely, lack of funds. They should be in a position to spend £10 where at present they spend only £1. This would enable them to influence public opinion a great deal more, whereas on their present meagre basis they must largely content themselves with internal work amongst the electrical industry itself.

I have given the above instance of the greater use of electricity in America, which is also true as regards Switzerland, Italy, Sweden and many European countries, because I maintain that the British engineer is altogether lacking in the spirit of commercial publicity, both with regard to his inventions and with regard to himself.

The engineer undoubtedly is the head of the modern community. The people are transported by him, lighted, warmed, fed, given their news, their entertainment, their clothes, their telegrams, their national defence, their fuel, water, furniture, buildings and sanitation—all due to the engineer. But although all this is due to him, although he does more for the civilized community than any other profession, he is as isolated and unknown as though he lived on a desert island. He is so obscure that writers and journalists (of the lay Press) do not even know where to find him. They can write of art, music, travel, even of medicine, quite sensibly; but they publish the most ridiculous news about engineering work simply because they have no immediate access to the engineer. Even when he reads their nonsense the engineer opens not his mouth.

Some years ago a novelist wrote a book in which a power station was described. It was a building filled with immense zinc rods in gigantic porous pots—and that is about as near the public ever gets to us. There is a gaping chasm between. I suppose that if that novelist had inquired at his club for a reliable electrical engineer to inform him, he would in all probability have been directed to the nearest plumber.

I could go on giving instances of the engineer's utter lack of touch with the community for which he does so much, but I think that members will understand what I mean from these few examples.

I am not ambitious enough to propose offhand a detailed remedy for this state of affairs. Like the question of German reparations, it is somewhat complicated. The solution of our dispute with Germany would have been very easy, however, if someone had found a means of inducing in our late enemy a change of heart. Similarly I suggest that the solution of this relatively small engineering problem will best be brought about by a change of mind. I realize that a complete change of mind is the most difficult of all things to induce. Sometimes it takes generations, but I feel that I shall have made some little progress towards my end if I have made members think about the disadvantages of our present situation. An evil clearly understood is already on the way to remedy. No good engineer approves of the idea of advertising in the ordinary way. But in the endeavour to dissociate ourselves from all suggestion of advertising, is it not possible to go a little too far in the other direction?

Our Institution, I think, has followed a happy medium, but there is at least one other body which has made for itself such rigorous laws that their effect simply is "Unto him that hath shall be given." The professional code of the body I have in mind so operates as to ensure that the more prosperous members shall obtain the bulk of all important new work. The enormous lists of work already carried out by these senior members together with their large connection and affluence act as an advertisement, though of course it must not be so called. In consequence the juniors, who have no advertisement of this kind but are nevertheless bound by the self-denying ordinance of their profession, are placed at a cruel disadvantage. The position is not quite without its humour. The greatest opponents of advertising in this body are the seniors who have already secured the advertisement they require.

Besides, there are ways and means of obtaining publicity which do not come under the ban. These methods of advertising are quite efficient, yet they are not discountenanced. It is like betting, which may be carried on if we are careful to bet in a certain place and manner. For instance, there is the expert who makes such a practice of speaking in every discussion that eventually his name becomes as celebrated as if it occupied the whole front page of a daily paper. In fact, it is a much better method, for he not only gets his publicity free of charge but he gets it amongst the very men from whom he can expect patronage. I am not blaming people of this type. From many points of view they are to be commended. I wish that we all of us spoke up more and oftener.

Members will agree, however, that a system which forbids one type of advertising whilst permitting another is not entirely satisfactory. It allows only the more energetic amongst us or the best elocutionists to come to the front. Sometimes it happens that the silent members have something of value to impart, but they have no gift of public oratory. They are "mute, inglorious Miltons," and so they will always remain. This is a defect of many good engineers. They are far too reluctant to speak. It is one of the phases of the question with which any reform movement would have to deal.

I have for a very long time thought that part of a schoolboy's training (especially those that intend to be engineers) should include instruction in debate.

Some members will shudder at the thought of these benches being filled some day by a whole battalion of glib young orators. My plea is not for the wholesale manufacture of hot-air merchants. Talking is too often the negation of doing; but the really effective speaker is the man who gets to his feet only when he has something of consequence to say. Let us hope

that the trained debater of the future will have acquired not only the gift of self-expression but the wisdom contained in the old adage—"Stand up, speak up, shut up."

Were any court of inquiry to hold an investigation, they would come across some surprises. They would find, for instance, that an exaggerated horror of publicity did not conduce to the best engineering work. In the case of the body that I have mentioned the monopolizing of all big new work by the senior members, who are often overloaded and no longer young, means that such work may be deputed to clerks and to beginners. Thus the client is badly served and the reputation of the profession suffers. A reasonable system of publicity would have given the underloaded and quite capable rising men much more of this work to do.

In this connection, a universal defect of engineers is their lack of appreciation of the Press. Here I may say at once that I have taken some trouble to find out how the engineer is regarded by the Press which may be credited with some knowledge of this question of publicity.

The lay Press finds that the engineer is aloof and non-communicative. He fears reporters and gives them evasive answers. Now I contend that instead of ignoring the lay Press, the engineer should consider what advantage could be taken of the situation, not for himself personally but for engineering in general. There may be an opportunity for him to correct some ridiculous impression and to replace a silly description by an accurate one which will stir the public imagination.

Unfortunately this attitude of hostility towards the lay Press is often extended towards the technical Press. Knowing many members of the technical Press as I do, all of them trained engineers and most anxious to fight our cause at every turn, I really think that this is most unfortunate. If something has happened that must not be mentioned, if some project that must not be reported is on the carpet, the best way to deal with the technical Press is to make them fellow conspirators. Tell them exactly what the mystery is if we possibly can, and put them on their word of honour not to print a word; but do not do this needlessly and frequently or they will grow tired of it. There are so many things that might quite easily be told to the Press, yet are withheld out of a spirit of distrust or lack of sympathy or fear of responsibility.

Bureaucracy is often at the bottom of this uncommunicativeness.

The reason why it is so difficult to obtain interesting news from some of our big manufacturing firms is that every official is afraid to mention facts before consulting the next official above him, and as this system ultimately leads to the managing director, who may be in the South of France and have a dislike of all newspapers, nothing but uninteresting or misleading information is available to the Press.

The bigger a British concern is, the less are its personal sympathies and the smaller is its appeal to the public, even to the technical public (ourselves).

That is a rather serious state of affairs for this country. Big manufacturing firms in America fully recognize the value of publicity and go out of their way to publish news. The American public are permitted to know the service that the engineer can offer them, and that means increased business not only for American engineers but for America generally.

The failure of the British engineer to appreciate publicity has grave disadvantages. As a result he suffers in status, in public esteem and in remuneration; more than that—the products constructed by his genius are restricted in quantity.

Not only are engineers at fault as individuals. When they band themselves together in technical bodies they are usually driven by a desire for the approbation of their own kind to forgo the approbation or even the notice of the public who are their customers.

Further, when engineers combine to form a big trading and manufacturing concern, the bureaucratic spirit of its officials and the consequent fear of responsibility tend to cut off all communication with the firm's clients. Such news as clients receive is obtained only from the catalogues.

In fact, turn which way we will in the British engineering field, whether to individuals, to certain professional associations or to great trade groups, we find that the conditions invariably tend towards the isolation of the engineer and all his work. The public who are so deeply indebted to him and from whom he obtains his living hardly know of his existence.

It seems to me that it is a totally wrong and unnecessary situation. I believe it largely accounts for the fact that although the British engineer is the best in the world, he is very far indeed from being the best appreciated. It accounts for the fact that the legislators penalize him and that in many cases non-technical officials succeed in making him a subordinate.

The engineer up to the present has been too silently doing his work; but add to his training the art of self-expression and nothing can prevent him from taking his place at the head of affairs—whether it be in Parliament, in industrial life or in town councils—where most of the money expended is for work that will eventually be done by engineers. If one looks at the lists, one will notice how many lawyers are in Parliament. Their profession requires that they can speak lucidly in public. But how many engineers do we find in Parliament?

I hope that the engineer of the immediate future will see his opportunity and assume his natural right to direct as well as to construct. If he has the advantages I have spoken of—the trained mind as well as trained hands, the sound knowledge of finance and modern business methods, and finally the power of self-expression reinforced by practical knowledge—with all these advantages he cannot fail to influence the course of events and so render invaluable service not only to his profession but to the country as a whole.

NORTH-EASTERN CENTRE: CHAIRMAN'S ADDRESS

By THOMAS CARTER, Member.

"THOUGHTS BY THE WAY."

(ABSTRACT *of Address delivered at* NEWCASTLE, *22nd October*, 1923.)

ENGINEERING.

When Thomas Telford and others of the loving subjects of King George the Fourth formed themselves into a Society for the general advancement of Mechanical Science, their object was to promote the acquisition of that species of knowledge which constitutes the profession of a Civil Engineer, being the art of directing the Great Sources of Power in Nature for the use and convenience of man. We are all civil engineers in the original sense: the title was used to distinguish its holders from military engineers, who were the only engineers from their first coming to England with William of Normandy in 1066 right down to the eighteenth century. When we remember that it is only about two hundred years since the modern engineering movement in Britain began, and when we think how to-day it permeates the whole national life; when we recall that whereas the early engineers had to grope in the dark for information and help, everyone of us has the chance of learning more than they ever knew, though few of us have the wit and the brain to snatch it; when we recollect that at first engineering was not thought to be a gentlemanly job, but that King George the Fifth himself is now our patron, we begin to realize the enormous change that has taken place in what is but a day or two of the history of the world. So we go from stage to stage: John Bright said truly that we stand on the shoulders of our forefathers and see further. This twentieth century has already witnessed amazing developments: aeroplanes, not long ago things that we almost broke our backs to see as they flew above us, became as common as sparrows during the war, although the first flight from England to France was accomplished only in 1909; moving pictures, exhibited about 20 years ago as a scientific novelty, have now become a necessity, it may be of sometimes questionable value, in the lives of millions, requiring, in place of two licensed cinematograph theatres in London in 1909, no less that 289 in 1919; a huge industry has arisen in the motor-car trade; wireless telegraphy and telephony are sturdy youngsters rapidly growing up; ordinary telephony, the other and older form of a most marvellous thing, is coming more and more into use even in this country. It ought not to be forgotten that many of these things increase the complexity of affairs, and add to the difficulty of doing ordinary business thoroughly and with due thought, because they hasten everything and speed up the rate at which we live. All this is inevitable, no doubt; but in taking stock of our blessings, we must count their cost and strike a proper balance.

THE LAST TEN YEARS.

We may spend a little time usefully in reminding ourselves of a few of the far-reaching changes brought about during the last ten years because of the war, with its never-ending influence, as well as in the normal course of the development of things. Japan (very much in our sympathetic thoughts lately), starting from a foremost place in the Far East, has forged ahead enormously, her foreign trade increasing from 92 millions sterling in 1910 to 438 millions in 1920. Europe itself is utterly changed, with kings overthrown, and with new and in many instances hitherto untried methods of government set up. Europe was the creditor of the United States before the war for 4 500 million dollars, but owed the United States 13 500 million dollars in 1921. In our own country the cost of living is still about 70 per cent above its pre-war value. As a nation, we spent about 134 million pounds in 1900; in 1913–1914 the total had grown to just over 200 millions, while in 1922–1923 it was not far short of 1 000 millions. There is, too, a deadweight debt of over 7 000 million pounds claiming interest and redemption at the rate of about 350 millions per annum; while the 7 000 million pounds are mostly war pounds of low value, we must pay the charges at a fixed percentage rate, in pounds of now greater value, relatively, therefore, more difficult to obtain.

It is calculated that more fuel and iron were taken out of the earth during the ten years from 1911 to 1921 than during the whole of the nineteenth century; and we are still tending to use our resources at too great a rate. The study of fuels, however, is attracting special attention; low-temperature carbonization of coal is being investigated as a means not only of increasing efficiency but also of improving the state of the atmosphere by the avoidance of smoke. Having squandered our fuel almost without thought for so long, we can scarcely pride ourselves on our desire to lock the door of the stable now before the last hair of the horse's tail has finally passed outside; but let us take it as a sign of grace, and encourage it in every possible direction.

THE FOUNDATION OF THINGS.

Engineers above all other men need the spirit that will overcome difficulties. It is the faith that expects to finish a job some day that is the justification for ever starting it at all; that is what we need supremely. More particularly is it needed in that abstruse branch of engineering—I am right in calling it engineering, am I not?—that for forty years has been seriously tackling

the question of the mechanism of the universe. Man has found out very little as yet; what we can learn from the past, wonderful though it be, is as nothing to what is waiting to be revealed in the future. The man with the most profound experience of how things may work is of necessity the humblest of all men because he knows that he does not know.

The warp of the universe is unrolling itself from moment to moment so that we may help to complete the pattern worked out for the endless piece. Some of the pattern we have discovered, while some is not yet clear; moreover, some that seemed clear in the past is no longer entirely so; and we are coming more and more to regard all theories as provisional, and as open to possible revision at any time. We are as the blind would be who tried to read a book printed in Braille type without having been taught what the symbols stood for; even if they had been told the story a little they would have to find out the meaning of the symbols as they went along before they could follow it word for word. No more fantastic than that was the undertaking of Lord Kelvin when, following earlier speculators, he set out to propound a definite view of what the atom might be like; his work has been continued by J. J. Thomson, by Rutherford, by Bohr, and by many others of enormous courage, each drawing the curtain aside a little more from the final picture.

Some Technical Problems.

Much attention has been given from time to time to output coefficients, mass factors, or size factors, as they are variously called, these being expressions that attempt to set out the relation between output and dimensions. The usual assumption for dynamos and motors is that their output depends on the volume of the rotating part, that is, on its diameter squared multiplied by its length, commonly known as its d^2l; and the statement is ordinarily given in the form of a curve connecting d^2l with watts per revolution per minute. It has been too little emphasized, though Carus-Wilson in 1898 and others before and since have pointed out, that watts per revolution per minute is an expression not really involving the idea of speed at all. Watts are work per second, measured in joules per second, and hence the watts per revolution per minute are 1/60th of the joules per second divided by the revolutions per second, that is, 1/60th of the joules per revolution. But the work per revolution done by a rotating body is, numerically, equal to 2π times the torque exerted by it; hence the watts per revolution per minute are $2\pi/60$ times the torque of the rotor in units corresponding to joules, that is, $(2\pi/60) \times 10^7$ times the torque of the rotor in dyne-centimetres. Torque has nothing to do with speed, but it is merely the product of the radius of the rotor and the total tangential force exerted on the surface of the rotor by the interaction of the magnetic field of the machine and the current in the rotor conductors. As is well known, the important constants in an electrical machine are the ratio of pole span to pole pitch, the flux density in the air gap, the ampere-wires per unit length of rotor periphery, the diameter and the length of the rotor core, and the speed of rotation. Heating problems, and commutation problems in machines with commutators, determine the possible relations of these constants to one another, but the general statement, always true, is that the watts of a machine are the product of π^2, pole-span ratio, air-gap density in lines per unit area, ampere-wires per unit length, rotor diameter squared, rotor length, and speed in revolutions per minute, divided by 60 and by 10^8; or, in symbols,

$$\text{Watts} = \pi^2 \psi B_g a_w d^2 l n / (60 \times 10^8).$$

This is independent of the unit of length so long as all the quantities are expressed in the same unit. Taking direct-current machines as an example, I have found that the air-gap density and the ampere-wires per unit length of periphery may be expressed by purely empirical formulæ as quantities dependent on the rotor diameter, and when these empirical expressions are substituted in the general formula, it becomes :—

$$\text{Watts} = (1/205)\left\{d^4/(d + 16\cdot5)(d + 33)\right\} ln,$$

when d and l are in centimetres, and

$$\text{Watts} = (1/12\cdot5)\left\{d^4/(d + 6\cdot5)(d + 13)\right\} ln,$$

when d and l are in inches. These empirical formulæ have no real physical meaning; they merely happen to fit certain facts with some approach to accuracy.

In passing from the question of output coefficients I would suggest that the different opinions held about this, as about every other problem, arise from the different personalities of the holders. We all stand and look at the same thing; no two of us stand at the same point, and consequently different aspects are presented. The trouble is that each of us swears that he has seen the whole thing; it is the old story of the two knights and the shield over again, and I believe that this explains the different philosophies, religions, schools, and political parties that have existed since the world began. There are things that matter, about which we all agree that we dare not compromise; there are things essential to the stability of the nation that we must accept and do, whether we like them or not; but many a question, seeming great to those who strive about it, so great that it obscures the light of day, could be settled in a word if it were but realized that there must always be a relativity of view, and if some attempt were made by the disputants to change places one with another in an endeavour to arrive at some common acceptable conclusion—an honest and courageous endeavour, with no turning of a blind eye to what it is thought should be invisible.

Industrial Problems.

Most of us know far too little about economics; economic science is largely experimental and empirical because its data are changing from day to day with changing conditions, and it must adapt itself with perfect flexibility to things as they are before it can attempt to advise on the future. During the war, when apples were very scarce, I saw one, only one, on a plate in the fruit stall at King's-cross station.

I asked the girl in charge how much she wanted for it; and she answered, "A shilling." "Is it really worth it?" I asked her. She said, "If you want it enough, you will pay a shilling for it." I am not an expert in economics, and neither, I imagine, was the girl; but I am sure that she summed up a considerable part of it all in her answer. The relation between cost prices and selling prices; advertising campaigns to create and to stimulate desire; the advisability or otherwise of a corner in wheat; are not all these regulated and determined by the very principle enunciated so light-heartedly about the apple? So it is that now and again some mysterious Saharavitch or Braunschild or Stonyfellow, sitting at the centre of his web of vast financial dealings, can so control the threads in accordance with these very needs and desires of ours that a touch of his finger sends some of the mighty to ruin and raises up others from obscurity to take their places, while he himself is more powerful than them all.

It would be entirely out of place for me to say anything in detail about modern industrial problems, linked as they are to so great an extent with highly controversial questions at home, and dependent as so many of them are on international affairs of so wide and complicated a nature that we dare not enter on them now; but although we cannot suitably undertake a particular examination, we may pause to recall one or two general principles. If we take, as one out of many possible examples, the relation between employers and unions of manual workers, must we not think of it as having arisen out of something that was originally very like the relation between father and son? The old days—in many ways, though not in all, the better days—witnessed a fatherly interest in his apprentices and his journeymen on the part of their master, and on their side a feeling of gratitude for much knowledge imparted to them. Let us carry down the simile, and remember that only fifty years ago, a mere nothing in history, did we begin in any real way to think that all children might be worth a general education. That was an almost frightening experiment. There have been, and are, all sorts of mistakes in carrying it out that only the further education of the educators will remedy; and, meantime, a vast nation of rather crudely instructed people has arisen, so few of them having grasped any essentials, and so many of them wanting heaven before they are ready for it, that earth is like to become hell for us all through sheer lack of knowledge of how to steer clear of slippery downward slopes. Now let us think together: if our sons and our daughters, not long at school and with just enough knowledge to make them imagine they know everything and want to rule everything, come and tell us that we are old fossils, that we don't know what is good either for us or for them, that our sort of people has had its day, but that in their magnanimity they are willing to blame the system that produced us rather than us ourselves, do we then and there hale them before the magistrate for breach of contract? Or, if we suggest to them that some things might be better done, do they say that we are trampling them to the dust and are not fit to be their parents? Often enough there is anger and sternness, I agree; but in the great majority of these troubles, anger and sternness are moderated by a sense of fitness that recognizes the equal humanity of the temporary antagonist and the certainty that all our lives are so interwoven that the good and the hurt of one are the good and the hurt of us all; and a friendly talk, with a will to agree on both sides, smooths away the difficulties and leads to a lasting good understanding. I venture to suggest that the very same broad principle would settle many terrible troubles in the industrial world if it could but be applied; and why not?

I fear that political and parliamentary interference in these matters is almost necessarily bad; Parliament does not undestand the problems. Industry itself must somehow devise the means for the solution of its own problems, and the first step is to realize that every man, every class, every group, every party must hold individual views, destructive, perhaps, of each other, until some wider and better view is put before each of them and is made so attractive that it will lock them all together in a determination to find a way out of their darkness hand in hand. We hear much of the demand for a fair day's pay for a fair day's work; but the implication of that, not always fulfilled, and not always even remembered, is that a fair day's work is going to be done. I do not speak without knowledge when I say that a sitting down together, with goodwill all round, will lead to almost amazing results to the advantage of all; I have the best of reasons for knowing the splendid effect of mutual loyalty and trust and support. Sentiment, the cynics say, has no place in business; I say it is a lie, and a very stupid libel on humanity. If every man in industry really made up his mind to think of industry before himself, what a revival there would be! And how beneficially it would react on himself; for, as always, the seeking of the greater things causes all the rest to be added as a gift. The success of industry inevitably is the greatest interest of all of us. The more we have ourselves of knowledge and education and training, the more may industry, and the nation itself, rightly demand from us. The times are changing, and many ancient things are being shaken: let us see to it that the world is carried across from the old to the new on the broad shoulders of men of understanding.

Other Problems.

I am sure that engineers ought to be more in public life than they are; many problems have to be dealt with there that would be more fitly solved if engineers, with the advantage of their knowledge, training and experience in large affairs, were in a position to advise and had some say in their settlement. One of the strange and disturbing things about public life at present is that those who enter it to govern others often show by their public actions that they are unaware of the first principles of how to govern themselves; I feel that here the engineer's habit of dealing with intricate problems dispassionately might serve to counteract much violent haste that only slows down real progress towards what it would achieve.

Much that is known has not even yet been written down in books, and although we are far from the days

when each man had practically to begin at the beginning and find out things afresh because there were no records, there is a refinement in work and a skill in craftsmanship that cannot be acquired except from those who have themselves learned from a still older generation in their youth and so make us the heirs of centuries if we learn from them in our turn. When our interest is first awakened we are all eager to learn, and our undisciplined efforts are absorbed in copying others: only later do we pass through a stage of more precise understanding to generalization and invention and discovery for ourselves. How vitally, therefore, it matters that the foundation should be well laid at the beginning; and if we find an older man, willing to help us because we are young, how much more secure will the end of our work be!

The Training of Engineers.

Education cost us as a nation over 19 million pounds in 1913–1914 and over 55 millions in 1922–1923; yet Professor Burnett of St. Andrews, in his Romanes lecture at Oxford, expressed the view that ignorance is increasing to such an extent that there is a possibility of another dark age. Professor Burnett also warned his hearers against thinking that "there existed somewhere a stock of ready-made knowledge, which had only to be doled out liberally to satisfy all needs. That was altogether wrong. . . . What could be supplied from stock was merely the sediment of dead knowledge, though even that was valuable, since it furnished us with the necessary tools for the real activity of knowing. But it was not itself the real thing. The only knowledge worth distributing was living, first-hand knowledge." Anthony Trollope remarked to Miss Dunstable, who said that one doesn't ponder over soap bubbles, "Pardon me, Miss Dunstable, one does, but nine hundred and ninety-nine do not." Hence we have so terrible an occurrence as the grave statement in a newspaper that scientists are seeking a new ray with which they will "defy the normal law of gravity." What do people who say these shocking things think the law of gravity is? And how do they propose to "defy" a natural law, when all they can do is to prove it right or wrong? The hopeless confusion between a political law, which is merely a public sanction and may be defied and disobeyed, and a natural law, which can no more be defied or disobeyed than rhomboids can be argued with and cajoled into looking more like pelicans than they do—this confusion, I say, would be ludicrous if it were not symptomatic of the state of much current so-called knowledge.

I want to suggest that, important as is the provision of the right sort of education for those who offer themselves to be educated, it is even more vital to select for that education only those who can use it properly. If the community allows us to be born and to grow up, it is, I maintain, its bounden duty somehow to see that we are offered the sort of life to live that will be best both for us and for it. The aim of all education ought to be, first, to fit us for our share in the general work of the state as citizens, and second, to prepare each of us for some individual contribution to that work according to any particular fitness we may have. Without resorting to specialization at too early a stage, skilled teachers ought to be trained to discover the characteristics of the children in their care, so that eventually engineers may be educated as engineers and not, for example, as drapers, and, on the other hand, one who should be getting ready to write books may not by accident stray into the engineering course of some university. Provide means for educating engineers; but see that engineers are provided also. Under such a regime as that we should be able to pay our duty to the State in return for the right to live our proper life.

We dare not send down our designs into the works bearing the legend "We think these are correct"; we must be sure, for the construction of a machine is not like a book-keeping transaction in which an error can be corrected, or like a wrong payment, which may be adjusted by the passing of a cheque. A slide-rule is the servant of a brain, not a substitute for one; and the compression of calculations, like the compression of the results of the work of centuries into a few laws and expressions and formulæ, is a worse source of pitfalls and a more fertile field for the springing up of mental sluggishness than most other things. Short cuts are only good when we know where they lead to, and even then they may rob us of the experience that comes of going round the longer way that may bring us sooner home.

Purely intellectual training is to be shunned: it limits and binds and confines. The pure theorist cannot go out into the world of commerce and meet his fellows, mostly not pure theorists, with any chance of success. For that reason, the purely technically trained engineer is unfitted in most instances to sell the machines he designs or builds; to his theory must be added knowledge of men and of their ways if he is not to be beaten every time by the keen man trained to deal with human beings in the very practical school of contact with them. The sense of when to compromise and when to win by appearing to yield or by actually yielding is only certain after much seeking for it. Two precious possessions are the ability to suffer fools gladly, and the knowledge that you do not yourself inflict on the other man that painful need. Things to pray for are the instinct for the right moment and the realization that to arrive at the wrong moment may be fatal: the early bird, on the spot at the proper moment, got the worm; early arrival is not the lesson of that proverb, for the worm, which must have been there even earlier, got the bird, if I may put it so, and was destroyed.

Let us realize supremely that the man who thinks that his training has come to an end with the end of his apprenticeship or when he has gained a university degree is already as one dead and altogether damned; the only live men are those who seek to learn from every occasion something that will serve them well in the future. And of these live men they will live longest who remember that it is not so much achievement that brings happiness as the striving after it, and that "merely to pass through experiences is nothing, but to preserve a clean heart amidst all that comes is everything."

CONCLUSION.

Even if we forget the wider, greater, higher things—the stars, attracting us less than the signs that flash in Piccadilly-circus; the immensities of space, impressing us less than the enormity of our own wonderfulness; the music of the spheres, less distinct to us than the brawl and noise of this present life—nevertheless these rich beauties are always around us, to be seen sometimes when for a moment we open our eyes, and to be used then to refresh us and to keep us from being uglier than we might be. And if we contemplate more frequently those unseen realities that are eternal we shall be caught up into a higher view of what we may accomplish; some of life's discords will resolve into a grand harmony; we shall understand better that while of most things it must be said: "And this also shall pass away," we may view their passing with serene calmness because the few things that remain are sufficient for us; we shall not have to say to ourselves when we have done all that was commanded us: "We are unprofitable servants; we have done that which it was our duty to do," for we shall have recognized and tried at least to do the little more that counts for so much.

Hear, finally, one of Robert Louis Stevenson's "Prayers written at Vailima"; and let us try to catch its spirit for our guidance. "The day returns and brings us the petty round of irritating concerns and duties. Help us to play the man, help us to perform them with laughter and kind faces, let cheerfulness abound with industry. Give us to go blithely on our business all this day, bring us to our resting beds weary and content and undishonoured, and grant us in the end the gift of sleep."

IRISH CENTRE: CHAIRMAN'S ADDRESS

By ROBERT N. TWEEDY, Member.

(ABSTRACT *of Address delivered at* DUBLIN, *24th October*, 1923.)

If some years back this Irish Centre was languishing, it was not because the parent Institution neglected her child, but because the Centre itself could not sustain at full brightness the glow of life with which it was endowed. Members did not produce enough papers out of their native ranks, they were not over-energetic in importing papers, and many of them did not read the *Journal*, although they all grumbled that it was the only return they received for their subscriptions.

Doubtless there was an ever-growing need of reforms, and the most urgent need of all was closer contact, greater intimacy between the parent body and her outliers; but, ever since close contact has been established,—and for this I think we ought to be particularly grateful to those who have occupied this chair during the past few years—we have felt perfectly confident that the Institution is ready and eager, not only to do full justice to her outliers across the narrow seas and the wide oceans, but to make sacrifices for them.

Our parent Institution recognizes full well—and did not need to be forced to recognize—that motherhood has responsibilities as well as rights. Her children recognize on their part that they are bound to her by real ties, which, however, are intangible, and in a great measure indefinable. They vary in their nature and strength with each individual, according to his temperament.

While one man may find pleasure in belonging to the Institution which claims Kelvin, Siemens, J. J. Thomson, Hopkinson, Fleming, Lodge, and a host of other famous men, another will feel an affectionate pride because he is derived from the nucleus of learning and experience from which vital cells innumerable have been distributed over the whole world; and a third will delight in the reflection that the hall-mark set upon his technical ability adds authority to his zeal for the education of his fellows.

The Institution was founded "to promote the general advancement of Electrical and Telegraphic Science . . . and to facilitate the exchange of information and ideas on these subjects amongst members of the Institution and otherwise. . . ." If there could be anything essentially non-national anywhere it is the Institution of Electrical Engineers. It is extra-national, not national or even international. Flags, policies, tongues, colours, sex, opinions, are all one or all nothing to the true spirit of the Institution. It exists solely as an instrument for the promotion and exchange of technical culture for the world at large.

The fact that the majority of the members of the Institution resident in Ireland are citizens of Saorstát Éireann, while the remainder are citizens of Great Britain, should not weigh with the members resident here or elsewhere, and certainly would not weigh with the Council. Goodwill and allegiance to the common banner of scientists throughout the world, vague though it may sound, is the sublimated purpose of the Institution to which we belong. Boundaries, barriers, political

prejudices, and national feuds sink far below our horizon when we meet in Council, or Committee or open session. We meet then not as citizens of any State, but as citizens of the world at large, charged by the spirits of the glorious pioneers of our vocation to continue their work for humanity.

In Ireland we have no well-established traditions in electrical engineering, such as exist in all industrial countries, and that disability works covertly against us. As the resources of the country are developed that lack of accumulated tradition will become a danger unless Irish electrical engineers have anticipated it by taking suitable action.

I can see no better way and certainly no easier way than the hard-beaten high road over which so many thousand electrical engineers have passed since 1883, when the Institution absorbed the Society of Telegraph Engineers and Electricians. The tradition of the Institution is continuous and complete from the days of the earliest telegraphic circuit and the first electric lamp down to the present moment. It is not an English tradition or an Empire tradition but a world tradition. Irishmen will not be degrading their regained liberties by adhering to the Institution which has meant so much to civilization as well as to the profession and the industry of electrical engineering. On the other hand, if we support it feebly or not at all it will be many years before we shall have built up an independent analogous structure attractive to the new generations as they arise, and carrying weight with the Irish public.

The electrical engineer, whether he be an adviser or an executant, but in either case a man properly qualified to undertake work of importance, finds his path beset with numerous abuses and overgrown with the weeds of prejudice and ignorance. The legal and medical professions overcame similar obstacles to progress and public safety by strengthening their guilds, and there is no other solution for us.

I feel that this session may be the most critical time in the history of the Irish electrical profession, and I offer no excuse for turning my address into a sort of domestic homily. The members of the Irish Centre of this Institution have the clay of the future of their profession in their hands. They must mould it as they will. Let us be guided in that moulding by thoughts which have passed through a filter close-meshed enough to reject all but those considerations which will ennoble the profession, and, in so doing, benefit our brethren in Ireland, in the British Commonwealth of Nations, and throughout the world.

Decisions ought not to be made by individuals or by groups within the Centre. The Irish section of the profession should adopt no policy until the whole Irish Centre of the Institution—not the Committee acting alone, nor in Northern Ireland alone—has threshed out the whole matter frankly and openly. The Institution cannot, of course, be a party to its own dismemberment, or to an official discussion involving a question of dismemberment, but it is assumed that the majority of qualified electrical engineers in Ireland are members of the Institution. Therefore the easiest way to reconcile opposing views within the profession in Ireland is by meetings of the Irish Centre.

We must remember that the problem before us is rather terrifying in appearance because it has two heads springing from one trunk. Obviously that is an abnormal phenomenon in science as well as in nature, and the problem involved is first of all to get both heads looking in one direction, and then to metamorphose them into one normal head of benign appearance equipped with a single active intelligence.

In plain unfigured language the Irish Centre should do everything in its power to prevent its disintegration either through the defection of members to form a purely national body within Saorstát Éireann, or by reason of the refusal of members in the north to work with members in the south. Mutual understanding and unalloyed goodwill are the only instruments through which our purely scientific aims and objects can be made to transcend and obliterate political divisions. There must be no whisper of sectionalism in our councils, but councils there ought to be. Personal contact is the finest solvent of human differences, and the Committee of the Irish Centre must set itself to discover some method of contact.

One has to admit with profound regret that there is an almost entire severance of continuity between the northern and southern sections of our Centre. Technically one, we are actually separated, although the outgoing Committee did everything it could do to throw a bridge of fellowship across the gap. Given goodwill everything is possible, and it is the great task before us this session to create or to foster that quality. Our two past-chairmen when attending the Council meetings in London took every opportunity to dispel the somewhat distrustful atmosphere which seemed to exist in the northern part of this Centre, and I shall continue an effort which must have a good effect ultimately. The main work must be done here, and the first thing to do, in my opinion, is to obtain at first hand a statement of grievances in order that the Committee may see what can be done to redress them. Speaking for myself I should like to see several northern members on the Committee, and at least one meeting out of three held in Belfast or Derry. If that were done we should get more papers from Irish members, and we could have a meeting every fortnight during the session instead of about once a month. There might not be a considerable attendance of members at these meetings, on account of the distance to be covered, but there would be immeasurable satisfaction in the thought that the electrical minds of the country were working together, planning an identical programme of much wider and more mutually beneficial scope than would be possible for two anæmic Centres in a small country poorly developed in the engineering sense.

The second head of the problem upon which I am touching takes the form of a suggestion which has been made that Irish electrical engineers should secede from what is termed an alien Institution. I think every man should ask himself what value he attaches to his personal connection with the Institution. Unless he is careless about money, it is to be presumed that the least assessment he can make is that the letters M.I.E.E. or A.M.I.E.E. are worth the current subscription, otherwise he would have resigned his right

to use those letters after his name. There is, then, definitely, a certain amount of prestige or status attaching to the bearer of the letters. The member can come nearer the true estimate of value if he will answer for himself the question: "Would I abandon these letters for the letters of some other Institution, native or foreign?" Maybe he would, in which case there is nothing more to be said, for he will believe, justifiably enough, that neither he nor any other member of the Irish Centre will be damaged by secession.

If he has the courage to admit to himself that he would not abandon membership, I think he should probe the matter still farther as an altruist. He should say to himself: "It is true that I value the advertisement to the world of my qualifications by the display of these letters, and so long as I pay the current advertisement rate I am entitled to display them and shall display them, even in preference to those of the strictly national body which I intend to set up? I can use my title with due effect not only in Ireland, but wherever I travel or settle abroad. But what about the youths of this and the next few generations? I may adhere for practical purposes to my comparatively narrow new society, and continue membership of the I.E.E. merely for its advertisement rights, but I must do all I can in loyalty to induce young engineers to enter the Irish Society rather than the Institution. If I do that successfully, what will be the status of those young men from the advertising point of view when they are competing for positions in Ireland? Furthermore, seeing that these youths cannot be bound like the old-time serfs to Irish soil, what will be their status in respect of competition for foreign positions?"

When our friend has proceeded thus far with his intimate inquisition it may be necessary, depending upon the answers he has given to the foregoing questions, to put others. For instance: "Is it worth while to enter Ireland in a kind of race for professional prestige against the mother of all scientific electrical institutions? Have we any chance against a de-nationalized—in other words, a truly scientific—Institution already numbering more than 11 000 members throughout the world? Is it even worth while setting up a subsidiary or auxiliary institution for the sake of having it national? Would it live? Would it deserve to live from the scientific point of view?"

"But," says someone, "was there not only the other day an instance of the Institution interfering in Irish politics? What was this Committee of the Irish Centre which presumed to advise the Government in drafting the Electricity Undertakings Bill?" Let it be understood at once that this is not even half a truth. The Institution is not empowered by its Bye-Laws, as I read them, nor by its Charter, to take hand or part in legislation. In the case in point the Council of the Institution absolutely vetoed any action by the Irish Centre which could be construed as interference of any kind. What actually happened, and what may happen again, was that the Government official who was entrusted with the arduous and highly technical preliminary work upon the Bill, sought the advice and assistance of the Chairman of the Irish Centre, selecting him naturally and properly enough as the focus of the profession in Ireland. He was bound to refer the matter to the Committee, who in their turn referred it to the Council. The Council ruled that the Committee of the Irish Centre could not act in the manner suggested, but that it was competent for the Committee to put before the Ministry concerned names of members who would act as an *ad hoc* advisory Committee upon their own initiative and responsibility and without reference to the Institution or to the Committee of the Irish Centre. This suggestion was accepted by the official in charge of the Bill; a Committee was formed, and is understood to have done useful national work as a group of citizens with a particular form of prestige attaching to them by virtue of their membership of the Institution. Nothing, it seems to me, could have been more correct; nothing more suitable as a precedent for the future.

I submit that it is nationally, ethically and professionally, right for citizens of any country to give advice, or to offer to give advice to the Government of their country upon technical matters in which they are, by implication, expert. I should consider it an uncitizenlike action to refuse or to withhold such assistance. That a Society or Institution should give advice ex cathedra, even if it is empowered to do so, is open to grave doubt, and there can be no shadow of doubt that an Institution originating in one country, however international its purposes may be, would be acting not merely unwisely but impertinently if it should presume to advise the Government of another nation. That applies with equal force to the Institution *vis-à-vis* the components of the British Commonwealth of Nations, as to the Institution *vis-à-vis* France, or Russia, or the United States of America. Nevertheless a Government might ask, without derogating itself, for technical advisory assistance from the resident members of that Institution which had the greatest prestige amongst the nations. In Ireland, I take it, for many years to come that Institution would be the Institution of Electrical Engineers to which we have the honour to belong.

As our industrial side grows we may expect to receive accessions to the Irish Centre from across the waters, engineers normally resident in other countries, but we should aim very definitely at keeping the Institution constantly before the growing generation. There should be something done by way of propaganda in the technical schools and universities, and this much more in the interest of the budding engineer than in the interest of the Institution. The earlier a young man becomes familiar with the Institution by studentship, the sooner he is likely to pass through the ascending grades to the full membership to which he is sure to aspire. The presence of Students and Graduates of the Institution at our meetings is desired and appreciated by the committee, and I hope that the programme for this Session will attract them and will induce them to bring others who are not yet enrolled upon the Institution lists. When our roll of Students becomes sufficiently long we shall ask the Students to assist us in organizing a special Students' programme, and I think that might include with much advantage visits to many electrical stations and factories which have

lost their appeal to the older members. The Irish Centre acting collectively could do splendid educative work, not only for prospective and selected Students but for the public at large.

Last session I outlined a power policy for Ireland, and nothing has happened since to weaken my belief that our financial credit depends largely upon the adoption of a policy of that kind. The way in which the Liffey scheme is handled by the Government is of enormous importance to the country. It is the first large scheme in the Saorstát, and I tremble to think of the national issues which hang upon it. It is of far more than local importance, and I am not at all happy at the thought that the Government may be content rather to await the outcome of the silent struggle between the several interests which wish to develop the Liffey Falls, than to tackle resolutely the problem of which this scheme should be a part. Ultimately it would be but a small part, but its present importance is so considerable because it is the originating nucleus, and because it is of immediate interest to the capital city.

The credit of this country is just as much or as little as its citizens like to make it. Superficially it seems to be low at present, but I have never faltered in my belief that the possibilities were never greater, and that the engineering profession has graver responsibilities and brighter prospects before it than any other section of the community. Unity of purpose, unity in action, and a clear conception of the goal are all needed, and are all attainable by goodwill and the sacrifice of self to service.

Two events which have occurred recently ought to be sufficient in themselves to remove the gloom which was settling upon the electrical profession and trades. I hail with joy the first number of *Irish Engineering*, and you will join with me, I know, in congratulating those who are responsible for the new venture upon their courage, their delightful optimism (which in my opinion is entirely warranted) and their really astonishing ability as publishers and editors. For years we have felt the need of an Irish journal which on the one hand would keep us in touch with progress in all parts of the world, with particular reference to Irish conditions, and which on the other hand would act as an effective ventilator of subjects which are stifled or stunted unless they are bathed in an atmosphere of crisp, practical and wide discussion. The advent of this journal is of good augury, and every engineer should feel himself bound to support it by every means in his power.

The other excellent augury is the establishment of the Electricity Supply Association of Ireland, which appears to be thoroughly representative of producers of electricity. Such an Association may grow to have enormous powers in a modern State, so one prays that this Irish Association, formed in the first year of our independence, with developments of unknown magnitude before it, will be guided and inspired in all things by that sense of community service which needs development infinitely more than our material resources, because it has relation to that fundamental sense of religion in man, which is in some danger of being torn out by the roots.

I would suggest to that Association the urgent need for pressing the Government, both in and out of the Oireachtas, to press forward certain recommendations that have been under consideration for a long time.

Possibly the most important of these, and the simplest and cheapest to put into effect, is the organization of a Hydrometric Survey. Another is the Geological Survey of the very partially and inadequately explored coal measures with numerous borings; and the third is to continue and to prosecute vigorously the admirable work upon the utilization of the Irish peat deposits, which has been carried so far by the British Fuel Research Board. In that connection I draw attention to the Report for the years 1922–1923 which leaves no doubt in my mind that the large-scale production of peat fuel in Ireland calls for nothing now but native ingenuity applied to the special and unique problem of devising apparatus for getting the whole of the peat out of bogs ranging from 20 ft. to 35 ft. in depth. The problem has been solved already for the shallower bogs of other countries. Surely we shall not be baulked by this embarrassment of riches!

All these things are rendered the more urgent by the deplorable conditions which persist and worsen on the Continent and in England. As the outlet for foreign trade decreases we shall be forced to become self-dependent to a greater degree than we are at present, and unless we anticipate this shrinkage by hastening the development of our internal resources we shall become impoverished to an extent which I do not like to contemplate.

In conclusion, I want to refer briefly to one phase of the useful work which this Institution might do. Our immediate past-Chairman brought before the Committee the question of standards in electrical engineering, and a meeting representative of consulting engineers, manufacturers and contractors was convened to consider the matter and to make recommendations to the Committee.

The subject has for many years attracted much attention in England, and there is a mass of information available for our guidance. Time does not permit me to do more than express a hope that a matter of such moment to everyone of us, and of even greater moment to the user of electricity, will be pursued with energy during the present session.

MERSEY AND NORTH WALES (LIVERPOOL) CENTRE: CHAIRMAN'S ADDRESS

By E. M. HOLLINGSWORTH, Member.

(ABSTRACT *of Address delivered at* LIVERPOOL, *5th November*, 1923.)

The optimistic prophecy of a universal cheap supply of electricity, to be given from a limited number of "super-stations," has not been fulfilled, and the introduction of the 1919 Electricity (Supply) Act has not, to any great extent, brought about the improved conditions then anticipated. At the same time, there has never been more anxiety to effect improvements, and the great necessity for conserving coal and generating electricity on more economical lines has brought about many advances in power station practice. The most notable of these advances, which I propose to survey in this address, are the application of higher steam pressures and temperatures, the more satisfactory treatment and heating of feed water, the increased speed of turbo-generators for a given output, and the stage reheating of steam.

Regarding the movement in the direction of extremely high steam pressures and temperatures, it cannot be said that those concerned lack courage; on the other hand it has to be admitted that our knowledge of the properties of metals to withstand such conditions is still very imperfect. In other words, the advocates of high limits have outpaced the metallurgists, and the question arises: Will the gain in thermal efficiency be obtained only at the sacrifice of reliability? The test of service alone can answer this.

Regarding the selection of site for a large power station, the advent of the extra-high-voltage cables of large carrying capacity has eliminated one of the difficulties of this problem, in that proximity to the load centre is no longer necessary. The factors of importance are: An abundant supply of cooling water, facilities for railway transport, and large areas adjacent for the storage of coal and disposal of ashes.

Recent practice in the design and lay-out of stations has, generally speaking, evolved a standard type of building having simplicity as the main note. The boiler house and turbine room are usually side by side on the same level, the multiple-deck arrangement being no longer adopted. Great importance is now attached to daylight illumination and to the satisfactory ventilation of the buildings, for these refinements have considerable bearing on the maintenance of maximum operating efficiency.

The mechanical handling and conveying of coal is carried out in various ways, depending upon the local conditions, the type of railway wagons available, and the internal and external storage arrangements. The machinery commonly employed includes various types of wagon tippers and rotary tipplers, together with telpher plant and conveyers. Several stations, more especially where some of the coal supplied is waterborne, make use of pneumatic plant, and such plant offers the advantage of greater flexibility and speed, but at considerably higher operating cost as compared with the methods in more general use.

The present-day power station requirements of greater evaporative capacity for a given floor space, and higher steam pressures, have decided the question of the type of steam-raising plant, namely, the water-tube boiler with its integral superheater; the marine type, steel-encased complete unit usually being employed in large stations.

It is beyond the scope of this address to refer to the various makes of boilers or to the many improvements in design and constructional details which have brought about, among other advantages, more effective water circulation and greater evaporation per square foot of heating surface. It is, however, of interest to note the great advance in size and output of the units now installed, due not to any probable gain in efficiency, as compared with smaller plant, but primarily to the necessity of reducing the size of the boiler house within reasonable measure of the turbine room. Even with the large boilers now being installed there is still a disparity in the ratio of approximately 1·75 to 1. Only a few years ago, boilers of 6 000 sq. ft. heating surface and 25 000 lb. evaporation per hour were considered large units, but these are small compared with units of 16 000 sq. ft. and 120 000 lb. actual evaporation, now in operation in this country. In America, boilers of 200 000 lb. evaporation per hour are becoming quite common.

The selection of the most suitable steam temperature is largely a question of the ultimate strength of the materials available, and according to expert opinion it is quite practicable to employ a total steam temperature of 750° F. Respecting the use of the higher steam pressures, there is considerable divergence of opinion as to the net advantage to be gained, for reference to the data of a number of the largest British and American central stations recently completed or approaching completion, goes to show that the adoption of the higher pressures is by no means general. Of 12 British stations referred to, one is working with a steam pressure of 475 lb. per sq. in., two have adopted 375 lb., two 320 lb., four 250 lb., and three 200 lb. per sq. in. The total steam temperatures range from 550° F. to 750° F. The engineers on the other side of the Atlantic are evidently more optimistic as to the superior possibilities of higher steam pressures, for of 12 American stations, two have decided upon a pressure

of 550 lb. per sq. in., three have adopted 400 lb., two 375 lb., one 350 lb., and five 300 lb. per sq. in. The steam temperatures range from 625° F. to 725° F. In two of the American stations some experimental plant at a pressure of 1 200 lb. per sq. in. is being installed, to work in conjunction with the main plant.

Turning now to the design of boiler furnaces, the improvement in connection with mechanical stokers has been very marked during the past few years, and, so far as the mechanism for feeding and distribution of coal and for the ejection of ashes is concerned, it is difficult to see where any further great improvement can be made. From the combustion and furnace efficiency point of view, however, there is still room for more satisfactory results, and the stoker is yet to be designed that will efficiently deal with all grades of coal, particularly the low-calorific-value slacks which many British stations are compelled to use. The results of experience with the coals available in this country have brought about the general adoption of the travelling chain-grate type of stoker which, for the satisfactory combustion of the lower grades of coal, are arranged for balanced draught with pressure-variation control at different portions of the grate. Unfortunately, with this type of stoker the furnace requires brickwork arches for complete combustion. These arches are a source of weakness and, as their span is limited by the rise of the crown, two or more of them have to be provided for in the furnaces of large boilers.

In American stations using, comparatively speaking, an unvarying quality of coal having a low percentage of ash and certain coking properties, the underfeed multiple-retort stoker is very popular, and this type offers the advantages of simplicity of furnace design, no arches, and fewer metal parts subjected to heat.

On the question of furnace efficiency, the adaptability of pulverized coal is receiving consideration, especially in America, where a number of trial plants have been installed, and are, from all accounts, giving good results. One of the objections to this method of firing is the necessity for providing the plant required for crushing, drying and pulverizing the coal, and the cost of operation. Apparently the latter item is not so serious as was at first thought with the latest plants installed, and is compensated for where the coals used have a high ash content. The likelihood of grit being emitted from the chimneys can be met by dust extractors. Amongst the advantages claimed for pulverized coal are: More accurate control of the fuel and air supply; thorough combustion of coal of widely varying grades, little ash to handle, and a negligible amount of combustible matter carried over; no smoke or soot troubles; reduced banking losses, and uniformly high efficiency. As to the economical efficiency of such plant, there are few actual figures available, but it is of interest to note that the makers guarantee efficiencies slightly better than those obtainable when firing the same quality of coal with mechanical stokers, working under similar conditions.

With modern high-capacity boilers, whatever method of firing is adopted, the upkeep of the brickwork setting is troublesome. The erosion of firebrick by molten ash, the leakage of air into the furnace, and the minimizing of heat radiation from the walls, are problems receiving attention. Furnace design in the future will probably be in the direction of dispensing with brickwork and surrounding the chamber by water-cooled surfaces. One of the features in the modern settings for large boilers is the height of the furnace. The advantage of this is that combustion is practically completed before the gases enter the tube nests, minimizing the amount of heat impinging on the lower tubes (so liable with forced draught) and also the amount of solid matter carried over into the flue. At the same time it is undesirable to increase the height of the furnace beyond certain limits, for radiant heat is a factor in furnace efficiency.

The advisability of utilizing, as far as possible, the heat contained in the waste gases passing to the main flue, and of increasing the radiant heat in the furnace, has led to the preheating of the air for combustion. The advantage of this has long been recognized, but until recently had not been applied in power station practice. Other methods of heating the boiler feed water are tending to displace water-heating economizers, and air heaters are now substituted or are used in conjunction with the latter. Further, the improvements in design and construction of mechanical stokers and boiler settings have minimized possible detrimental effects with air heated to about 350° F.

Another waste-heat refinement is the placing in the lower part of the furnace, where the ashes and clinkers are automatically dumped, of metal water tanks through which the feed water passes on its way to the feed heaters.

Efficient combustion is dependent upon the correct ratio of fuel to air, and therefore the advisability of having some means of accurately controlling the air supply has led to the introduction of several automatic regulating systems, but so far there is little information concerning their application.

The removal and disposal of the ash and clinker has all along been somewhat of a problem, and with present-day power stations it is a matter of importance almost equal to those of the coal and condensing-water supply. Dealing with large amounts of ash and clinker must obviously necessitate having in use the most suitable system for the specific conditions. Several stations have adopted the simplest arrangement possible, namely, large-capacity hoppers under each boiler, from which the ashes, in some cases crushed and quenched, are discharged into railway trucks, or as an alternative (where height of boiler basement is a consideration) into small steel wagons. In other stations the ashes and clinker fall from the hopper into a water trough, along which they are carried to a sump or ash-pit by a quantity of the circulating water discharged from the condensers, or by water circulating round the system. Other variations of this system are where the ashes and clinker fall into stationary water and are conveyed by a drag-link conveyer, or by water flushed through at intervals. Ash-handling by the coal conveyer arranged to return through the ash tunnel is no longer considered good practice. Suction ash plant, however, still finds some favour, notwithstanding its heavy

maintenance and operating costs as compared with those of the simpler systems. This system offers the advantages of cleanliness and flexibility for a congested lay-out.

The increased flue-gas temperature resulting from operating boilers at high pressures has brought economizers into favour again, for apparently maximum efficiency of plant cannot be obtained without their use, and many engineers express the opinion that the highest overall station efficiency lies in a compromise between feed-water heating by stage bleeding, and air and water-heating by utilizing the waste heat of the gases leaving the boilers.

The general adoption of higher pressures and temperatures has brought into greater prominence the question of feed-water purification; and the desirability of removing all scale-forming impurities, and also of taking steps to prevent any tendency towards priming and corrosive action, is universally admitted. This question concerns not only the steam-raising plant, but also the turbine and condenser. There are a number of well-known softening plants which render most waters suitable, as regards scale and the neutralization of free carbonic acid, for feed-water make-up, but many stations go further still by using evaporators, thus obtaining distilled water. The most perfect treatment of the water, however, may not prevent its causing corrosion, for the greater the purity of the water the greater is its tendency to absorb oxygen. Modern stations, therefore, employ a feed-water circuit closed as far as possible to prevent aeration from atmospheric contact, and in many cases, where very large boilers are installed, one or another of the de-gassing methods is also applied. For boiler-feed purposes, the steam turbine or electrically driven centrifugal pump, is now standard practice. The adoption of steam or electric drive is a question of station heat-balancing arrangements. Automatic regulation of the feed water to the boiler is very desirable, and there are reliable regulators on the market.

The higher the efficiency of the plant installed, the greater is the necessity for scientific supervision and control, and for the complete equipment of instruments for the attainment of the most economical results.

On account of the higher pressures and temperatures involved, the pressure-drop between boiler and turbine, the design of valves and fittings, and the arrangement of steam piping with special reference to the best means of dealing with expansion and contraction, are problems of much greater importance than in the past. The increase in pressure and capacity of the steam-raising units has certainly made for greater simplicity in the lay-out of the steam and feed piping.

Passing to the consideration of the turbine room equipment, considerable progress has been made during the past few years in the direction of increased efficiency and reliability of generating plant, and in improved steam-cycle conditions. The general growth of turbo-generators to the sizes now being installed has been considerable in a comparatively short period, and the development of the higher-speed machines has been still more rapid. The voltage and frequency adopted for generation tend more and more for general supply to become standardized at 6 600 volts, three-phase, 50 periods per second, and for this frequency the maximum speed is 3 000 r.p.m.

In the case of an isolated station, the maximum demand, the amount of plant available as stand-by, and, to some extent, the demand during light-load periods, are the important factors deciding the size of the set. With a base-load station feeding into an interconnected system, the problem is somewhat simpler. In this country the size of sets has so far been limited to 30 000 kW at 1 500 r.p.m., and to 20 000 kW at 3 000 r.p.m. The latter size will be the most economical yet produced, taking into consideration both capital cost per kilowatt and performance, for it is anticipated that the efficiency will be little lower than with a set of the same capacity operating at 1 500 r.p.m. It must be admitted, however, that the lower-speed set has the advantage of reduced stresses and therefore greater reliability. In America, where station capacities are much greater, there are sets up to 60 000 kW in use.

The continual tendency towards obtaining the maximum output at the maximum speed, combined with more stringent steam and vacuum conditions, i.e. the importance of increasing the heat-drop between the stop valve and the exhaust outlet, has brought about many changes in turbine design. Perhaps the most difficult problem in connection with greater output at increased speed and under high vacuum, is that of keeping the length of blades, blade speed and stresses, within reasonable limits, and at the same time reducing the leaving losses to a minimum. The methods most recently developed for obtaining increased leaving area are those known as the "duplicate exhaust" and the "multi-exhaust." The adoption of bleeding for feed-water heating reduces the quantity of heat rejected to the condenser, and consequently decreases the leaving losses to some extent.

The greater the temperature range the greater the possibility of casing trouble, due to distortion and steam leakage. In all probability the tendency will be more and more in the direction of the subdivision of the turbine into two cylinders, high-pressure and low-pressure, on one shaft. Such an arrangement also means some increase in efficiency, and, further, simplifies the system of reheating the steam before it passes to the low-pressure portion of the turbine. The higher the steam pressure, the greater is the necessity of adopting the reheating cycle.

Of the various other problems due to the changed and more severe conditions of working, those of the most suitable material for blading, and the precautions to be taken to prevent rapid deterioration, are of importance. Regarding corrosion, it is considered that the closed feed-water circuit and de-gassing system will prove beneficial. Further, most stations are now taking the precaution of preventing steam leakage into the turbine when standing. It is also usually the practice to leave the air pump in operation for some time after the turbine has been shut down.

The improvement in the design and construction of the steam end of the turbo-generator would not have been possible if corresponding advances had not been

made on the electrical side. Perhaps this statement should be put the other way round, for electrical designers maintain that the electrical portion has all along been a little in advance. Space does not permit more than a passing reference to improvements in the design and construction of large high-speed alternators. Although it cannot be said that the present design has reached perfection, considerable progress has been made in reducing mechanical and electrical weakness in such machines, and obtaining more efficient ventilation, particularly in the sets operating at 3 000 r.p.m., with the small diameter and long rotor construction. Reliability has also been increased by more effective methods of holding the rotor coils and stator end connections, giving greater ability to withstand short-circuit stresses.

Investigations as to the relation of temperature to the life of the insulating medium have given more confidence and a greater tendency towards the acceptance of machines designed to work at higher temperature limits, although there would appear to be need for caution with regard to some of the high temperatures proposed.

Notwithstanding the fact that water cooling, as compared with air cooling, means an increase in output, the former has made but little headway so far as the rotor is concerned, and still less in connection with the cooling of the stator. The method at present generally employed is to pass a continuous supply of fresh air through a "dry" or a "wet" type of filter to the alternator. Unfortunately, with the best of these filters the air will always contain some dirt, and a very small percentage in the large volume of air passing will mean a considerable weight of dirt carried into, and deposited on, the windings of the alternator. This serious shortcoming has resulted, therefore, in the development of the closed-circuit system of ventilation, in which the same air is used continuously and is cooled by being passed through a surface cooler. An advantage of this system is the minimizing of the fire hazard, in that the amount of oxygen in the air circulating would have little effect in maintaining combustion. The cooling effect is obtained by passing through the cooler a quantity of the condenser circulating water. There are cases, however, where the condensate is also passed through, and in this way some of the heat generated in the alternator is recovered for the feed water.

Condensing equipment has kept in step with the steam turbine development, otherwise the present-day economical results could not be attained. It is now possible to obtain surface condensing plant which will produce a vacuum so close to the theoretical limit that only in detail, and, possibly, in reduced operating power, can any further developments be looked for. Present-day practice in condenser design allows, as far as possible, for a uniformly effective cooling surface, a tube arrangement giving the minimum resistance to the vapour passing through, and limiting the heat transference to a comparatively low rate. This latter point is important, for with the cooling surface so designed there is some margin to meet such emergencies as a rise in the temperature of the circulating water, dirty tubes, or excessive air leakage into the condenser.

The necessity for maintaining a very high percentage vacuum, which means dealing with a correspondingly large volume of steam—for to obtain a slight increase in vacuum means a considerable increase in the volume of steam condensed—has rendered still more important the question of ample exhaust area, so as to ensure the resistance and vacuum drop between the turbine and condenser being reduced to a minimum. It is now the practice to connect the condenser direct to the turbine, that is, without an expansion piece, and to obtain the necessary flexibility by mounting the former on springs. When working at higher temperatures there is all the more necessity to provide for free expansion in the design and lay-out of the turbine and condensing plant.

The difficulty of obtaining continuous condensing service over long periods, and especially with dirty circulating water, has, in the case of large units, brought about the adoption of the duplicate set, or a single condenser so arranged that half the water side can be cleaned while the unit continues running under slightly reduced vacuum on the other half.

The usual method of controlling the supply of circulating water is by throttling on the delivery side of the pump, but the variable-speed motor, or the two-pump arrangement as adopted in some cases, gives advantage in the direction of economical operation.

Beyond adopting efficient screening plant and taking steps to prevent air leakage in delivery pipes to limit aeration, it is not practicable to improve the condition of the circulating water with the object of preventing corrosion of the tubes and other parts of the condensing plant. This trouble has long been a source of worry to makers and engineers alike, and, although a great deal of investigation and research work has been carried out, it cannot be said that we have travelled far towards a solution of this problem. Corrosion has in a number of cases been reduced by the application of electrolytic methods, but unfortunately the treatment found satisfactory in one case is of little use in another. Each case has to be treated independently; there are many variables, and time is the most important factor.

The power required, and therefore the cost of obtaining the highest vacuum possible under given conditions, is a serious matter, and with fractional-load stations it may be more economical to work with a somewhat lower vacuum; with a base-load station, however, the highest vacuum will mean the greatest economy.

Respecting condensing auxiliaries, the requirement of high vacuum has brought about many improvements in the apparatus used for extracting the air from the condensing system. Probably the most popular of these extractors is the multi-ejector, which, compared with other methods, offers the advantage of simplicity and also economy of working when the waste heat can be efficiently included in the station heat balance. Depending upon the condition of circulating water and feed-water supply, it is becoming the practice to duplicate the condensate and other pumps, usually having each set from 75 per cent to 100 per cent of full capacity. Practice also tends more and more towards the use of motor-driven auxiliaries, notwithstanding that many engineers consider steam-driven

auxiliaries to be more reliable. The electric drive has the advantages of lower first cost, more adaptability, and also greater economy, that is, when the waste heat from the steam drive cannot be fully utilized. Further, it may be considered to be equally reliable, particularly where motors are duplicated on the same drive and supplied with energy from different sources.

As regards the systems for auxiliary supply, house turbo-sets generating alternating- or direct-current energy, as the case may be, are now adopted in many stations, in some cases the whole of the auxiliary supply being obtained from two or more house sets. In other cases one set is in use in parallel with the main busbars through transformers, and so interconnected that in case of trouble on the main system the auxiliary supply is automatically thrown on to the house sets. This is a move in the direction of improved efficiency, but possibly at the sacrifice of some reliability. To obtain still greater efficiency, however, the tendency is to dispense with house sets and to take the supply from an auxiliary machine on the main generator shaft, with a stand-by supply through transformers or converting plant, as the case may be.

Power station apparatus for controlling large amounts of energy efficiently and safely is undergoing almost constant change in design, owing to the increasing capacity and voltage of the plant and equipment now employed. The more general interconnection of large stations is now a factor to be taken into account, for the switchgear is thus liable to be called upon to deal with short-circuit currents of enormous value, notwithstanding the limiting effect of reactors which in many cases are introduced between sections of the busbars and tie bars, and other points in the system.

The practice of direct connecting the generators to their step-up transformers, i.e. forming one unit, with control apparatus on the extra-high-voltage side, which may be at 33 000, 45 000 or even 66 000 volts, has brought about the most notable advance in switchgear design. In this country there are oil circuit-breakers now in use at 33 000 volts, for which is claimed a rupturing capacity up to 1½ million kVA, but this is, of course, an estimated figure only. In order to isolate the control apparatus to the greatest possible extent, it is now usual to separate the switch and transformer house from the main building. Such houses are of very considerable dimensions, for the space required for the gear to control energy at 33 000 volts is something appreciable, as, apart from the necessary spacing of busbars, etc., there must be accessibility to all parts for inspection and testing purposes, and ready withdrawal of oil switches and other details. Such gear is operated by electric remote control from some central position, by means of solenoid or motor, usually the former.

Whilst the majority of stations in this country have installed switchgear of the type relying for security against short-circuits by wide spacing of the live parts in air, and enclosed in stoneware or brickwork cubicles, the close-spaced enclosed compound-filled type of gear is finding considerable favour. This type has certainly, amongst its advantages, that of robustness and reduced space required, but the parts are not quite so accessible as with the cellular type of gear. Probably British engineers will continue to install the most reliable switchgear available, but there are many stations in America, and a number on the Continent, where the switchgear lay-out does not include cubicles, and the only safeguards are rails placed round each circuit unit. In this country we certainly go to the extreme limit, as regards special protection, to minimize danger to life and to secure continuity of supply. Of course, the Government regulations here are much more stringent than those in force in other countries.

Other developments in switchgear design include improved methods of mechanically or electrically interlocking the oil switches and circuit breakers with the isolating and selector switches, and of securing the latter against any possibility of being blown out. Improvements in the design and construction of current and potential transformers have given greater confidence in these details. It is now usual to include resistances in circuit with the latter to limit the current due to a fault. Modern practice does not include potential transformers in the main busbars, and small-ratio current transformers are not installed.

The previous remarks as to the fullest advantage being taken for the protection of switchgear in this country, also apply to the automatic isolation of faults in generators, transformers and feeders, for British practice makes full use of the various protective systems available. No doubt such practice will continue until some revolution in plant design dispenses with their necessity. In other countries practice leans to the opposite extreme, for in the majority of cases the protective devices are of the simplest kind. Several American undertakings are taking steps to ensure greater protection by such means, but owing to the size and complications of the systems the problem offers many difficulties. The necessity for electrically operating the switchgear has evolved supernumerary control, which automatically indicates the existing conditions of the system, as regards both the generating and the dispatching of energy.

In such an address as this it is impossible to refer in any detail to a subject of such magnitude as power station practice, but it is hoped that sufficient has been said to make clear the present trend of development. Before concluding, however, it may be of interest to make a few observations regarding present-day generating efficiencies, and those anticipated in the future, due to the application of higher steam pressures and heat-balance refinements. The results of power station efficiencies for 1922, recently published by the Electricity Commissioners, are somewhat disappointing, in that the maximum overall thermal efficiency does not reach 18 per cent and shows very little improvement on the maximum of the previous year. Further, the case for higher steam pressures is not helped by the fact that some of the best results are from stations working with comparatively low pressures and under no better load factor conditions. Thermal efficiency is not the only factor in economical generation; capital and maintenance costs are also of importance, but the returns certainly emphasize the necessity for making every

effort to obtain increased thermal efficiency as a net advantage.

The figures given by the Commissioners show that there are stations at present generating 1 kWh for 18 000 B.Th.U.'s of heat, and in America there are stations approaching completion where figures of 12 000 and even 12 000 B.Th.U.'s, equal to an overall efficiency of 24 per cent and 28½ per cent respectively, are mentioned, but to obtain the latter result some of the plant will be required to operate at a steam pressure of probably not less than 1 200 lb. per sq. in.

These results will not be obtained by increasing the pressure and temperature ranges only, but also by reducing existing heat losses and by improvements in other directions. For instance, the operating efficiency of large present-day boiler plant, including superheater and stoker-fired furnace, may be taken to be at least 80 per cent, with coal of approximately 10 500 B.Th.U.'s. It is maintained that an increase of 2 per cent can be obtained with pulverized-coal firing, under similar working conditions.

Turbo-generator steam consumptions have been reduced to 10 lb. per kWh, including the auxiliaries, and an efficiency ratio of 77 per cent, including the generator, can be obtained. Improvements now pending in turbine construction will, it is anticipated, lead to an increased efficiency ratio. Things are moving rapidly in these times, and we may realize sooner than expected the possibility of producing 1 kWh for, say, 1¼ lb. of inferior coal.

British engineers and manufacturers of plant will not be behind those of other countries in their endeavour to achieve the last word in economy, and so to cheapen the production of power as to place the industries of our Empire in a position to meet all competition in the markets of the world.

NORTH MIDLAND CENTRE: CHAIRMAN'S ADDRESS

By Major H. Bell, Member.

(Abstract *of Address delivered at* Leeds, 13*th November*, 1923.)

At no period in the history of this Centre, in common with that of the Empire, have greater problems arisen than those which face us at the present time, and it is with the conviction that we, as a territorial unit of the parent Institution and members of an increasingly important section of the community, will play our part successfully and with advantage to others, that I look with equanimity upon the approaching session.

I feel I shall be voicing the thoughts of the whole of the membership of the Centre when I suggest that the events of the past month are such as to indicate that broad changes in fiscal policy are likely to take effect at no very distant date and, although fully realizing that within the precincts of the Institution is the last place in which anything in the nature of a political controversy should arise, I am tempted to offer a few observations on this subject in the hope that they will enable us to envisage more correctly any change which may come about and the more readily adapt ourselves to such change.

Previous to 1914, it was an oft-heard cry that the British electrical industry, then relatively small in point of capital invested, was stifled by reason of foreign competition, but in the ranks of our profession this belief was naturally not unanimous; I say "naturally" because the electrical industry, more than any other, embraces so wide a field of operation that whilst development is taking place in some of its branches, depression might easily exist in others.

Assuming that a change in fiscal policy is about to take place, we are justified in speculating as to its probable effect upon ourselves as a body, and I take it that I shall encounter few dissentients when I suggest that at any rate the immediate effect of any such change must be beneficial and that there will at once be a greatly increased demand within the Empire for British electrical manufactures. To supply these successfully it will be at once conceded that they must be the equal of, and in fact superior in every way to, those of all competitors.

The great war, however harmful its effect, certainly achieved one thing in that it stimulated in other countries, collaterally with our own, an intense scientific development in which electricity invariably figured in the vanguard, this stimulus being in some cases the result of dire necessity and in others of enhanced opportunity. Whatever the cause, however, it will be patent that if we are to achieve the superiority of which I have just spoken we must leave no stone unturned to ensure that we are in every sense equipped to meet these altered and more scientific conditions.

The burthen of my foregoing remarks may be briefly summed up by saying that in the future it will be doubly incumbent upon us, as an important branch of an Institution to which the peoples of this Empire are daily turning with increasing dependence and esteem, to apply ourselves with all our vigour and energy to those problems in connection with our internal economy which will tend to increase our sphere of utility, our efficiency, and the goodwill of others towards us.

As one of the principal factors in the attainment of these ideals, I should like to refer to the time-worn theme of the infusion of new blood into the Institution. After five years of hostilities, with their attendant partial disorganization of educational effort, and after a further five years of industrial dislocation, the steady influx into the Institution of the requisite number of adequately educated students has naturally been somewhat disturbed. It behoves us to ensure as far as possible that this state of affairs is remedied and that every entrant into the local ranks of the electrical profession, if his educational qualifications are appropriate, shall contemporaneously become a student of our parent Institution and an active participant at the meetings of this Centre. He will of necessity only develop into the latter if the suitable germinating influences in the shape of goodwill, sympathy and enthusiasm are apparent in the attitude of his older confrères. He must be encouraged to look upon the Institution as his Alma Mater to which he can at all times go for technical assistance and advancement, professional guidance and happy associations.

It is, of course, impossible materially to assess the advantages to be derived by an intending entrant from membership of the Institution. In order to achieve the highest ideal and the greatest degree of esprit de corps such material advantages should theoretically be nil and I think that, with regard to the infusion of new and suitable blood, broad success will come the more readily if both intending candidate and sponsor clearly envisage this desirable principle.

It is extremely gratifying to be able to state, by reason of the happy relationship existent between the North Midland Centre and the two Universities more immediately concerned—due largely to the co-operation and enthusiasm of the respective faculties—that the Students' Section of this Centre is to-day really "alive," but in view of the increased electrical developments which I have ventured to foreshadow earlier and which we have every right to expect, this is not of itself enough, and we must, by all legitimate means, contrive that the intellectual activities of the younger classes

are fostered to a degree which will ensure at all times a personnel adequate in every sense to meet the increased responsibilities which are destined to devolve upon the Institution.

Turning to a general review of electrical progress as more especially affecting this particular Centre, we are fortunately able to record that in spite of an unprecedentedly long and severe period of industrial depression, the electrical industry has escaped more lightly than is, generally speaking, the case in other trades. The reason for this is difficult to determine, unless possibly it is due to the fillip which has undoubtedly been given to domestic usage by reason of the greater standard of comfort now demanded by the public. The electrical industry is to-day so highly specialized that we each understand comparatively little of the others' pursuits and activities, but it is correct to say that the electricity supply industry may be looked upon as a barometer showing the condition of the trade generally.

It will be well within the minds of most of the members that specific and highly detailed information is now available in the shape of the Annual Report of the Electricity Commissioners, which report has been available for the past three years, and I make no apology for drawing your attention to several interesting facts revealed on perusal of the recently published Third Report.

One of the primary objects of the setting up of the Commission under the Electricity Acts of 1919 and 1922 was the formation of Central Authorities for the achievement of the cheaper production and more complete and penetrating distribution of electricity to all who desire to make use of it. The report in question brings to light the fact that such bodies have already been set up in 15 of the most important areas of the Kingdom. For the year under review 12 of these areas produced over half the total energy generated by public service corporations in the country, equivalent to approximately 3 000 million units. The total production of all undertakings for the year shows an increase of $17\frac{1}{2}$ per cent over the previous year.

It will be obvious that the reorganization of the various undertakings concerned, following upon the more precise delimitation of their areas of supply, has resulted in a largely increased installation of generating and ancillary plant amounting for the year to over 400 000 kilowatts, as compared with 170 000 kilowatts for the previous year, the total increase during the period since the setting up of the Commission amounting to the stupendous total of $1\frac{1}{4}$ million kilowatts. These additions, translated into monetary value, which of necessity is what more immediately concerns us, represent an expenditure of £26 000 000.

The foregoing figures are sufficient to demonstrate that the Electricity Acts of 1919 and 1922, although the subject of serious contention in their passage through Parliament, have resulted in very real and inestimable benefit to the electrical industry as a whole. Further perusal of the report shows that there are now existing in the country at least three public service plants producing over 200 million units annually, and six plants producing over half this figure.

My object in drawing attention to these few salient facts is to endeavour to show that Great Britain has "electrically" awakened and is now taking a place commensurate with her commercial greatness. It will be a matter of general interest and satisfaction to all that the efforts of the Commissioners have been successful in achieving an appreciably greater degree of standardization of voltage—the absence of which has hitherto done much to hamper and restrict the general development of the industry.

In passing, also, I am prompted to draw your attention to the steady but persistent increase in transmission pressures, a matter of paramount importance in connection with the cheap distribution of electricity. A pressure of 33 000 volts seems to have become recognized as a standard transmission voltage, no fewer than eight undertakings having carried out developments at this pressure during 1922–3, and it is further interesting to note that there already exists one underground system operating successfully at 66 000 volts.

With regard to the conservation of fuel, about which so much has been written since the closing stages of the war, it is gratifying to find that, due to a variety of causes, not the least of which has been the centralization of generation, there is a steady and persistent decrease in the amount of fuel required to produce a unit, corresponding to a drop of approximately 10 per cent for each of the past two years. The actual saving in this item last year over the preceding year amounted to more than £500 000. I have pleasure in drawing your attention to the fact that our Sub-Centre includes in its area two undertakings which conjointly figure as second in the national list of minimum fuel consumptions. In point of fuel economy, the British supply industry compares extremely favourably with its transatlantic neighbour, operating as the latter does on a scale of so much greater magnitude.

After careful consideration of the foregoing facts, taken in the aggregate I feel sure there will be little difference of opinion amongst us that in spite of the abnormal trade depression existent throughout the Kingdom, no matter what the cause, our industry has escaped in a large measure its ill effects.

I am somewhat loth, after the above remarks, to strike a minor key, but I should like to offer a few observations on the topic of electric street traction. It will, I know, be a matter for common regret that the development which has been so obvious and insistent in nearly all other branches of the industry has unfortunately passed by the door of the street tramway, and I suppose I shall not engender any dissent when I suggest that there is little difference between the electric tramcar of to-day and that of two decades ago. Contemporaneously with this dormancy other means of locomotion have improved at so phenomenal a rate that opinion to-day is very divided as to whether the tramcar, as we at present understand it, will not evanesce like its predecessors the horse tram and the steam tram, or be relegated to the comparative obscurity of our smaller provincial towns. Unfortunately, this is the treatment which has been already meted out to it to a considerable extent in the United States, and the growing disinclination of street authorities in this

country to give additional wayleave facilities would seem to indicate that similar defection may take place here.

Viewed in perspective, it would be difficult to diagnose the exact cause of the present unpopularity of the street car, but probably the absence of progression which I have previously indicated is the dominating influence, coupled also with the fact that traffic problems are now becoming so acute in even the smallest of towns that there is literally no room left for it. With commendable commercial spirit most of the large tramway undertakings have realized the inevitable and have availed themselves of the improvement which has taken place in other forms of locomotion, with the result that, though possibly the country is the gainer, yet the electrical industry and contemporaneously this Institution are, to some extent, the losers.

I cannot help feeling personally that there is probably a *via media* in this matter and that, given concentration of thought and new energy in its development, there is still ample possibility for improvement in the trolley car which would at any rate place it on a more equal footing, in point of speed and noiselessness, with its younger rivals. Another very interesting speculation in this connection is as to whether the present relative decline of the electric car may not bring in its wake very real advantages in the way of a more intimate association between the electrical and the automobile industries through the medium of the "electrobus" in one form or another, and I do not think that by any means the last word has been heard in connection with this type of vehicle.

In contradistinction to the lack of progress in street traction, the star of railway electrification appears to be in the ascendant, and signs are not wanting that not only is electricity to take its natural place in the operation of all of our denser suburban lines where, of course, its success is well assured, but that additionally in this proverbially conservative island of ours, main-line development is being planned and will be put into effect at no distant date.

Closely allied to locomotion is the problem of electric ship propulsion and it is rather a matter for regret to have to record the fact that, due to the extraordinarily depressed state of maritime transport, there has been, with certain few exceptions, little real progress in this country since the cessation of hostilities. The United States, on the other hand, due possibly to the encouragement derived from the construction of the "New Mexico" and her sister "dreadnoughts," has applied the experience gained thereby to a number of mercantile vessels. It is satisfactory to note, however, despite the tremendous activities of the United States Shipping Corporation during the war and the impetus which these naturally gave to marine design and progress in that country, that the last three electrically propelled vessels sailing under the American flag were built, engined and electrically equipped entirely in this country.

I feel that my remarks would be incomplete if before closing I made no allusion to the forthcoming British Empire Exhibition to be held at Wembley, commencing in the spring of 1924. There is evidence on every hand that the electrical industry is fully alive to the desirability of being represented in a manner befitting its present importance, nearly all sections being represented through one or other appropriate organizations. It only behoves us therefore individually to do all in our power by our presence and in all other possible ways to assist towards the success of this great effort admirably and opportunely conceived by the Mother Country and her Dominions.

Finally, in common with all my predecessors I ask your material support for the Benevolent Fund of the Institution. At no period of its existence has the fund been more inadequate than it is to-day to meet the very real necessities arising.

SCOTTISH CENTRE: CHAIRMAN'S ADDRESS

By R. B. MITCHELL, Member.

"THE ELECTRICITY SUPPLY BUSINESS AND ITS FUTURE."

(ABSTRACT *of Address delivered at* GLASGOW, 13*th November*, 1923.)

DEVELOPMENT.

The scope of this subject is so very wide that it is impossible to consider it in all its bearings at one meeting. To touch briefly upon some of the vast possibilities which lie before us in this sphere of industrial activity may be of interest.

It is, I think, realized by only a few that we in this country lag considerably behind America in so far as the uses of electricity are concerned. In Chicago, for instance, a state of development has been reached in which the demand is 700 units per head of the population. We in Glasgow have only attained to 130 units per head, and only very few undertakings in the country have gone beyond this figure.

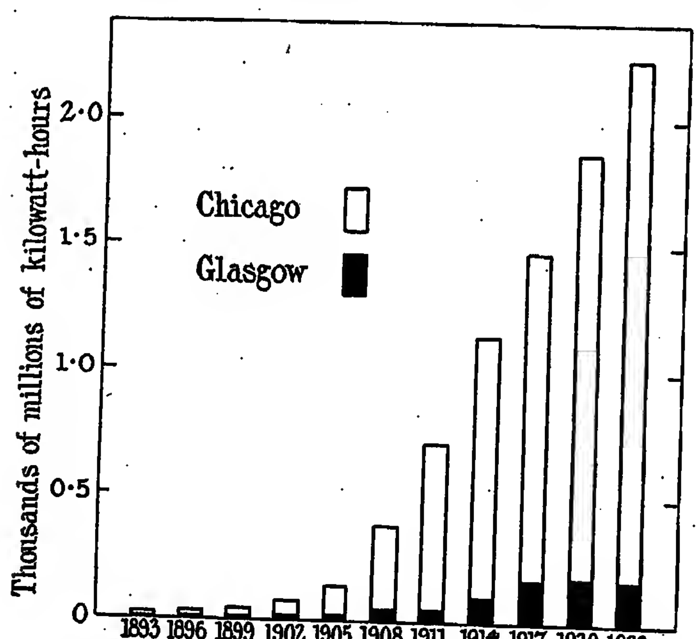

FIG. 1.—Comparative outputs of electricity.

It is interesting to trace the growth of the electricity supply in Chicago throughout the years, and compare it by means of curves with similar development in Glasgow (see Fig. 1). It will be noted that for a long period of years the line is on the horizontal, later on trending upwards to the enormous outputs of the present day. The curve for Glasgow shows very badly in comparison.

The possibilities before us in this country if we assume that the curve of development in this country will follow closely on the lines of those of the large cities on the other side, are boundless. During the past few years the tides of output and maximum load have ebbed and flowed in an unusual degree. In what may be termed the "boom" year of 1920–21, the tide may be said to have been at the flood after steady expansion at a rapid rate during the years of war. In the year following, came a rapid falling-off, and, in the current year, a turn for the better.

The curves of output and maximum demand in Glasgow during the years 1915–1923 (see Fig. 2) may, I think, be taken as typical of the experience of the majority of similar undertakings throughout the country. If the curves of output from month to month during the past four years are followed (see Fig. 3), the rise and fall and again the steady recovery will be seen in a more marked degree, in spite of the fact that trade is still very bad and unemployment general. It will be noted that for the first months of the present year, beginning on the 1st June, the output exceeds that of 1920–21, the boom year.

If the experience in Glasgow reflects that of other

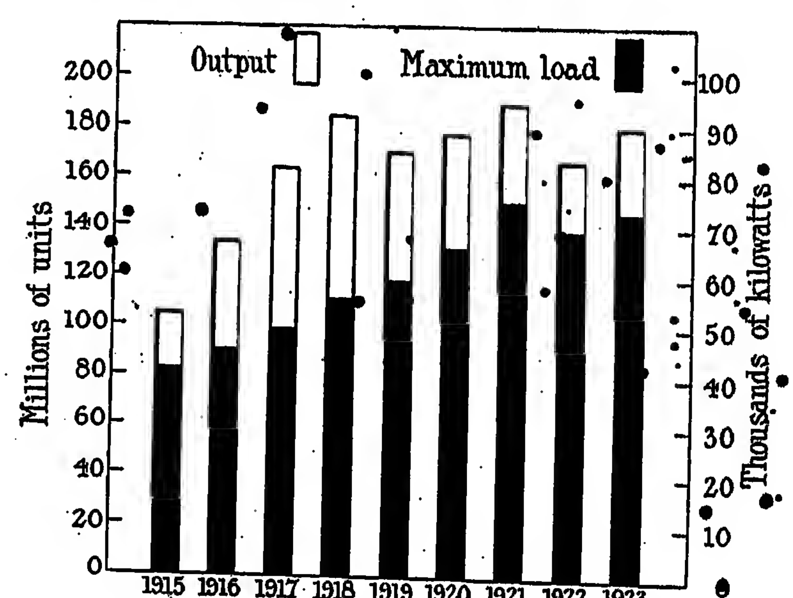

FIG. 2.—Annual output and maximum load.

undertakings, then those engaged in the business of electricity supply will require to set their houses in order, so that when this flowing tide sets in it may be adequately coped with.

GENERATING STATIONS.

The first thing which will naturally come up for attention will be the power station, and I propose now to review briefly the trend of present-day development. In this country, while such water power as exists bids fair to be utilized at no very distant date, the steam station must continue to bear by far the most important share of the load.

The division of the country into districts by the Electricity Commissioners, and the formation and work of controlling authorities in these districts, will slowly

but surely bring about the closing down of the small and uneconomical stations and the concentration of power generation in large stations well placed as regards fuel and water supplies. Generally it will be well worth while to equip these large stations with the most efficient plant obtainable. The load factors of these stations will be much better than those obtaining at the present day, and not initial cost but economy of operation—consistent with reliability—will be the first essential.

Nowadays electrical engineers engaged in the design and lay-out of new power stations or the extension of existing stations have to face problems more numerous and difficult than any ever encountered in the past. In the boiler room the problems presented are the

In the turbine room, the capacity and type of the turbine most suitable for local requirements; the electrical drive of the auxiliaries; the provision of duplicate or triplicate supplies from different sources for this auxiliary drive; the question of heat balance, which brings in the possible stage bleeding of turbines; the reheating of steam and the utilization of the heated air from generators, all call for serious consideration.

In the switch house, consideration has to be given to the question of switchgear to be adopted, whether of open or enclosed type, also the voltage of generation and transmission.

In the boiler house the trend is towards larger and larger units, and it looks as if we may arrive some day at the stage when one boiler only is installed per turbine

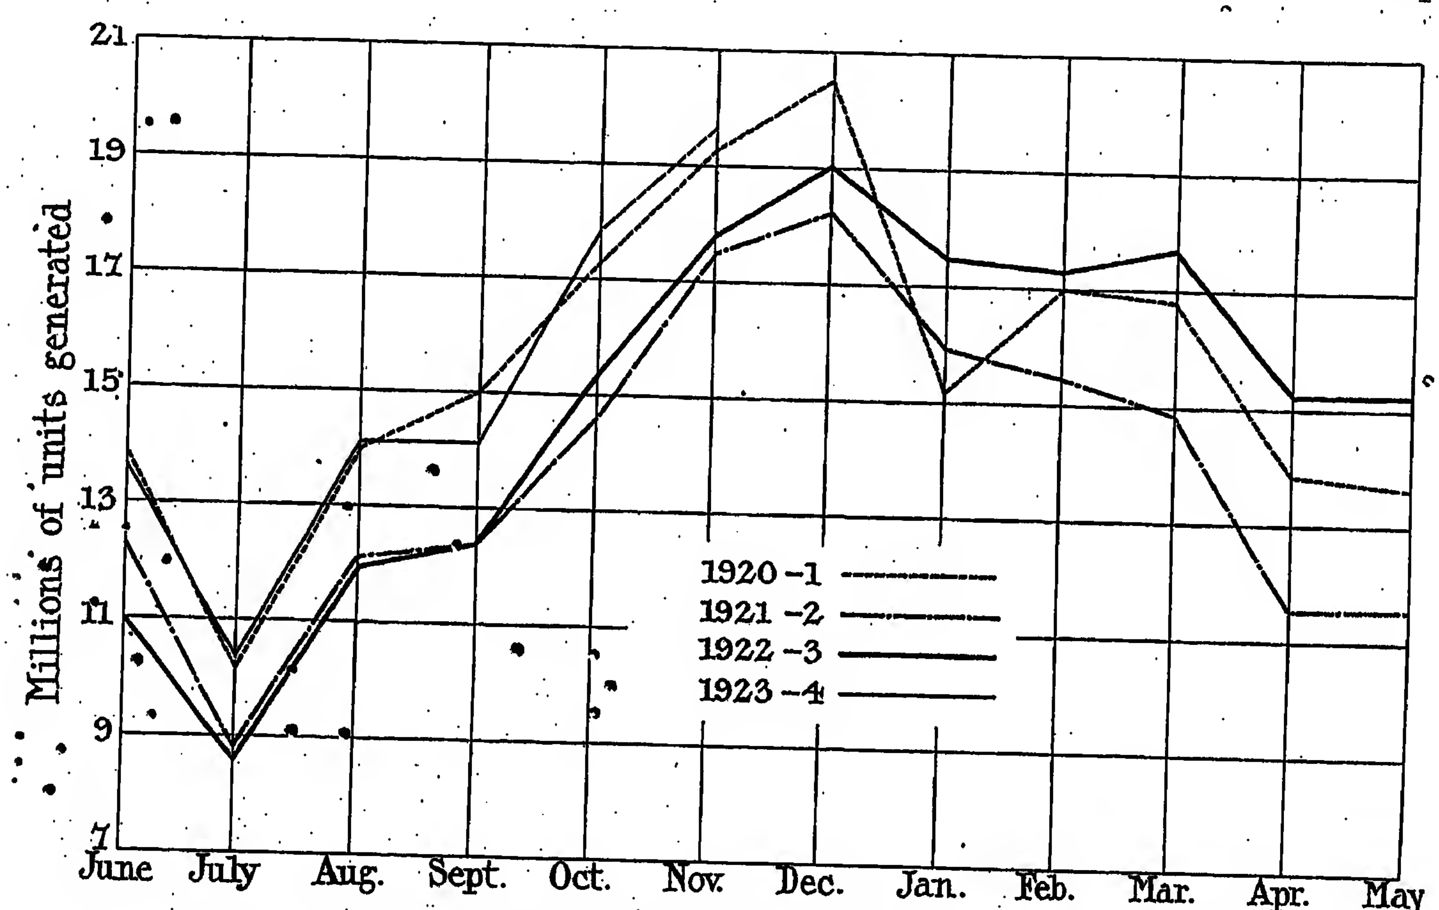

FIG. 3.—Glasgow Corporation Electricity Department: output comparisons.

high-pressure boiler and its combustion chamber, and the methods of firing (whether by coal on travelling grate or other stokers, or by pulverized fuel produced and burned in three or four different ways, or by gas firing, including the methods used for producing the gas). Then there is the system of ash removal to consider, whether by suction, by the simple direct method by means of wagons brought under the ash hoppers, or by one or other of the new hydraulic methods.

The utilization of every possible heat unit in the flue gases has also to be striven after, and here there is the possible use of either economizers or air-preheaters, or both. The feed pumps may be either steam-driven or electrically driven, or both types may be installed to be used as occasion requires for the maintenance of the heat balance. The feed water make-up, if obtained from a river or town supply, may require treatment to make it suitable for boiler-feed purposes or, as an alternative, the make-up may be evaporated.

unit instead of three or four as at present. This arrangement may have some advantages, but it has obvious disadvantages. My own view is that until load factors are very much higher than they are at the present day it is better to carry on with moderate-sized units.

Again, we hear of very high steam pressures being experimented with, a figure as high as 3 200 lb./sq. in. being mentioned. This very high pressure is chosen because at that figure no heat is absorbed in the change from water to steam. The pressure of the steam is reduced in passing from the boiler to 1 500 lb./sq. in., and passed into a high-pressure turbine, exhausting therefrom into another turbine of ordinary type at a pressure of 375 lb./sq. in. This development has not gone beyond the experimental stage, and no results are available. It marks a tremendous advance on present-day practice, but if put into use it does not appear to make for the ease of mind of central station engineers. Boiler makers anticipate no difficulty in

providing boilers for these high pressures, but the valves and boiler mountings generally present a real difficulty, and much development is required if these appliances are to be brought into line with other parts of the plant.

Increases in the efficiency of steam turbines may be looked for from increases, by stages, of pressures and temperatures to the highest figures possible. It has been stated that turbine designers anticipate no particular difficulty in designing machines for 1 200–1 500 lb. per sq. in. This is a subject of great interest to engineers at the present time. For these high-pressure machines two cylinders will undoubtedly be used, and in the high-pressure cylinders the parts will be small, with consequent safety.

With the increase in steam pressures and temperatures, it becomes more and more essential to use pure water for boiler make-up purposes. The present-day practice is strongly towards the provision of evaporators to ensure that the feed water is absolutely pure.

We may look forward to the operation of all large valves in power stations by hydraulic or electrical means.

While boilers are increasing in size, so are stokers. Until recently a boiler of, say, 50 000 lb. per hour capacity was provided with three stokers of the travelling-grate type. The provision of two stokers, or even one, for a boiler of this size is now considered to be quite good practice. We read of a single travelling-grate stoker, 24 ft. wide by 18 ft. 3 in. long, being supplied for a boiler in the Calumet station of the Commonwealth Edison Company, Chicago. It is stated that results from this stoker have been very gratifying, an overall efficiency of 81 per cent for the boiler unit having been obtained over long periods.

Gas-firing of Boilers.

The firing of boilers in power stations by low-grade gas, produced as a by-product from coke ovens or smokeless-fuel processes, is, I believe, limited only by the supply of gas available. There is a great need of smokeless fuel in large cities, the use of which would help in some measure to solve the ever-present smoke problem, at any rate so far as the domestic chimney is concerned. Glasgow, I am glad to say, is taking the lead in the consideration of this question, and a committee of the Corporation is at the present time going into the question of ways and means. The Electricity Committee has co-operated in agreeing to take such gas as is available from the process for boiler firing, at a price equivalent to the cost if ordinary coal were used direct.

A supply of gas from smokeless fuel or other processes, sufficient for the requirements of a large station, can hardly be expected. The extent of the plant which would be required for a station of, say, 100 000 kW capacity, which might consume in the ordinary way from 700 to 900 tons of coal per day, may be realized when it is kept in mind that the heat value of the gas is only one-fourth that of the coal from which it is produced. This is apart altogether from the question of the reliability of the supply. On a limited scale, however, the system is quite feasible, and I think it will be agreed that the firing of boilers by gas is an ideal method.

Powdered Fuel.

An alternative method of boiler firing which is now receiving more and more attention is that in which coal in powdered form is used, the powder, mixed with its proper proportion of air, being blown from nozzles into the combustion chamber. Here we have a method quite different from that of gas-firing in that it is applicable to stations of any size without materially increasing the space required.

The cost of installation of pulverizing plant is about equal to that of chain-grate stokers, but the cost of operation is necessarily greater. The question then is: Does the improved efficiency of combustion—the possibility of using lower-grade and cheaper fuel, the flexibility of operation of which is undoubted—of the pulverized fuel plant more than make up for the increased cost of operation and maintenance? It must not be forgotten that up-to-date stokers with well-designed combustion chambers will burn efficiently the lowest grades of fuel.

Efficiencies of Power Stations.

In the Annual Return issued recently by the Electricity Commissioners, it is interesting to note that the highest thermal efficiency obtained by any station in the country was 17·80 per cent, representing 19 163 B.Th.U.'s per unit delivered. This may be quite a creditable figure, but it can no doubt be greatly improved. The return will be of great benefit if it only serves to foster the spirit of emulation among engineers and staffs of stations in the various grades.

I think it is safe to predict that thermal efficiencies of 25 per cent will before long be obtained. This figure will be arrived at by the use of higher pressures and temperatures, preheating and bleeder feed-heating, and a close study of heat balance. A thermal efficiency of 25 per cent, representing 13 500 B.Th.U.'s per kWh, is predicted for the Weymouth station of the Edison Electric Company of Boston, U.S.A. The coal consumption in this case will be less than 1 lb. per kWh, since the calorific value of the fuel used is 14 400 B.Th.U.'s per lb.

Thermal efficiency is not everything; it is the total cost of the unit delivered at the consumers' terminals which is the real criterion. Reliability, capital charges, operating and maintenance costs, must be taken into account. The day may come when these factors will be included in the Commissioners' Reports, and the usefulness of the Reports thereby very much increased.

Air Preheaters.

It is essential nowadays to utilize fuel, on account of its cost and its value as a national asset, in the most efficient way possible. Consequently, with the view to securing the greatest economy, attention is being directed to stack temperature, and the possibility of recovering heat units from the gases entering the stack, which would otherwise be wasted.

I believe that air, preheated to a moderate degree before it enters the furnace, is a good thing, as there

will not only be the saving in heat, but also combustion will be improved and it will be possible to burn low-grade fuels efficiently. It is argued that an increase in the furnace temperature generally increases the rate of radiant heat transfer to all boiler surfaces exposed to the direct rays of the fire. If sufficient boiler surface is exposed, a greater proportion of the heat from the coal is absorbed as radiant heat with preheated air than is the case without preheating. Under such conditions, less heat remains to be absorbed by convection and the flue-gas temperatures are lowered. In other words, the total heat transfer will be increased, and the boiler efficiency will be further improved by the use of preheated air. In view of this argument it seems likely that air heaters, along with economizers, to ensure that stack temperatures will not be much above 300° F., will come into general use. The difficulties arising with brickwork, etc., in combustion chambers when air is preheated to a very high degree, say when economizers are dispensed with altogether, have not so far been overcome.

Dalmarnock Power Station : Comparison of two Methods (A and B) of Running Auxiliaries.

	Method A	Method B
Average load, kW	16 489	17 109
Steam pressure, lb./sq. in.	268	268
Steam temperature, ° F.	770	758
Vacuum at exhaust flange (bar. 30 in.), in. Hg.	29·076	29·145
Temperature at exhaust, ° F.	84	83
Condensate temperature :—		
At condenser, ° F.	55·5	55
At heater outlet, ° F.	99	123
Circulating water :—		
Inlet temperature, ° F.	49	49
Outlet temperature, ° F.	59	59
Total auxiliary consumption, kW	596	723
$\frac{\text{Aux. consumption} \times 100}{\text{Total output}}$, per cent	3·62	4·2
Steam per unit generated, turbine, lb.	9·91	9·9
Steam per unit generated, overall, lb.	10·55	10·77
Coal per unit generated, lb.	1·72	1·684
Heat units per unit generated, B.Th.U.'s	17 358	17 396
Coal per unit delivered, lb.	1·78	1·75
Heat units per unit delivered, B.Th.U.'s	17 964	18 077
Calorific value of coal, as fired, B.Th.U.'s	10 092	10 330
Boiler room efficiency, per cent	80·79	79·79

Overall efficiency :—		
Per unit generated, per cent	19·64	19·6
Per unit delivered, per cent	19·00	18·86

Conditions of test :—

A—With auxiliaries driven from a unit transformer connected directly to the alternator, the air pump being of the steam ejector type exhausting into feed heater. Electrical feed pump.

B—With auxiliaries driven from small house turbine exhausting into feed heater, the air pump being of the Leblanc type. Steam feed pump.

Power Station Auxiliaries.

At Dalmarnock, the turbine-room plant was modified in several directions so that experience could be obtained with the different systems of operation. One of the questions to be settled was the relative efficiencies of driving auxiliaries (1) by steam, and (2) by electricity. At Dalmarnock the auxiliaries have electric motor drive, and these can be supplied either from (i) house turbo-alternators exhausting into contact heaters, or (ii) (*a*) works transformers or (*b*) unit transformers on each alternator.

A series of tests was carried out recently to obtain information on this point, with interesting results. Turbine designers usually maintain that the house turbine method is the more efficient one. The test I am about to describe does not bear out this contention. The method of conducting the tests was to isolate one turbine unit and three boilers from the remainder of the station, and operate the turbine first with its auxiliaries driven from a unit transformer connected directly to the alternator, the air pump being of the steam ejector type exhausting into feed heater; and secondly, with the auxiliaries driven from a small house turbine exhausting into feed heater, the air pump being of the Leblanc type.

The two different systems are referred to as "A" and "B" in the table. In the first case an electrically

driven feed pump was used, while in the second a steam-driven pump was in operation for the boiler feed. It will be seen that the overall efficiencies obtained are practically identical in both cases, so that in this respect the use of the unit transformer scheme is thoroughly justified. The separate drive for the auxiliaries has, however, a great advantage during fault conditions or when the station is suddenly overloaded, as in these cases the speed of the auxiliary motors can readily be maintained, whereas with the unit transformer system the speed must fall with the drop in frequency of the main machines.

Safe Operation of Large Power Supply Systems.

The parallel operation of all plant is the ideal method from a standpoint of efficiency, and if automatic protective gear could be entirely depended on there would be no need to adopt any other system of operation. It is, however, impossible to avoid occasional short-circuits between phases, and when these occur the electrical and mechanical stresses are liable to cause serious failures of apparatus such as oil switches, and in this way bring about dislocation of the system. With complete interconnection the re-establishment of the supply after a serious fault is also difficult. The use of reactances to limit short-circuit currents has been widely spoken of, but the remedy is in all cases expensive and cumbersome, and in the case of 25-period systems hardly practicable. Experience in Glasgow has shown that with 60 000 kW on the busbars the substation oil switches are capable of rupturing the short-circuit currents produced. It has therefore been arranged that in this city, when the load on the system exceeds 60 000 kW, the busbars at the power station will be sectionalized, so as to keep the maximum short-circuit current within safe limits. In addition, the 6 000-volt distribution systems will be divided into definite networks each of approximately 20 000 kW capacity, the scheme being analogous to the feeder and distribution system which has proved so convenient in low-tension working.

Load Factor.

The improvement of load factor is all-important and supply engineers will be forced to take advantage of every opportunity of bringing this about. Conditions obtaining in post-war years have been all against the attainment of good load-factor figures. The discontinuance of night-shift working due to dull trade, the early closing of shops and the introduction of summer time, have all helped to reduce load factors. In my opinion, engineers must not be content simply to wait for better times but must attempt to stimulate the use of all appliances which will consume energy during the hours of light load. In dwelling houses this might be done by the heating of water during the night for use during the next day, and in business premises by heat storage at night in suitable appliances, also for use during the next day. Special low rates would be given for these supplies during restricted hours, and the only difficulty to be surmounted would be to ensure that the current would be used only within the restricted period. I believe that a great deal of business will be done in the future on these lines, and it will all help towards the lowering of the rates at which electricity can be sold.

Domestic Load.

The encouragement of the use of electricity in dwelling houses for purposes other than lighting, or in other words the development of the "domestic load," is another matter ripe for the serious consideration of the supply engineer. It is now being given the attention which it has all along thoroughly deserved. It should not need reiteration here that the domestic load is a desirable one, if only for its stability. It is much more stable than the industrial load which fluctuates with the state of trade. People have to cook their food and warm their houses irrespective of trade conditions. Not only cooking and heating but also water heating in bulk can be catered for. There is a very large business to be done in domestic water heating. Of course the rate of charge must be low, but I maintain that a very low rate can be quoted for this business and a profit obtained. I have always been a keen believer in the possibilities of the domestic load, and I consider that the time has now arrived when domestic load problems are well worthy of consideration not only by engineers in charge of undertakings but by the Institution as well. The Electrical Development Association is doing very valuable work in the encouragement of domestic propaganda, and is well worthy of the support now being extended to it by manufacturers, contractors and supply undertakings.

Domestic Supplies.

From an analysis of domestic consumers' accounts, it is apparent that the revenue from these consumers where lighting only is installed may be increased from five to six times by the introduction of cooking and heating appliances.

The old belief, formed some 20 to 25 years ago—that electricity is expensive and is only for the wealthy—dies hard. The selling staffs of supply undertakings are constantly having this objection raised by people who have little or no experience of the use of electricity. Even the consumer of some experience is slow in realizing that in using electricity for cooking and heating he is cutting out other expenses, e.g. for coal, gas, firewood, etc., which amount to a considerable sum when taken over a period of, say, 12 months, and he is very apt to grumble when the electricity accounts are rendered, even while fully appreciating the benefits of the electric service.

With regard to the rates of charge for domestic electricity, it is apparent that there is to be a general adoption of the two-part tariff, viz. a fixed charge based on the rental, floor area, cubic capacity or number of rooms in dwelling houses, and a running charge per unit used. To be attractive, the running charge should be fixed at the lowest possible limit, even at the expense of the fixed charge. Consumers naturally think in terms of the running charge, and the lower this is the more inclined they are to use electricity freely. It is only right that the two-part tariff should be offered

as an alternative to another tariff which should suit the small or the moderate user.

To my mind, a tariff for the small user should assess him at a certain number of units—equivalent to his lighting consumption—at the ordinary rates for lighting, and all units over this quantity at a much lower rate. New consumers would find this rate fair and equitable and they would gradually extend their use of electricity in the home to a greater and greater extent, until the day arrived when they would find it profitable to change to the two-part tariff. On both of these tariffs, one meter only is necessary. It is time that the duplication of meters in private houses, and in many other premises as well, should be abolished.

To develop this domestic load, it is necessary that every facility to use the supply should be placed in the way of the consumer. If he is unable or unwilling to purchase outright the heavier appliances, then these should be hired to him—at all events those appliances which are fairly large current-consumers; I refer more particularly to cookers and fires. From my own experience, I know that there is a great and ever-increasing demand for electric cooking and heating appliances on hire. It is rather astonishing that even in the case of fires, which can be purchased for very moderate sums, people for the most part prefer to hire. Probably the explanation is that if the hire charge includes the installation of the wiring and also the maintenance of the heating elements—as it ought to do—the consumer is relieved of a deal of worry and possible expense.

I do not consider that it is sufficient, having established suitable rates—and also, it may be, hiring schemes—to wait on business coming in. Propaganda without a suitable rate is useless, but, given this advantage, a reasonable propaganda will bring in business in a much more satisfactory way. In Glasgow recently, within the space of a fortnight at a demonstration of electric cooking and heating appliances held in one of the new housing areas, 166 fires and 38 cookers were hired to residents in that area. This was accomplished by means of a circular letter addressed to each house, inviting the people to come to see the demonstration. Later on, at a housing and health exhibition held in this city, orders for the hire of 258 fires and 52 cookers were received within three weeks. These results are, in my opinion, very satisfactory, and show what can be done by means of a little publicity.

Every opportunity should be taken to bring to the notice of the public the benefits to be obtained by the use of electricity in the home. In some large towns it may be necessary to go further than the hiring of appliances. In this city, for instance, there are 250 000 dwelling houses. Of this number only 14 000 have electric lighting installed, and the great majority of dwellings are not owned but only rented by the occupants. It seems to me that the only hopeful means of taking in this class of property is for the supply undertaking to inaugurate a scheme of wiring on hire or hire-purchase terms.

In municipal undertakings particularly, I believe that this suggestion might well be adopted.

It has already been stated by others that the domestic load is an "off-peak" load, and, on this account, very favourable rates can be quoted for domestic supplies. My own experience bears out this contention, and goes to show that the proportion of this load which comes on at peak time is very small, and may be put at from five to ten per cent of the connected load. In addition to this, the diversity of use is very high, and connections may be made freely within limits without fear of overloading distributors.

The factors applicable to the domestic load make it apparent that the capital charges—on the generating plant on account of its being mostly off-peak and on mains because of the high diversity factor—on units used must be very low, and therefore the undertaking can afford to charge low rates and still be sure of realizing a profit. It may be argued that in suburban districts the houses are sometimes widely apart, and to introduce the supply may be considered hopeless on account of the small return to be expected per yard of distributor laid. While this may have been so when lighting only had to be considered, I maintain that nowadays the situation has completely changed, due entirely to the possible other uses of electricity in the home. From a scrutiny of actual accounts it is clear that the "other uses" of electricity in dwelling houses increase the consumption in the majority of cases from 8 to 30 times and, as already stated, the revenue from 5 to 6 times that for lighting only.

Battery Vehicles.

The value of electric battery vehicles to power supply undertakings is not fully appreciated. The load is entirely an off-peak one and if even half of the horse transport work could be transferred to battery vehicles, it would represent an enormous amount of business. American supply undertakings have been much more progressive in this respect and at least 15 000 road battery vehicles are in operation in the United States. It should be noted that the electric battery vehicle is relatively much more expensive in America than in this country. In America one can obtain 12 Ford cars for the price of one electric vehicle, whereas in this country only 5 could be obtained. The Ford car is not generally accepted as a unit of currency, but it may serve to drive home the fact that the electric battery vehicle has made progress in America against even stronger opposition than it encounters here. In addition, the cost of petrol is much lower in America than in this country, while the cost of electricity is approximately the same. My own experience with good makes of battery vehicles has been very satisfactory and a life of 20 years (or say 200 000 miles) with very small repair charges should easily be attained. Batteries, too, are now greatly improved, but it seems to me that it really lies with the battery makers to decide whether or not the electric vehicle shall make real progress here.

Welfare.

I cannot conclude this address without referring in a few words to the subject of welfare in industry, a subject so closely affecting electricity supply undertakings. When the war broke out the cry was "munitions." Men, women, boys and girls, who had little or

no experience in mechanical operations, came from all parts of the country into the munition works which sprang up. Their physical, moral and spiritual welfare was of paramount importance. These mixed assemblages of people required the good influence of guides, especially when they were quite away from home influences. It was at this time that the Government did one of the wisest and greatest things of the whole war—they set in motion on a large scale a method which I hope is going to have an immense and lasting influence. Welfare schemes were organized for the special purpose of looking after the human side of these works. The actual results of this spirit of goodwill and fellowship were, I believe, astonishing. It was clearly demonstrated that work can be a pleasure, and also that this better feeling contributed to better work and a higher degree of efficiency. It brought all grades, including directors, managers, officials, foremen and workers, into closer touch and sympathy with each other. It dispelled many false views which kept men apart. It showed even that discipline can be exercised with goodwill. When men recognize that they are all operating for the common good, a spirit of self-sacrifice appears and glorifies all that is done. I speak with experience of actual operation of Whitley schemes, allied with welfare in the Glasgow Electricity Department.

It is now fully four years since, acting on instructions from the Corporation, a Whitley scheme was formed in the department to deal with what might be termed "domestic matters," and a welfare section, allied therewith, to deal with matters affecting the employees out of working hours. Sub-committees representative of trade and grade, each consisting of five members, the chairman representing the management, were formed in all sections of the department. These sub-committees send representatives to main committees, representing generation and distribution, the chairman of these committees being the superintendent of each section. Above these Committees again is a central committee, numbering 11, divided between management and employees. A welfare supervisor (part-time only) does the secretarial work of all committees.

This scheme, as already stated, has been in operation for four years and is an unqualified success. The men are now fully alive to the benefits which have been derived from the working of the scheme, and take a keen interest in the deliberations of the committees. A better feeling prevails all round, and I am convinced that the work of the department is being better done by a more contented body of men. All matters which cannot be settled in sub-committee are brought to a higher committee, and it is evidence of the good feeling prevailing when it can be said that the Central committee has not required to sit for over eight months.

For the success of a scheme of this kind, much depends on the tact and discretion of the welfare supervisor. One is astounded at the varied nature of the problems which this official has to handle, and in his capacity as a go-between between management and worker it is all-important that he should be the right man in the right place.

It may be argued that this subject has nothing to do with electricity, but we are, or should be, all interested in the humanizing of industry, and why not in electricity supply as in anything else. I recommend strongly, from my own experience, the establishment of such schemes as the one described, not only in electricity supply but in all other great industries throughout the country, and not from the materialistic point of view only, but from the humanitarian as well.

It is essential, I think, that an interest should be taken in the welfare of the worker, not only during his working hours but also in his leisure time. The employees should be encouraged and helped in the establishment of clubs for the carrying on of the various sports and recreations suitable for the time of the year and to the tastes and capacity of all classes and grades. The employees should be entrusted entirely with the carrying on of these clubs under general supervision.

Electricity supply is now vital to the prosperity of the country, and is rapidly assuming greater and greater proportions. It is essential that everything should be done to ensure its continuity. I am convinced that the proper carrying on of these schemes in electricity supply will go far to eliminate one of the factors which during the past few years have endangered this continuity to a serious extent.

DUNDEE SUB-CENTRE: CHAIRMAN'S ADDRESS

By J. C. Christie, Associate Member.

(Abstract *of Address delivered at* Dundee, 11*th October*, 1923.)

I propose to consider briefly the origin and the merits of some of the units of measurement in common use. This is a subject upon which it might be thought that the last word had long since been said, but a little consideration will show that it has been handled in an unscientific manner and is far from being so simple and perfect as it might be.

The first step towards a science of measurement was to learn to count, but our early ancestor found the purely abstract operation too much for his power of brain, so for a time he worked out his problems in concrete form with stones and twigs. Later he learned to cut notches on the twigs, and so came to make those marks which were the forerunners of our present numerals. Soon he began to feel the want of a counting machine ever ready by his side, and there, in the human hand, he found it. The hand was an instrument wonderfully adapted to those uses which had hitherto been required of it. It was the outcome of a long period of development, and survived as the fittest possible tool for grasping a stick or swinging from a branch. Unfortunately, this instrument was by no means equally suitable for its new purpose. It did fairly well until its owner got so far as ten; then, having no more fingers, a difficulty arose, and our early mathematician had to start again at one. It was therefore necessary to keep count of the number of complete tens; and so, in those far-off days, our notation was fixed upon a decimal basis. Here, at our very first step, we blundered badly. Certainly, had we chosen a scale of nine or of eleven in place of ten, things would have been worse; but, on the other hand, a scale based upon the number twelve would have been better, and, in my opinion, the scale of eight would have been the best of all.

To make a change now from the decimal scale is, I am afraid, impracticable. It would mean a period of confusion extending over a whole generation, and I fear that none who have passed school age would ever become thoroughly at home with a new multiplication table. All we can do then is to accept our notation as it stands, a decimal notation, and make the best of it. But we can never make the best of it so long as our various scales of measurement are not founded on the same base as our notation.

The great advantage of our Arabic notation over other systems is not that it is decimal, but that it is perfectly regular, and in the early days it was those nations who used this efficient tool who did good work in the science of numbers. Some progressive nations, like the Roman Empire, made little progress in this direction, the reason being clear if we try to multiply together the numbers MCIX and XLVII, using Roman numerals throughout. But before we condemn the Romans, let us remember that our British system of weights and measures bears exactly the same relation to the metric system that the Roman system of numerals bore to the decimal notation.

After the development of numerals came the introduction of units of measurement. In each case some convenient but quite arbitrary unit was first adopted, and naturally our ancestor concerned himself first with the simplest of all measures, that of length. Length being of one dimension only, is naturally one of the fundamental units, from which the units of two and three dimensions are derived. Any arbitrary length may be chosen as the unit, but the size which is most convenient depends upon the size of the things which are to be measured, and in general it is best to have a unit considerably smaller than the objects to be measured, so that fractions may be to some extent avoided. Thus to measure furniture we shall find the inch convenient. To measure houses we shall prefer to use the foot, while to measure counties we might use the mile. We see, therefore, that one unit is not enough. A range of units is required, and one would think that it was evident that a simple relationship between each step of the range was a great advantage. As our numerals follow a decimal scale, it would seem very simple to have our units follow the same scale, so that conversion from one unit to another could be effected without any calculation other than altering the position of the decimal point. This gives us a range in which each succeeding unit is ten times larger than the last, and for many purposes this works well. In some cases it is found that there is no need for such a close range of units, and then some of the intermediate steps can be omitted. We see an extreme example of this in the case of the measurement of electrical resistance, where we find the ohm a convenient unit, and then discover that the next larger unit required is one million times larger, namely the megohm. Sometimes it is the other way round, as in the case of our silver coins, where it is found that to have one unit ten times the size of the next gives too big a jump, and we then have to use intermediate units. This is where we notice the inconvenience of having a decimal notation. If we had a notation based upon a number on the binary scale, that is to say, if our notation were founded upon eight, which is a power of two, instead of upon ten, we could readily divide our unit by two, and these parts again by two, and so on without getting into awkward fractions. With the scale of ten this cannot be done, and I believe it is this more than anything else which prejudices the metric system and gives our British workman his

love for the inch, which is so conveniently divided into eighths. Here we have the weak point of the decimal system, but in spite of that I think that if our notation cannot be altered, then we should certainly make the best we can of it by converting all our scales to the same decimal base.

It still remains to find a fundamental unit with which to start, and man had found it so convenient to have his counting machine always by his side that he took his first units from the same source, and we find him measuring length by the foot, the pace, the forearm, the hand, the thumb, the span and other similar units derived from his own body. Thus, one of the earliest measures of length, that used by the Egyptians at the building of the Great Pyramid, was called the cubit, and is supposed to have been the distance from the elbow to the tip of the middle finger. Where great accuracy was not required, these units, based upon the size of the human body, were undoubtedly very convenient, and served well for a long period, and it is only in comparatively recent times that the necessity seems to have been felt for establishing standard units of greater accuracy.

In the reign of Edward II we find the English Parliament concerning itself with the matter, and in 1324 it was enacted that "The inch shall have the length of three barley corns, round and dry, laid end to end; twelve inches shall make one foot; and three feet one yard." It was not until the reign of Henry VII that the yard was chosen as our fundamental unit of length, and was fixed at something slightly under 36 inches of our scale. In 1834 a Commission was appointed, which sat for several years and finally produced the imperial yard. This was presented in the form of a bronze bar, 38 inches long by 1 inch square, near the ends of which two gold plugs were inserted and across these plugs fine lines were drawn. At 62° F. and 30 inches barometrical pressure, the distance between these two lines is one imperial yard, our standard of length.

For the introduction of a decimal system of measures our thanks are chiefly due to France. Towards the end of the 18th century it was suggested by Talleyrand that the Kings of France and England should appoint commissions to work together to determine the length of a pendulum swinging seconds. England did not respond to this invitation, but the French commission met and finally decided to adopt a standard of length derived from the size of the earth. It was intended to measure with care the length of the meridian of Paris from the North Pole to the Equator, and take one ten-millionth of this quadrant as the unit of length, to be called the metre or the measure. Actual measurement was begun of a part of this meridian extending from Dunkirk to Barcelona, but the fates as well as the British were against them, and the work was brought to a standstill by the Revolution. Some years later the work was completed, and a bar was made composed of 90 per cent platinum and 10 per cent iridium. It was made somewhat in the shape of an **H** beam, with the standard metre marked off along the neutral plane, so that the length would not be affected even should the bar deflect. That the determination of the metre has since been found to be somewhat inaccurate, and to be in fact more nearly true for the meridian of New York than for that of Paris, is a matter of no consequence, for to all intents the metre is just as much an arbitrary unit as the yard, and either would do equally well so far as its derivation is concerned.

In 1870 France again called an International Convention with a view to the universal adoption of the metric system, but again the fates were against her, for this time the matter was delayed by the Franco-Prussian War.

Whatever fundamental unit of length be adopted, the range to be measured is a wide one, from the smallest object known to man, the electron, on the one hand, to the vast spaces dealt with in astronomy on the other. For these varied measurements we have a wide range of units, with the Ångström unit, which is 10^{-8} cm at one end of the scale, and the light-year, which is 6×10^{12} miles, at the other.

As knowledge progressed, it was seen that there would be a great advantage in having some relation between the different units. Thus, if the yard be the unit of length, it is clear that the adoption of the square yard as the unit of area will simplify all calculations involving these two units.

It was also seen that the more complex physical units could be expressed in terms of a few of the more simple ones. Thus velocity, being an expression of the time taken to move through a distance, depends solely upon the units of time and length. Similarly it was seen that most of the physical units could be expressed in terms of the three fundamental units of space, mass and time. These were taken as the centimetre, the gramme and the second, and from their initial letters the name of the C.G.S. system of units was derived. This was the system which Lord Kelvin advocated in place of what he called "our absurd, ridiculous, time-wasting, brain-destroying British system of weights and measures."

When we measure a length we measure the whole of it, and to do otherwise would seem absurd, but when we measure certain physical quantities, we are in the habit of measuring, not the whole quantity, but merely the amount by which the quantity exceeds a certain minimum. That is to say, we measure from a false zero. This is how we ordinarily measure pressure and temperature, for example.

Pressure is commonly measured in at least three ways. We measure it in pounds per square inch from atmospheric pressure upwards. This is called "gauge pressure." We measure it in feet of water from atmospheric pressure upwards. This is called "head." And we measure it in inches of mercury from atmospheric pressure downwards. This is called "vacuum."

None of these methods of measurement is wholly satisfactory, especially as the atmospheric pressure from which we measure is itself a varying quantity, and these different ways of measuring the same thing have the effect of obscuring many otherwise clear problems in connection with condensing plant. For measuring boiler pressures there is perhaps something to be said for the present method, but even if we wish to measure from the pressure of the atmosphere, and not from the absolute or true zero, we should at least

decide what the unit is going to be, and stop using two of the three units now in common use.

The measurement of heat remained a puzzle for a long time, and this is not surprising seeing that it was only during the 19th century that men first began to understand its nature. It was obvious that more heat had to be put into 10 gallons of water than into one, when both volumes were raised to the same degree of warmth, therefore the apparent warmth or temperature of a body was no measure of the quantity of heat which it contained. Two distinct things had to be measured, the temperature and the quantity of heat. The temperature was the easier problem and was tackled first. Temperature is somewhat analogous to height, and in the case of a mountain tribe it might serve for most purposes if all heights were measured from some convenient point in the village, such as the level of the doorstep of the chief of the tribe, but the use of such a scale would not indicate any very high degree of intelligence on the part of the tribe. It would give the natives no true indication of the relative heights of the different parts of their country above sea-level, and all heights below the chief's doorstep would have to be reckoned as negative. In the case of height, even sea-level, though convenient, is only an arbitrary datum line; but in the case of temperature we have a true natural zero from which to measure, and yet we do not use it. Temperature was first measured indirectly by means of one of the effects of heat, such as the expansion of some substance, but there was no justification for assuming that this expansion was exactly proportional to the temperature, and indeed with some substances, such as water, this is far from being the case, although we now know that in the case of mercury the error at moderate temperatures is very slight.

Before we can measure temperature intelligently we must have a clear idea as to what it is that we are trying to measure. Every body is composed of a vast number of molecules, and, whatever the structure of their component atoms may be, these molecules as a whole remain motionless so long as the body is perfectly cold. Such a body is at the absolute zero of temperature. If the body be now slightly warmed, what happens is that kinetic energy from an outside source is imparted to the molecules, or in other words the molecules begin to move. In the case of a perfect gas these molecules dart about freely, but are continually colliding with each other and maintaining a rain of blows against the sides of the containing vessel. It is this effect which we call pressure, and in the gas thermometer, where the volume is kept constant, this pressure gives a true measure of the temperature by which all other thermometers must be calibrated.

In addition to the measurement of temperature, we have also to measure heat itself. For a time it was thought that this was something material, but it is now known to be simply energy in a special form, and may, therefore, be measured in the same units as any other form of energy.

This brings us to the most important of all the measurements made in a power station, the measurement of energy. The modern steam power station is simply a large machine for the conversion of energy from one form to another. It receives its raw material in the form of potential chemical energy, and its product is this same energy in a form more convenient for distribution and for use. The conversion is effected in a very roundabout way. First we take the chemical energy and convert it into heat energy, then convert this into mechanical energy, and lastly we convert the mechanical energy into electrical energy. We have thus three distinct processes going on in the power station, and these processes are carried out by the boiler, the turbine and the generator respectively. As we transform our energy three times, we have to deal with it in four different forms, chemical, thermal, mechanical and electrical, and in all these forms we must be able to measure it; but in each case we are measuring the same thing, namely energy, and there is no reason why we should not adopt the same unit of measurement in each case, merely using multiples or submultiples of this unit according to the size of the quantity to be measured. Unfortunately, when the problem was tackled long ago by the scientists of the early days, each worked in his own circumscribed department of science, and each introduced his own unit of measurement. Thus, the physicist measures energy in ergs. The chemist makes measurements as to the chemical energy stored in the coal, and he measures this in British thermal units. The mechanical engineer makes similar measurements, but, attacking the problem from a different point of view, he uses the foot-pound as his unit; while the electrical engineer uses a unit which he calls by the clumsy and ambiguous name of the Board of Trade Unit, or better, the kilowatt-hour, or better still the kelvin. The result of this is that we find energy measured by a weird and wonderful collection of units. We have ergs, joules, kilowatt-hours, calories, British thermal units, foot-pounds, horse-power-hours and kilogrammetres. The effect of having so many different units to measure the same thing is that results which should be obvious at a glance become hidden away behind names which bear no obvious or exact relation to one another, and simple comparisons are only made at some little trouble, and often are not made at all. Thus the engineer receives one ton of coal from the colliery, and he may know that its heat value is about 11 000 British thermal units per pound, but it is not obvious to him that what he has really taken delivery of is potential energy sufficient to raise the weight of the coal through a height of some 1 600 miles, or to raise a weight of 1 000 tons upwards of a mile and a half, or the equivalent of 7 216 Board of Trade units.

Let us now glance at the electrical units. These are all based upon the three fundamental units, the centimetre, the gramme and the second, and there is therefore a simple and definite relation between the electrical units, such as the coulomb, the ampere, the volt, the farad and the henry, and the other C.G.S. units, such as the joule and the watt.

The watt, for example, is not an electrical unit. It is simply a measure of power, and is in fact the C.G.S. unit of power multiplied by 10 000 000, but it is so simply connected with the electrical units that it is only necessary to multiply current by pressure, amperes

by volts, in order to express in watts the power in any electrical circuit where the power factor is unity.

The electrical units being based upon the fundamental units, electrical resistance is measured in terms of length and time, while the ampere and the volt are measured in terms of length, mass and time. Take the volt, for example. The fact that the volt can be expressed in terms of length, mass and time is by no means obvious, but let us consider how electrical pressure is produced. Electric pressure is generated in a conductor when that conductor is cutting magnetic lines of force, and the pressure produced depends solely upon the rate at which the magnetic lines are being cut; or in other words, the pressure depends upon three things, the length of the conductor, the speed at which the conductor moves, and the strength of the magnetic field through which it moves. Of these three things one is already expressed as a length; the second, which is a velocity, can be expressed as length divided by time; while the last, the magnetic field, can also be traced back to the fundamental units, for the strength of a magnetic field depends upon its distance from a magnetic pole of a certain strength. The strength of the magnetic pole is measured by the force with which it will repel another similar pole at a certain distance. A force is measured by the velocity which it produces in a certain mass in a certain time. If we now remember that a velocity is just length divided by time, we find we have reduced our definition of electrical pressure to terms comprising only length, mass and time. If we use the centimetre, the gramme and the second for our units, we arrive at a unit of pressure which is inconveniently small for practical use, and in actual practice we multiply this unit by one hundred million, and the resulting unit is familiar to us all under the name of the volt.

Unfortunately, our method of building up the electrical units upon the fundamental units of length, mass and time is not perfect. For one thing, it defines the strength of a magnetic pole by the mechanical force which it would exert upon another similar pole at a given distance. This definition fails to take into account the magnetic permeability of the medium in which the test is made, and further, it misses the important thing about a magnetic pole, which is not the mechanical force exerted by it upon another pole, but the strength of the magnetic flux proceeding from it. It is this fact which introduces the awkward factor 4π into so many electrical expressions.

The fate which befell the metre has also overtaken the electrical units. It has not been found possible to represent these theoretical units with sufficient accuracy for practical purposes, and in practice to-day our electrical units, like the unit of length, are represented by physical models. But although we know that the metre in use to-day is not any exact fraction of the size of the earth, but merely the distance between two marks on a metal bar which is kept in Paris; and although the ohm is not exactly one thousand million C.G.S. units of resistance, but merely the resistance of a certain column of mercury at a certain temperature; and although the ampere is not one-tenth of the C.G.S. unit of current, but merely that current which when passed through a solution of nitrate of silver under certain specified conditions deposits silver at a certain rate; there is nevertheless a scientific interest in comparing our units with some fixed quantity in Nature; if any such exist, and it would seem that there are certain such fixed natural units. One of these is the mass of the atom, say of hydrogen. Another is the wave-length of light at a given part of the spectrum; while another very minute measure of length which appears to be constant is the size of the electron, and it seems that here also we find Nature's own unit of electricity. In round figures, the number of electrons which equal one coulomb is 9×10^{18}. It is not suggested that our practical units should be changed to suit these natural units, but it seems possible that in the future our existing units may be defined in terms of them, so that they may be verified at any time.

There is no doubt that the rapid advance which has been made in electrical engineering is largely due to the exact system of international units which we possess, but many of our earlier and more common units are by no means equally simple and convenient. I think that the improvement of these is overdue, and I believe that the more the subject is considered and discussed, the sooner the improvement will be effected

WIRELESS SECTION: CHAIRMAN'S ADDRESS

By E. H. SHAUGHNESSY, O.B.E., Member.

(Address delivered 7th November, 1923.)

I desire first to say how much I appreciate, and to thank you for, the honour you have done me in electing me as your Chairman for this session. When this Wireless Section of the Institution was formed in 1919 after the war period of intensive development of radio telegraphy and telephony, there was so much matter ready for publication that the success of the first session was assured. It is a matter for satisfaction to know that the interest in the development of the radio art has been well maintained since the war and that the Wireless Section has been able to maintain full sessional programmes with well-attended meetings and do so much to foster that interest. I am glad to say that the prospects for an active session this year are quite satisfactory, and I should like to emphasize the fact that the meetings of the Wireless Section are open to all the members of the Institution.

I intend this evening briefly to review a few radio developments and then to give an account of some of the experiences met with in completing the Leafield high-power station.

BROADCASTING.

Perhaps the most striking development in radio work is that of broadcasting. The question of erecting broadcasting stations in this country was raised early last year when representatives of a large number of firms met at the General Post Office to discuss the subject. Many of these firms intimated their desire to erect stations, mostly in London. It was evident that rather than have a large number of stations of different powers and with programmes of different quality, with no definite guarantee of continued service for any period, it would be better if all the interests concerned would combine to produce a more workable arrangement. A scheme was produced which made it certain that purchasers of radio receiving apparatus would be given programmes for a period of at least two years from good stations of a standard power. The scheme provided for unified control of the stations and was put into operation 12 months ago. It is interesting to note that this country appears to have started its broadcasting under conditions which the directors of the Radio Corporation of America indicate in their annual report for 1923 as being essential for success.

What has been the result of this monopoly of broadcasting? The British Broadcasting Company have been able to collect an efficient staff of technical men and have had the advantage of, the assistance of, and co-operation with a large number of the radio and telephone experts in this country, and by a pooling agreement between the larger firms have been free from all troubles as regards the patent situation.

I remember that at the first meeting of the trade at the General Post Office, Mr. Dane Sinclair suggested that in order to reduce the heavy cost of running eight different programmes nightly the Post Office trunk lines should be hired, at any rate for partial simultaneous transmissions, but there were many of us who thought that the overhearing troubles, attenuation and distortion, would be too much to permit of any large degree of satisfactory simultaneous broadcasting of musical programmes. The Post Office engineers, however, have been able to select or make up such good trunk lines for this purpose that the engineers of the British Broadcasting Company have had every opportunity to exercise their skill and ingenuity.

I think that the quality of the broadcast music is a scientific development of no mean order, and that the successful simultaneous broadcasting may be said to have given this country the lead in that branch of the art. I feel confident that these results could not possibly have ben obtained in so short a time if the British broadcasting had been in the hands of several groups and different authorities.

Broadcasting should prove to the non-technical man that radio-telephony cannot supplant ordinary wire telephone exchanges, for by now he knows how easy it is to overhear speech and how very difficult it is, when comparatively near to a sending station, to get any speech but the one making the most noise.

Loud-speakers.—Twelve months ago there were very few loud-speakers which were either satisfactory or pleasant. So much attention has been given to this problem and its associated problem of well-designed low-frequency amplifiers using suitable valves, that to-day there is a much wider choice of satisfactory loud-speaking equipment.

Considerable incentive has been given to the manufacture of receiving valves, and a number of makers have successfully produced dull emitter valves consuming only a small amount of filament power. In 1913 Mr. Franklin showed me a valve working in the Marconi Company's station at Letterfrack and I then thought that valves would only be used by skilled electricians. To-day broadcasting has made valves almost as familiar in households as ordinary electric lamps. These things are good for the advancement of the art as well as for the trade.

Interference.—I fear that some interference with broadcast reception in areas near the coast is unavoidable, as the ship-and-shore service is essential. The report of the Broadcasting Committee ascribes much

of the interference due to ship-and-shore station spark sets to the indefiniteness of tuning of the wave-length authorized. We have recently carried out trials using a $1\frac{1}{2}$ kW spark transmitter in the General Post Office, London, adjusted to the correct wave-length and with as good a resonance curve as is obtainable for efficient range. Signals could be received on a valve receiver at North Foreland over a wave-band of from 470 m to 850 m. Arrangements were made with the Broadcasting Company to transmit a programme from Birmingham (420 m) whilst this test was taking place, and this programme could not be satisfactorily received at Dollis Hill, Ilford or Grove Park owing to the London spark interference. It was, however, possible to reduce considerably this interference by the use of rejector circuits.

Using the same aerial on the General Post Office and a tonic-train valve transmitter (800 note), the North Foreland station was able to read signals over a band of from 470 to 750 m, but the maximum signal tuning was sharper than with spark. The disturbance to the Birmingham reception on receivers not using reaction at the places mentioned above was about equal to the strength of the Birmingham signals. On using reaction on the receiver at Dollis Hill the strength of Birmingham was considerably increased without affecting the tonic-train disturbance.

The comparison of signal strength at North Foreland, using crystal reception, showed, however, that with 5 amperes in the Post Office sending aerial, signals were readable on spark transmission and were not audible with the same aerial current on tonic-train transmission. With tonic train using 8·5 aerial amperes the signals were just audible but dead weak at North Foreland. As most of the British and foreign ships are fitted with crystal receivers it will be seen that changing to tonic train with present power would considerably reduce the working ranges. Using valve reception at North Foreland the spark reception was only slightly stronger than the tonic train.

Radio Telephony.

An interesting demonstration of radio telephony was given early this year by the American Telegraph and Telephone Co., in conjunction with the Radio Corporation of America and the Western Electric Co. The time chosen for the demonstration was the most favourable period of the year, but it showed that conversation across the Atlantic could under these conditions be carried on by a system which employed less power and a narrower wave-band than would be required when using the ordinary methods of modulation. The other aspects of long-distance radio telephony remain unchanged.

Reception.—Apart from the Beverage antenna, of which I cannot speak from experience so far as reception is concerned, there seem to have been no recent improvements on the use of the well-known methods of high-frequency, selectivity, limiting and selective note tuning, and the employment of directive aerials which have been in use in this country for some years for long-distance reception.

Transmitting valves.—The life of transmitting valves is steadily improving. We have kept careful records of the lives of rectifying and oscillating valves actually in use at working stations, and the figures obtained may be of interest. At a station where 10 valves are in use, in 1921 18 valves were renewed after an average life of 450 hours, in 1922 five valves were renewed after an average life of about 1 000 hours, and up to the present time this year three valves have been renewed after an average life of over 3 000 hours, several of the valves now in operation having already run over 5 000 hours. At another station where 14 larger glass valves are in use they have been working for over 4 000 hours, and only one has been burnt out. The periods stated are, of course, actual working periods and do not include any idle time.

All these are glass valves of the General Electric Company's make, and the increased life is, I think, due to detailed improvement in manufacture and a better understanding of the management of the valves by the station operating staff. It is imperative that the valve filaments be run on a constant voltage if long life is to be obtained. I think that we have every reason to expect a life of from 6 000 to 8 000 hours from the valves now in use.

There has also been marked development in the power output of individual valves. Some of the Western Electric Company's anode water-cooled valves were installed at Northolt in July last and are still running. These are rated to give an output of 10 kW at 10 000 volts on the anode. We carried out an overload test on three of these valves at 12 500 volts on the anode for three hours and obtained an output of 42·5 kW in the aerial, or over 14 kW per valve. The anode of this valve is rated to dissipate 10 kW. With an output of 10 kW at 10 000 volts on the anode at 66 per cent efficiency it will be seen that there are satisfactory working factors of safety on both anode volts and dissipation.

The Holweck valve is another type of water-cooled valve. In this, all the parts are easily demountable and a working pump is permanently attached to the valve whilst it is in operation. An input of 10 kW at 5 000 volts on the anode has given an output of 8 kW oscillating energy. It has the advantage that a burnt-out filament can be renewed at a very low cost in a very short time. I understand that one of these valves has been working in the Eiffel Tower station for some time.

The Admiralty have successfully developed the silica valve, and valves with an output of 5 kW with 10 000 volts on the anode have for some time been made commercially by Mullard.

An Admiralty silica valve with an anode capable of dissipating 24 kW was exhibited before this Section last session by Mr. Morris Airey. This type of silica valve at 12 000 volts on the anode has an input of 33 kW and an output of 21 kW. The development by the Admiralty of silica valves of this and higher powers is proceeding. The filament of this type of valve can be renewed expeditiously at a small fraction of the cost of a new valve.

I think we should now rate valves on their output power anode volts and anode dissipation. With the

smaller power valves the permissible anode dissipation was a reasonable index of the permissible output, but with the larger power valves the permissible anode dissipation is no indication of the maximum output.

The Leafield High-power Station.

I shall now deal with some experiences we have had at the Leafield high-power station. A description of this station has already been published and I do not propose to cover that ground again. The station is equipped with 250-kW Elwell-Poulsen arcs. Some people thought that because the patents for the Poulsen arc had run out, arcs were necessarily antiquated, but the real development of the arc had taken place in quite recent years and the latest type exceeded in power and simplicity any other proved type of high-frequency generator. As a secondary consideration in the choice was the fact that the cost was reasonable, the patent monopoly having run out.

Leafield was the first high-power station to be erected in the middle of England, and as soon as it was operated reports of the large number and strengths of the harmonics and other undesirable emissions received from our friends caused us much perturbation. However, as the staff became more expert in adjusting the flow of methylated spirit into the arc chamber, the correct arc length and the correct field strength, these undesirable emissions were appreciably reduced, but it is still felt that every effort should be made practically to eliminate them. It was suggested that these harmonics, etc., were due to the type of antennæ used, and that the wave-lengths of some of the emissions would be related to lengths of sections of the aerial circuit. Others suggested that the insulated stay sections were the cause of trouble.

Quite apart from harmonics, another type of undesirable emission produces a general rushing, noisy disturbance in the neighbourhood of a wave-length far below the fundamental wave of the arc station. This disturbance is called "mush" and with Leafield working at about 9 000 m the mush appeared between 2 000 m and 3 000 m.

Radiation from the station.—In order to pursue these matters, systematic tests were carried out in 1921 at the Dollis Hill experimental station, situated 101 km from Leafield. Absolute measurements of the emission were made on both the fundamental and the two next immediate harmonics, whilst comparative values of the emission on the higher harmonics were obtained by observing and comparing, using a shunted telephone, the strength of received signals due to them. The specific objects of the experiments may be stated thus:—

(1) To obtain a comparison of the energies associated with the emission on the fundamental wave-length and on the harmonic wave-lengths.

(2) To observe the relative proportions of these energies for various power inputs to the emitting aerial.

(3) To obtain a value for the radiation height h of the Leafield aerial.

(4) To obtain information as to the cause of the harmonic emissions.

Observations on the fundamental wave-length were carried out using frame aerials, whilst those on the harmonics were made using a single wire aerial 100–110 ft. high and having a top run of about 150 ft.

The principle involved in the operation of making the measurements may be described as follows: (1) The signal from the emitting station is tuned in on the aerial, whether frame or straight wire, until the strength in the receiver is a maximum. A local oscillator, set to exactly the frequency of the emitted oscillation, is then arranged to induce into a dummy aerial circuit having characteristics equal to those of the aerial, and the strength of the oscillation observed in the same receiver. (2) The local oscillator is then adjusted until the signal received is of exactly the same intensity as that received from the emitting station. When this is the case the voltage induced into the dummy aerial circuit is equal to the voltage induced into the real and similar aerial circuit by the emitting station. From the value of this voltage, the known characteristics of the receiving aerial, the distance separating the receiving from the emitting station and the current in the emitting aerial, the radiation values required can be calculated.

The method of measurement follows that of Vallauri and Round and was described by Mr. Lunnon in 1921 in the discussion* on "Long-distance Wireless Transmission."

The local oscillator, embodying the method of measuring the voltage induced in the dummy aerial known as the slide-back method due to Captain Round, consisted of a carefully screened set purchased from the Marconi Company.

Experience has shown that it is not a difficult matter for a skilled experimenter to equate two sounds of equal intensity to within about 5 per cent when the note is pure. When one of the notes is impure, however, the error may be of the order of 20 per cent.

The radiation height of an aerial depends primarily upon the distribution of current in the vertical portion. This will very possibly be different in the two cases of fundamental and harmonic emission.

To overcome this difficulty the radiation height for the harmonic emissions has been assumed equal to the radiation height for the fundamental emission.

The value of h (radiation height) in Table 1 (A).—In evaluating the radiation height h in Table 1 (A) the value of I_s taken was that recorded in the transmitting aerial. This current, which, during the tests, was given values of between 100 and 190 amperes is, however, responsible not only for the emission on the fundamental, but also for the emission on the harmonics, and hence the value of I_s which should actually be used is equal to the recorded current minus the current necessary to produce the emission on the harmonics. From values obtained for the equivalent currents in the aerial to produce the second and third harmonic radiations, it can be conjectured that the total equivalent current to produce the whole of the harmonics is bounded by the value of 1·5 amperes. Hence the error involved due to this cause in the evaluation of h (the radiation height) may be taken as being of the order

* *Journal I.E.E.*, 1921, vol. 59, p. 677.

of 1 per cent, and within the limits of experimental error. For this latter reason no correction has been applied to the mean radiation height obtained from the results given in Table 1 (A).

The harmonic emission.—Every harmonic up to the 16th has been observed, and the characteristics of the second and third have been determined absolutely, whilst those of the fourth and fifth have been determined relatively [see Table 1, (B) and (C)]. The experiments show that, generally speaking, the field strength due to an harmonic decreases with increasing order of the harmonic, and that the strength decreases with decreasing aerial current to a greater extent than does the fundamental.

With 150 amperes in the aerial at Leafield, however, the emission of the harmonics is strengthened. This was observed on harmonics up to the fifth and confirmed on separate times and separate days. The harmonic emission is stronger than when there was 177 amperes in the aerial, and a noticeable factor with this aerial current of 150 amperes was the comparative purity of the notes in the harmonics. The note obtained on the harmonics at all other currents was complex, and indicated that the emission was more in the nature of damped wave trains than that of pure continuous waves. This is presumed to be due to variable cycle-to-cycle characteristics of the arc and that at 150 amperes in the aerial the arc maintains a steadier characteristic with consequent purified wave-form and stronger harmonics. If this were the case it would also be reasonable to assume that the fundamental emission at 150 amperes would be improved [Table 1 (A)]. The tests do not show that this is materially the case. Such an effect might, however, be noticed at a more distant station.

Cause of the harmonics.—It is thought that the harmonic emissions are entirely due to the operation of the arc and not to radiation from stay wires or harmonic oscillation of the aerial.

Table 1, (B) and (C), and Table 2 show that the potential gradient, the square of which is proportional to radiated energy, decreases roughly in the ratio of 2 : 3 for each harmonic.

The harmonics are true harmonics inasmuch as their wave-lengths are (within the limits of the wave-meter used) true integral fractions of the fundamental wave-length. The facts that every harmonic is received, that they are true integral fractions of the fundamental, and that their strength is apparently independent of the possible normal modes of oscillation of the aerial, all indicate that the aerial itself does not oscillate harmonically, but that the emissions are due to forced oscillations set up in the aerial by the operation of the arc.

All the measurements were taken on a wave-length of 9 050 m, and the mean value obtained for the radiation height of Leafield was 72·5 m.

The individual values obtained by using different aerial currents of values between 127 amperes and 191 amperes did not differ from the mean value by more than 3 per cent. The height of the masts at Leafield is about 92 m.

By changing the fundamental wave-length to other values such as 8 750 m and 12 300 m and observing the wave-length values of the harmonics produced, it has been confirmed that these are produced by the operation of the arc.

Tables 1 and 2 give the values of the sending aerial current and the values of the potential gradient in microvolts per metre at Dollis Hill, and the values of the radiation height, radiation resistance and radiated energy deduced therefrom.

The results obtained are very interesting. With an aerial current of 191 amperes (representing an aerial energy of about 80 kW) on 9 050 m it is calculated that 3·95 kW are radiated. With the same condition the radiated energy on the second harmonic (4 525 m) is 0·000194 kW. With 176 aerial amperes on the third harmonic (3 016 m) the radiated energy is 0·00005 kW. It will thus be seen that the energy wasted in harmonic radiation from Leafield is a negligible percentage of the total radiation. It is, however, important to know that such a small amount of radiated power can cause interference. It has been suggested that the permissible undesirable emission from a transmitting station shall be a percentage of the power of the station, in the future a fixed maximum amount may have to be decided upon for the largest stations.

To investigate methods of reducing harmonic emissions, experiments were carried out at Stonehaven, where the aerial is supported on 250-ft. masts and where a 24-kW Admiralty Poulsen arc had been installed and where plant was available for building a coupled circuit. No reliable results could be obtained close up to the station as appreciable harmonic radiation was obtained from the primary circuit, the aerial being disconnected. A receiving station was erected at Aberdeen (about 16 miles from Stonehaven) and comparative tests were made using direct aerial and coupled-circuit working. With the direct aerial circuit the harmonics were pronounced and no difference was observed in their strength at Aberdeen whether either the marking and spacing wave method of working or the marking wave with silent spacing interval method of working was used.

When the primary of the coupled circuit was energized with the aerial and secondary circuit, disconnected weak fundamental signals but no harmonics were received at Aberdeen, the radiation being from the primary tuning coil in the Stonehaven station. When the coupled circuit was joined up to the aerial the harmonics were very distinctly reduced.

The "mush" with a plain aerial produced a disturbance at Aberdeen sufficient to swamp out very weak signals, but with the coupled circuits the mush was reduced to such a small amount that not even weak signals were disturbed.

It may be interesting to observe that with the direct aerial working, an input of 15 kW to the arc produced an aerial current of 39 amperes, and with the coupled circuit an input of 19 kW was required to produce the same aerial current of 39 amperes, the current in the primary circuit being 33 amperes.

Although experience has shown that it is not safe to assume that results obtained on small powers can be reproduced with facility on larger powers, these

TABLE 1.

Values of ϵ, H, h_s, R_r and Radiated Energy for Various Values of Aerial Current (I_s) at Leafield.

(A) Fundamental wave-length = 9 050 m.

* Values in these columns are interpolated from shunted telephone results.

results were considered sufficiently promising to justify further trials on a larger scale at the Northolt radio station where a larger arc had been installed and where the aerial is supported on 450-ft. masts. Both the mush and the harmonics from this station had proved disturbing to some communications near London.

In building up the coupled circuit here and finding the best values for inductance capacity and coupling, the primary condenser insulation was broken down on two or three occasions and plain aerial working was resorted to, with the result that on each occasion immediate advice of creating disturbance was received. Both mica-insulated and oil-insulated condensers were tried at Northolt, but the losses in the mica condenser were found to be much less than those in the oil condenser, probably owing to the oil being damp and dirty.

The new aerial tuning inductance proved to be of higher resistance than was expected. With direct aerial working an input of 28 kW to the arc produced an aerial current of 46 amperes, and with the coupled circuit an input of 35 kW to the arc produced the same aerial current of 46 amperes, the current in the primary circuit being 39 amperes.

Observations at Dollis Hill (about 7 miles from Northolt) show that with a coupled circuit working the harmonics were practically eliminated and the mush reduced to a negligible quantity. With direct aerial the receiving telephone had to be shunted with 20 ohms to get rid of the second harmonic, and with 120 ohms to get rid of the third harmonic.

With coupled circuit using an extra valve on the receiver on most occasions no harmonics were observable. On a few occasions when they were traced a shunt of over 1 000 ohms on the telephones caused them to disappear.

The mush when a plain aerial was being used prevented the signals from North Foreland from being properly heard at Dollis Hill, but when the coupled circuit was in use no difficulty whatever was experienced.

The wave-length of Northolt is about 7 000 m and the coupled circuit has been installed permanently for about 12 months. The Dubilier mica condenser in the primary circuit is subjected under working conditions to 30 000 volts at a frequency of about 40 000 p.p.s. and has behaved satisfactorily. These results have encouraged us to proceed with a coupled circuit for Leafield where the power and voltages to be dealt with are of a greater order, but the work is not yet completed.

In connection with the reduction of harmonics and mush, Pederson published a description of some experiments with a cooling shoe placed upon the top of the carbon electrode and capable of adjustment from a distance. The idea was that with proper adjustment the arc would rise between the electrodes, strike the cold surface of the shoe and be instantly extinguished. The copper anode is already water-cooled at the tip. The result would be to make every cycle of the arc exactly similar and reduce undesirable emissions. We have tried an experimental cooling shoe on the large arcs at Leafield, but have not yet been able to form any definite opinion of the effect. Several types of shoe tip have been tried but, owing to the intense heat of the carbon, on each occasion the tip has melted after about half an hour's working. Coating the Leafield carbons with a thin layer of insulating material seems to produce a slight diminution of the mush.

It might be concluded from these remarks that a large arc is a very disturbing element, but that is not the case. The receiving station associated with Leafield is at Banbury (20 miles away) and reception of Cairo and weaker stations is carried out there whilst Leafield is working on full power.

An experiment was carried out to determine whether satisfactory reception nearer to Leafield could be undertaken. A frame aerial pointing towards Leafield on the Leafield–Cairo line was erected 10 miles from Leafield. Cairo on 11 000 m and Marion on 11 600 m were read without any difficulty whilst Leafield was working on 12 300 m.

Neither must it be concluded that valve oscillators are free from harmonics. I hear a well-defined continuous-wave tonic-train valve station sending out groups of figures nightly. I get these signals with about six distinct maxima when swinging the condenser through a range of from 300 to 800 m at a receiving station which is, I believe, about 7 miles from this transmitting station. This is not a Post Office station.

It was stated in the Imperial Wireless Telegraphy Committee's Report of 1920 that 1 aerial ampere produced by a valve oscillator is equal to $1\frac{1}{2}$ aerial amperes produced by an arc. After the installation of a valve transmitter at Stonehaven a direct comparison was made. The arc set and the valve set were in turn connected to the same aerial and adjusted to produce 47·5 amperes at 4 800 m. The potential gradient measured at Dollis Hill was 63·6 μV/m for the arc and 62·5 μV/m for the valve. So far as experimental measurements of this nature are concerned, the potential gradients may be said to be equal. Berlin reported that the signal strengths from the two sets were approximately equal but that there was more variation with the arc. It must be emphasized that to get these equal results it is necessary to have the arc clean and in very good adjustment.

Insulation troubles.—When Leafield was put in operation it was found that if the aerial current was increased above 190 amperes the insulators on the mast stays brushed over. These insulators were carefully watched and when some of them were removed they practically crumbled in the hand. An inspection of the broken parts indicated that they had been subjected to intense internal heat. With arc working the aerial current is on continuously during the spacing interval as well as during marking, and the stay insulators get no rest from dielectric stresses and no chance of cooling down. Larger insulators and then two separate insulators in series were tried at each point, but after a period of working the trouble reappeared. It will be appreciated that the crumbling of stay insulators may result in the collapse of a mast during a gale.

It was not found possible to get a satisfactory insulation of the stays which would permit of a larger aerial current than 190 amperes being used in all conditions of weather. It was therefore decided to short-circuit the insulators in all the top stays of the masts and at the same time bond the stays to the mast

at their top ends, well earthing the bottom ends. The change was made gradually as no work could be done on the stays whilst the station was working. This operation took from June to September, 1922, and systematic radiation measurements were made at Dollis Hill on 8 750 m and 12 300 m as the work progressed. The mean results of the tests when the work was completed gave a radiation height of 76 m for a wave-length of 8 750 m, and a radiation height of 74 m for one of 12 300 m. Allowing for errors of observation, these results compare satisfactorily with the value of 72·5 m radiation height obtained before the change was made. From this we conclude that the radiation from Leafield has not been affected to any measurable extent by the cutting out of stay insulators. The result of the experiment has, however, allowed the normal working aerial current at Leafield to be increased from 190 amperes to 250 amperes without any fear of trouble from broken insulators. The insulators supporting the aerial have given us no trouble.

The aerial tuning inductance is 12 ft. in diameter and is supported on columns of hollow porcelain reels. In order to make them rigid, paxolin tubes were passed through their centres, hooked to the bottom support and clamped tightly at the top. After a period of working these caught fire and the porcelain was punctured. Dry wood was then tried but with no better result, and finally a wooden spider placed at the top of the tuning coils held the columns together and this has stood the test of time.

Recently during some building alterations to the aerial tuning inductance room a temporary wooden partition about 8 ft. from the coil became damp during a storm and shortly afterwards caught fire as the result of being in the field of the high-frequency currents. The builders had been warned to keep it dry but were of the opinion that the warning sounded like a fairy tale. The fear of any further trouble was overcome by erecting a screen of about 12 copper wires between the coil and the wooden partition.

INSTITUTION NOTES.

Local Centre in China.

The Council have sanctioned the formation of a Local Centre in China, with headquarters at Shanghai.

Associate Membership Examination Results: August 1923.

ROYAL CORPS OF SIGNALS.

Passed in "The Theory of Electrical Military Signalling."

Akehurst, Lieutenant C. H. (23rd Sikh Pioneers, I.A.).
Burt, Lieutenant G. M. B. (1st Bn. 12th F.F. Regt., I.A.).
Collin, Captain E. P. C. (18th Lancers, I. A.).
Dent, Lieutenant W. H. N. (Northumberland Fusiliers).
Gem, Lieutenant R. H. (The Buffs).
Harris, Captain J. N. A. (69th Punjabis, I.A.).
Hinds, Lieutenant C. D. (R.G.A.).
Hurst, Captain G. S. (4th D.C.O. Hodson's Horse, I.A.).
Jourdain, Lieutenant F. W. S. (Oxf. and Bucks. Lt. Infantry).
Leonard, Captain R. G. (5th Gurkha Rifles, I.A.).
McGregor, Lieutenant W. D. [1st (K.G.O.) Gurkha Rifles, I.A.].
MacMillan, Captain D. MacL. (3rd R. Bn. 3rd Sikh Pioneers, I.A.).
O'Sullivan, Lieutenant P. R. (Wilts. Regt.).
Palmer, Lieutenant W. J. (R.F.A.).
Ridley-Thompson, Lieutenant E. L. (The Queen's Bays).
Sugrue, Lieutenant W. F. (Beds. and Herts. Regt.).
Thompson, Lieutenant T. C. (The Royal Fusiliers).

The Physical Society of London and the Optical Society: Annual Exhibition of Scientific Apparatus.

Tickets of admission to the above Exhibition, which is to be held at the Imperial College of Science, South Kensington, on Wednesday and Thursday, 2nd and 3rd January, 1924, can be obtained from the Secretary of the Institution.

Committees, 1923-1924.

Among the Committees appointed by the Council for 1923–24 are the following:—

INFORMAL MEETINGS COMMITTEE.

The President.

Mr. J. R. Bedford.
Mr. J. Coxon.
Mr. P. Dunsheath, O.B.E.
Mr. R. Grierson.
Mr. A. F. Harmer.
Mr. E. F. Hetherington.
Mr. A. G. Hilling.
Mr. F. Pooley.
Mr. W. E. Warrilow.

The Chairman of the Papers Committee.
The Chairman of the London Students' Section.

LIBRARY AND MUSEUM COMMITTEE.

The President.

Colonel R. E. Crompton, C.B.
Prof. E. W. Marchant, D.Sc.
Mr. S. W. Melsom.
Mr. W. M. Mordey.
Mr. C. C. Paterson, O.B.E.
Colonel T. F. Purves, O.B.E.

Local Centres Committee.

The President.

Mr. C. T. Allan.
Major H. Bell.
Mr. T. Carter.
Sir J. Devonshire, K.B.E.
Mr. K. Edgcumbe.
Mr. F. Gill, O.B.E.
Mr. J. S. Highfield.
Mr. E. M. Hollingsworth.
Mr. G. A. Juhlin.
Prof. E. W. Marchant, D.Sc.
Mr. R. B. Mitchell.
Mr. J. D. Morgan.
Mr. A. Page.
Mr. R. N. Tweedy.
Mr. C. H. Wordingham, C.B.E.

"Science Abstracts" Committee.

The President.

Mr. Ll. B. Atkinson.
Mr. W. R. Cooper.
Mr. F. Gill, O.B.E.
Mr. W. M. Mordey.
Dr. D. Owen, Mr. T. Smith — Representing the Physical Society of London.

Ship Electrical Equipment Committee.

The President.

Mr. A. G. S. Barnard.
Mr. J. H. Collie.
Mr. B. M. Drake.
Mr. A. Henderson.
Mr. J. W. Kempster.
Mr. J. F. Nielson.
Mr. N. W. Prangnell.
Major A. P. Pyne.
Mr. S. G. C. Russell.
Mr. T. A. Sedgwick.
Mr. H. D. Wright.
Mr. C. H. Wordingham, C.B.E.

And	*Representing*
Sir W. S. Abell, K.B.E.; Mr. J. T. Milton	Lloyd's Register of Shipping.
Two representatives	British Electrical and Allied Manufacturers' Association.
Mr. T. Carlton	Board of Trade.
Mr. W. Cross	Electrical Contractors' Association.
Mr. J. Foster King	British Corporation for the Survey and Registry of Shipping.
Mr. J. Lowson	Institution of Engineers and Shipbuilders in Scotland. Electrical Contractors' Association of Scotland.
Mr. A. W. Stewart	Institution of Naval Architects.
Mr. H. Walker, O.B.E.	N.E. Coast Institution of Engineers and Shipbuilders.

Wireless Section Committee.

Mr. E. H. Shaughnessy, O.B.E. (*Chairman*).

The President.

Mr. B. Binyon, O.B.E.
Mr. S. Brydon, D.Sc.
Dr. W. H. Eccles, F.R.S.
C. F. Elwell.
Prof. G. W. O. Howe, D.Sc.
Admiral Sir H. B. Jackson, G.C.B., F.R.S.
Mr. G. H. Nash, C.B.E.
Mr. C. C. Paterson, O.B.E.
Mr. J. St. Vincent Pletts.
Captain H. R. Sankey, C.B., C.B.E., R.E.
Dr. R. L. Smith-Rose.
Mr. A. A. C. Swinton, F.R.S.
Mr. C. F. Trippe.
The Chairman of the Papers Committee.

And	*Representing*
Capt. C. E. Kennedy-Purvis, R.N.	The Admiralty.
Major R. Chenevix-Trench, O.B.E., M.C.	The War Office.
Major H. P. T. Lefroy, D.S.O., M.C.	The Air Ministry.
Major A. G. Lee, M.C.	The Post Office.

Wiring Rules Committee.

The President.

Mr. Ll. B. Atkinson.
Mr. H. J. Cash.
Mr. J. R. Cowie.
Mr. W. Cross.
Mr. J. Frith.
Dr. C. C. Garrard.
Mr. P. V. Hunter, C.B.E.
Mr. S. W. Melsom.
Mr. J. F. Nielson.
Major A. P. Pyne.
Mr. E. Ridley.
Mr. C. P. Sparks, C.B.E.
Mr. C. H. Wordingham, C.B.E.

And	*Representing*
Mr. E. G. Batt; Mr. H. H. Berry; Mr. J. R. Dick; Mr. A. R. Everest; Mr. C. Rodgers	British Electrical and Allied Manufacturers' Association.
Mr. W. F. Bishop	Cable Makers' Association.
Sir T. O. Callender; Mr. J. F. W. Hooper	Cable Makers (unofficially).
Mr. W. R. Rawlings; Mr. S. H. Webb	Electrical Contractors' Association.
Mr. E. J. B. Lowdon	Electrical Contractors' Association of Scotland.
Mr. B. M. Drake	Contractors (unofficially).
Mr. A. C. Cockburn; Mr. S. G. C. Russell; Mr. A. L. Taylor	Fire Offices (unofficially).
Mr. J. Christie; Mr. F. W. Purse	Incorporated Municipal Electrical Association.
Mr. E. T. Ruthven Murray	Incorporated Association of Electric Power Companies.
Mr. O. M. Andrews	Conference of Chief Officials of the London Electric Supply Companies.
Mr. J. M. Crowdy	Association of Supervising Electricians.
Mr. T. Martin Harvey	Independent Cable Makers' Association.

Sectional Committees.

Lighting and Power.

The President.

Mr. J. W. Beauchamp.
Mr. J. R. Bedford.
Mr. R. A. Chattock.
Mr. R. Grierson.
Mr. A. F. Harmer.
Mr. R. B. Mitchell.
Mr. A. Page.
Mr. G. W. Partridge.
Mr. C. P. Sparks, C.B.E.
Mr. W. B. Woodhouse.

Electricity in Mines.

The President.

Mr. C. T. Allan.
Mr. J. A. B. Horsley.
Mr. J. D. Morgan.
Mr. W. C. Mountain.
Mr. W. H. Patchell.
Mr. W. M. Selvey.
Mr. C. P. Sparks, C.B.E.
Prof. W. M. Thornton, D.Sc., O.B.E.
Mr. W. B. Woodhouse.

SECTIONAL COMMITTEES—*continued.*

Traction.

The President.

Mr. H. W. Firth.
Lt.-Col. F. A. Cortez Leigh.
Mr. F. Lydall.
Mr. A. H. W. Marshall.
Mr. G. W. Partridge.
Mr. J. Sayers.
Mr. R. T. Smith.
Mr. B. Welbourn.
and one other to be appointed.

Electro-Chemistry and Electro-Metallurgy.

The President.

Mr. W. A. Chamen.
Mr. W. R. Cooper.
Prof. W. Cramp, D.Sc.
Mr. S. E. Fedden.
Mr. E. M. Hollingsworth.
Mr. W. M. Morrison.
Mr. J. Swinburne, F.R.S.,
and 2 members to be co-opted by the Committee.

Telegraphs and Telephones.

The President.

Mr. H. G. Brown.
Mr. W. W. Cook.
Dr. W. H. Eccles, F.R.S.
Mr. S. Evershed.
Mr. H. H. Harrison.
Mr. G. H. Nash, C.B.E.
Col. T. F. Purves, O.B.E.
Mr. J. Sayers.
Mr. C. W. Schaefer.
Mr. F. Tremain.

Representatives of the Institution on Other Bodies.

The following is a list of representatives of the Institution on other bodies, and the dates on which they were appointed.

Birmingham Chamber of Commerce:

Mr. S. T. Allen (27 March, 1919).

Bradford Public Libraries Committee:

Mr. T. Roles (27 Feb., 1919).

Bristol University:

Mr. H. F. Proctor (6 Dec., 1917).

British Association, Fuel Economy Committee:

Mr. C. H. Wordingham, C.B.E. (9 Jan., 1919).

British Electrical and Allied Industries Research Association:

Mr. Ll. B. Atkinson (2 April, 1919).
Mr. F. Gill, O.B.E. (2 Nov., 1922).
Mr. R. T. Smith (30 Oct., 1919).
Mr. C. P. Sparks, C.B.E. (4 Oct., 1917).
Mr. C. H. Wordingham, C.B.E. (4 Oct., 1917).

Sectional Committee on Electric Control Apparatus Research:

Major H. C. Gunton (2 Feb., 1921).
Mr. C. H. Wordingham, C.B.E. (22 Nov., 1920).

British Electrical Development Association:

Mr. R. Hardie (18 Jan., 1923).
Mr. C. H. Wordingham, C.B.E. (18 Jan., 1923).
(One vacancy.)

British Empire Exhibition, 1924, Electrical and Allied Engineering Committee:

Sir A. M. Ogilvie, K.B.E., C.B. (23 June, 1922).

British Engineering Standards Association:

Main Committee:

Col. R. E. Crompton, C.B. (18 Jan., 1923).
Mr. Ll. B. Atkinson (1 Feb., 1923).
Mr. C. H. Wordingham, C.B.E. (18 Jan., 1923).

Sectional Electrical Committee:

Mr. F. Gill, O.B.E. (21 May, 1914).
Mr. J. S. Highfield (21 May, 1914).
Mr. R. T. Smith (21 May, 1914).
Mr. W. B. Woodhouse (19 Dec., 1918).
Mr. C. H. Wordingham, C.B.E. (18 Nov., 1915).

Sectional Committee on British Standards in Colonial and Foreign Trade:

Mr. C. P. Sparks, C.B.E. (26 Oct., 1916).

Sectional Committee on Machine Parts and their Gauging and Nomenclature:

Mr. J. H. Rider (8 Feb., 1917).

Sectional Committee on Petroleum Products:

Mr. H. W. Clothier (1 Feb., 1923).

Electrical Instruments Sub-Committee:

Mr. K. Edgcumbe (15 Feb., 1923).

Electrical Nomenclature and Symbols Sub-Committee:

Mr. C. C. Paterson, O.B.E. (8 Jan., 1920).

Overhead Transmission Lines Material Sub-Committee:

Mr. C. H. Wordingham, C.B.E. (30 Oct., 1919).

Pipe Flanges Sub-Committee:

Mr. W. M. Selvey (14 April, 1921).

Panel on Steel Conduits for Electric Wiring:

Mr. H. J. Cash (28 Sept., 1922).
Mr. J. M. Crowdy (28 Sept., 1922).

Conference on Standardization of Ball and Roller Bearings:

Mr. W. M. Selvey (26 July, 1921).

Darlington Board of Invention and Research:

Mr. R. M. Longman (15 May, 1919).
Mr. J. R. P. Lunn (15 May, 1919).
Mr. H. G. A. Stedman (15 May, 1919).

Engineering Joint Council:

Mr. J. S. Highfield (15 Feb., 1923).
Mr. R. T. Smith (15 Feb., 1923).

Imperial College of Science and Technology, Governing Body:

Mr. W. M. Mordey (12 April, 1923).

Imperial Mineral Resources Bureau Conference:

Mr. J. H. Rider (23 Jan., 1919).
Mr. W. B. Woodhouse (23 Jan., 1919).

Copper Committee:

Mr. B. Welbourn (18 Sept., 1919).

Miscellaneous Minerals Committee:

Prof. E. Wilson (18 March, 1920).

Institute of Metals, Corrosion Research Committee:

Mr. W. M. Selvey (19 July, 1923).

Institution of Civil Engineers, Engine and Boiler Testing Committee:

Mr. R. A. Chattock (19 Oct., 1922).
Mr. C. P. Sparks, C.B.E. (19 Oct., 1922).

Institution of Heating and Ventilating Engineers, Committee on Utilization of Exhaust Steam and Waste Heat:

Mr. P. V. Hunter, C.B.E. (29 Sept., 1922).
Mr. W. M. Selvey (29 Sept., 1922).
Mr. J. C. Wigham (29 Sept., 1922).

International Illumination Commission, British National Illumination Committee:

Prof. W. C. Clinton (13 Dec., 1917).
Mr. K. Edgcumbe (27 Nov., 1913).
Mr. Percy Good (18 Sept., 1919).
Mr. H. T. Harrison (27 Nov., 1913).
Prof. J. T. MacGregor-Morris (27 Nov., 1913).

International Navigation Congress, 1923, General Organization Committee:

Mr. F. Gill, O.B.E. (2 Feb., 1922).

International Road Congress (Fourth):

Col. R. E. Crompton, C.B. (6 July, 1922).

International Scientific Unions:

Committee on International Union in Physics:

Dr. A. Russell (18 March, 1920).

Committee on International Union in Radio-Telegraphy:

Dr. W. H. Eccles, F.R.S. (18 March, 1920).
Prof. G. W. O. Howe, D.Sc. (18 March, 1920).
Prof. E. W. Marchant, D.Sc. (18 March, 1920).

International Testing Association:

Mr. Ll. B. Atkinson (29 May, 1919).
Mr. C. C. Paterson, O.B.E. (29 May, 1919).

Leeds Civic Society:

Mr. E. C. Wallis (27 March, 1919).

Leeds Municipal Technical Library Committee:

Mr. W. B. Woodhouse (19 Dec., 1918).

Loughborough Technical College, Advisory Committee:

Mr. R. B. Leach (27 March, 1919).

Metalliferous Mining (Cornwall) School Governing Body:

Mr. J. S. Highfield (18 Sept., 1919).

Middlesbrough Technical College, Governing Body:

Mr. C. O. Brettelle (1 Oct., 1923).
Mr. P. S. Thompson (1 Oct., 1923).

Mines Department, Electrical Storage Battery Locomotive Committee:

Mr. R. T. Smith (7 Dec., 1922).

National Physical Laboratory, General Board:

Mr. Ll. B. Atkinson (21 Oct., 1920).
Dr. A. Russell (22 Nov., 1923).

Newcastle-upon-Tyne Chamber of Commerce:

Major A. P. Pyne (13 Nov., 1919).

Paris Conference on E.H.T. Lines, 1923:

Mr. P. V. Hunter, C.B.E. (1 Feb., 1923).
Mr. E. B. Wedmore (1 Feb., 1923).
Mr. W. B. Woodhouse (1 Feb., 1923).

Paris Conference on Weights and Measures:

Sir R. T. Glazebrook, K.C.B., D.Sc., F.R.S. (14 April, 1921).
Dr. A. Russell (14 April, 1921).

Professional Classes Aid Council:

Mr. W. B. Esson (26 July, 1921).

Registration of Electrical Contractors:

Mr. P. V. Hunter, C.B.E. (12 April, 1923).
Mr. W. R. Rawlings (15 March, 1923).
Mr. W. M. Selvey (15 March, 1923).
Mr. C. H. Wordingham, C.B.E. (15 March, 1923).

Röntgen Society Advisory Committee for British X-ray Industry:

Dr. W. H. Eccles, F.R.S. (21 Feb., 1918).
Mr. J. E. Taylor (21 Feb., 1918).

Royal Engineer Board:

Mr. C. H. Wordingham, C.B.E. (7 April, 1921).

Royal Society:

Alloys of Iron Research Committee:

Mr. J. Swinburne, F.R.S. (15 Feb., 1923).

National Committee for Physics:

Dr. A. Russell (16 Dec., 1920).

National Committee on Radio-Telegraphy:

Dr. W. H. Eccles, F.R.S. (4 Aug., 1920).
Prof. E. W. Marchant, D.Sc. (4 Aug., 1920).

Scientific and Industrial Research Advisory Council, Engineering Committee:

Mr. J. S. Highfield (9 March, 1916).

Society of Radiographers:

Dr. W. H. Eccles, F.R.S. (22 Jan., 1920).
Mr. J. S. Highfield (22 Jan., 1920).
Mr. C. C. Paterson, O.B.E. (22 Jan., 1920).
Dr. A. Russell (25 May, 1922).
Mr. A. A. C. Swinton, F.R.S. (22 Jan., 1920).
Mr. C. H. Wordingham, C.B.E. (22 Jan., 1920).

Transport Ministry, Advisory Panel and Committees:

Mr. Ll. B. Atkinson (30 Oct., 1919).
Sir J. Devonshire, K.B.E. (30 Oct., 1919).
Mr. J. S. Highfield (30 Oct., 1919).
Mr. R. T. Smith (30 Oct., 1919).
Sir John Snell (30 Oct., 1919).
Mr. C. P. Sparks, C.B.E. (30 Oct., 1919).
Mr. C. H. Wordingham, C.B.E. (30 Oct., 1919).

Women's Engineering Society:

Mr. A. P. M. Fleming, C.B.E. (19 July, 1923).

World Power Conference, 1924:

Mr. Ll. B. Atkinson (12 April, 1923)
Mr. R. T. Smith (12 April, 1923).
Sir John Snell (12 April, 1923).

INDUSTRIAL RESEARCH, WITH SPECIAL REFERENCE TO ELECTRICAL ENGINEERING DEVELOPMENT.

By W. WILSON, B.E., M.Sc., Member.

(*Paper first received* 31*st October*, 1922, *and in final form* 6*th December*, 1923; *read before* THE INSTITUTION 1*st November, before the* NORTH-EASTERN CENTRE 12*th November, before the* SOUTH MIDLAND CENTRE 14*th November, before the* MERSEY AND NORTH WALES (LIVERPOOL) CENTRE 19*th November, before the* NORTH MIDLAND CENTRE 27*th November, and before the* DUNDEE SUB-CENTRE 13*th December*, 1923.)

SUMMARY.

During the past 40 years radical changes in manufacturing conditions have rendered industrial research essential for the attainment of reasonable efficiency and progress.

Industrial research is divisible into two orders, the more general and the more particular, both being necessary for the production of a new article. The second is usually termed "Development," and is the special subject of this paper.

While British men of science and applied science have been pre-eminent for general research, little attention has been paid to development. Hence few inventions have, within recent years, been brought to their conclusion in this country, as compared with the great amount of original scientific work which has been successfully accomplished.

The reasons for this are analysed, and the cause is traced to lack of the co-operation necessitated by modern manufacture. This want is filled by development departments.

The various functions of the latter are dealt with. Their outcome is the removal of all non-standard work and technical troubles from the shops and drawing offices, and the provision of original and matured designs of new and improved articles for manufacture.

The negligible value of ordinary sources of novel suggestions is discussed, and the qualifications of a development man are deduced. The question of staffing the department, and the educational qualifications which the staff should possess, are then treated.

Practical matters, including buildings and equipment, procedure in development, the recording and filing of results and data, and the indexing of literature and information, are discussed.

A short summary is given of the principal industrial research organizations in Great Britain, with a brief discussion on co-ordination.

TABLE OF CONTENTS.

I. INTRODUCTION.

The past 40 years have witnessed a gradual but far-reaching change in the manufacturing system. In the first place, the increasing application of science to industry, and the growing complexity of the various products, have in general made it impossible for a single mind to carry on the complete administrative and technical direction of a manufacturing business. Secondly, the progressive standardization of all but the newest products has opened the way for quantity production, involving the manufacture of a greatly increased number of articles on the basis of a given design, and has thus introduced conditions favouring the growth of the factory and at the same time the specialization of its output.

Not only have these developments enhanced the value of the original design, since a much greater number of articles are now affected thereby, but the increased efficiency introduced by quantity production has afforded the means whereby the design can be far more fully considered. Thus the scientific staff has found a place in manufacture. Their work has been generally termed "industrial" research, in contradistinction to the "pure" research carried on for the extension of scientific knowledge.

The former is divisible into two well-defined orders; the first being the more general and theoretical, and the second the more particular and practical. Of these, the second is generally termed "development" and has been brought to a high state of perfection abroad. In this country its value has been recognized to a much smaller extent, to the disadvantage of many of our industries. The author is convinced that no procedure is more capable of benefiting the industry with which we are more especially concerned than the institution and furtherance of developmental research; and it is the purpose of this paper, first to distinguish between the various kinds of research and their application, and then to deal particularly with the essentially practical variety.

II. CLASSES OF RESEARCH WORK.

The above three types of research work are typically employed in consecutive order, in the production of new pieces of apparatus. First, an investigator in a university or similar laboratory makes a discovery while engaged in extending scientific knowledge. Secondly, a worker in an industrial research institution recognizes the possibility of utilizing the discovery in connection with his industry, and carries out a further investigation to ascertain its practicability. If the answer is in the

affirmative he makes a definite proposal, and may even support this with a primitive model. Finally, a development worker takes the matter in hand and, as a result of a third investigation, elaborates an actual product embodying the principles evolved by his two predecessors. The proposed apparatus, as submitted to him, may be fragile, inefficient, unreliable and expensive, its utilization being unwarranted or even impossible until various practical problems have been solved. This, then, is the function of the third class of worker, who renders the apparatus suitable for manufacture in the shops and for acceptance in the commercial field.

These three stages can be clearly recognized in the evolution of practically every industrial apparatus. Of these it will be sufficient to cite the dynamo as an instance. First, the production of force by electromagnetic means was investigated, notably by Oersted, Ampère, and Barlow, the last-named of whom actually obtained continuous rotary motion. On these principles Faraday then based his more utilitarian but extremely important investigations, leading to the construction of the first crude dynamo. Finally, the latter was developed to its practical form by Gramme, Crompton, Kapp, Ferranti, Hopkinson and others.

The distinguishing characteristics of the three orders may now be summed up. Pure research, to employ its usual but not highly satisfactory name, is unique in being undertaken entirely with a philosophic motive, and hence would probably be best described as "philosophic" research. In this respect it is contrasted with "industrial," "utilitarian," or "pragmatic" research, by which a proposal for an article of commercial utility is formulated. This proposal is converted into a finished and workable apparatus by what is most often known as "development," a title that is, however, ambiguous when its context is not supplied; and as practically the same ground is covered by the "technical research" of Mr. Swinburne, the latter term is preferred by the author.

III. Need for Technical Development.

If the evolution of modern engineering products is studied, it will be found in a surprisingly large number of cases to have been the outcome of pioneering work done in this country, which has unfortunately been discontinued at the end of the second stage, leaving the final development to be carried out abroad. A few examples of this may be worth recalling.

The industries depending upon the fixation of atmospheric nitrogen are the outcome of the philosophic research work of Priestley and Cavendish, followed by the more utilitarian investigations of Rayleigh. The development work was carried out abroad, largely in America and Norway. Other electrochemical products, derived largely from the researches of Davy, Faraday and Charles Watt, have only resulted in the establishment of new industries in Germany. Several types of alternating-current motor have the same history. Electrical engineering generally has been founded chiefly on the brilliant work of great British electricians, such as Faraday, Maxwell, Kelvin, Hopkinson and Thompson, yet much of the work of application and development has been carried out in America and on the Continent, while quite a considerable proportion of the apparatus actually manufactured in this country during recent years has been made to designs supplied from abroad.

Unfortunately, although we claim for our own technical men very much of the credit for industrial progress, it is those who complete the work that gain every other advantage, for we have grown accustomed to abandoning our enterprises just where they begin to be profitable. By permitting foreign nations to act before us in this manner we are conceding them the initiative, an error in tactics as serious in commerce as in war. In the Colonial and foreign fields the effect of this loss of initiative is especially evident, for prestige is there an important factor in determining success, and orders tend to be given to the actual authors of improvements and innovations. The latter also secure the very practical advantage that they turn out the improved product, and therefore give better value, for a considerable period before their copyists.

IV. Causes of the Present Position.

From time to time, theories of rather an alarmist nature are propounded to explain this state of things, usually by the allegation of national decadence in various respects. Such charges of deterioration cannot, however, be substantiated either against our investigators in pure or applied science or against the workers in our factories. Further, the outstanding success of our invention and manufacture during the war, not only in a few but in practically all industries, sufficiently proves our originating capacity. It is evident, therefore, that there must be a national peculiarity the effect of which was unfelt, or at least unnoticed, until manufacturing conditions were disturbed by the developments in industrial methods to which reference has been made.

Such a characteristic is to be found in the tendency against co-operation that is at once remarked even by a newcomer to this country from another part of the British Dominions. It is evident in our art, in our politics, and in our industries. Its effects are apparent not only between individuals, but between associations, between firms, between those who teach the theory and those who practise the profession. Its result is that for single-handed work we need fear no competition, but where co-operation is essential we frequently fail.

Unfortunately for us, the present industrial era is one in which the association of effort and of ideas is all-important. In every movement a time arrives when progress can be maintained only by co-ordination. This critical point was reached in engineering development when the foundations had all been laid, when the elementary discoveries had all been effected, and when the simple apparatus had all, or nearly all, been thought out. From then onwards, progress could only be made on more advanced lines, by employing higher theoretical principles, more elaborate tools and instruments, and more expensive construction. For this, not only is scientific work necessary, but most of it must be carried out in conjunction with the industry, and much of it in conjunction with the actual works. These two latter categories will be recognized as broadly corresponding to industrial research and development respectively.

The latter is unfortunately attended by peculiar difficulties, since it must be carried on by men of university status, in conjunction with a factory or group of factories, and these two elements have in this country proved very hard to combine. The author hopes that a discussion of the problems involved will be of advantage in furthering this form of research work, and thus in promoting the welfare of the industry.

V. Functions of a Development Department.

The broad function of a development department is to evolve new types of product for manufacture in the shops with which the department is associated. This also involves the evolution of new parts for an existing model, to endow the latter with new characteristics or to improve it in some desirable respect. In many cases the designing and drawing offices may themselves be able to effect a desired change, and merely require certain theoretical or experimental information which, on request, is then supplied by the development staff. Problems requiring higher mathematics will be submitted to them for solution. Problems and difficulties in the examination of the finished product will be passed on by the routine testing or inspection departments. Technical advice will also be afforded to any part of the factory when desired.

The general effect of such a department is to take upon itself all technical burdens from the shoulders of the staff and works. It thus incidentally performs two very important services. First, much of the worry and risk of failure is removed from the designing staff, and secondly, all work of a non-standard nature can be removed from the shops, as the model makers attached to the development department will now carry out all experimental or tentative construction. Those who are intimately concerned with manufacturing will have had experience of the absorption of time and disarrangement of routine that may be caused by the sandwiching of trial jobs between the regular items of work, and by the frequent visits of draughtsmen to the work benches. The aim of the development system is to put an end to this, and to enable both shops and staff to pursue their duties with a minimum of interruption.

In order to illustrate the above curriculum and to demonstrate its general applicability, the author proposes to outline the actual work to be carried out in two specific cases, so selected as to represent opposite extremes.

The first case is that of a factory employing several thousand hands, all engaged on mass production. It will be supposed that the designs are supplied to the factory in question by their customers, as was the case with munition firms during the war.

The peculiarity of such a works is that there is no apparent necessity for any theoretical department, if a materials test-room be excepted, and it is by no means unknown for a factory of this nature to be organized with no special provision for technical knowledge. The manager and foremen may be what are euphemistically called "practical men," i.e. they may be promoted workmen who have never received any technical training. Even the head of the gauge room may be a fitter with no knowledge of science or mathematics and no aptitude for study. It is possible, in short, for a factory with a pay-roll running into four or five figures, to include no more than about a dozen people, apart from the clerical staff, whose education has continued after they were 14 years of age.

Yet there are frequent problems, even in repetition work, that require solution by a highly trained man. The type of machine used in a modern workshop, the jigs, fixtures, and other machining accessories, and especially the gauges, have been designed with the assistance of all the resources of modern engineering science, and their use should therefore require a corresponding degree of knowledge in the workshop. In particular, limit-gauging is a definite and intricate branch of physical science, and proficiency in it demands a knowledge of geometry, trigonometry, applied mechanics and the properties of materials.

Keeping the factory as a whole just as it is, an immediate gain in efficiency out of all proportion to the cost would be effected by the institution of a small development department, the chief duties of which would be to act as consultant to the shops. Even one man with, say, a university degree in engineering and an enthusiasm for the work, would be able to reduce greatly the amount of scrap and to cause things to go more smoothly. He would be consulted if a gauge gave unsatisfactory results, and would be required to discover the reason and to correct the method of gauging employed. Jigs that were misdirecting their drills for some obscure reason would be put under his observation. Theoretical questions as to materials, illumination, heat treatment, rectification, and the like, would be put to him. He would suggest, or search for, scientific methods of overcoming the many small difficulties that crop up in such a works, while he would keep in touch with the general workshop practice applicable to his particular establishment.

As these functions do not, in point of fact, involve investigations of a very advanced nature, but do involve a close contact with the shops, the department might well include a small technical library for the use of the works staff, by the administration of which the head could the more effectively get, and keep, in touch with those in charge of the work, who would thus be the more ready to bring problems and troubles to him for solution.

The second and more advanced example is a department associated with an electrical factory, which is entirely self-contained, in that the whole of its products are designed within its walls. To begin with, the development staff will endeavour to produce new designs of apparatus for the shop to manufacture. Much of this work will be undertaken as a result of representations from the various sales, design, works or other departments, whenever one of these may realize that a change or an innovation is desirable. The development staff will also keep in close touch, by study and observation, with electrical practice as it concerns their products, and will thus themselves be able to initiate proposals as to future activities. These will be submitted to the management through the medium of reports, in which the objects of the proposed developments are given,

together with such details as to their nature as have been arrived at.

Since the development department in such a factory is either the point of origin or the clearing house for new products, it follows that it must be the repository for all technical data concerned in the design of the articles made in the factory. No development with which the department is not made acquainted, however trivial it may be, should be permitted in the shops. It would be absurd to assume that no member of the regular office or works staff is capable of introducing original improvements or novelties, and it is perhaps scarcely necessary for every single item of experimental design to be made up in the development shop or even under the surveillance of one of the development staff. But it may be stated definitely and emphatically that if the department is to be efficient in its functions it must know the whole truth with regard to the design and performance of all the products for which it is responsible. Draughtsmen and foremen are exposed to a natural temptation to experiment for themselves with models in the shops and test-rooms. This procedure re-introduces non-standard work into the factory curriculum; at the best it constitutes double-banking; it is a most expensive practice when everything is taken into account; and an efficient and economical outlet for such energy is now provided. Such people should be instructed to communicate their proposals in full to the development department, and any attempt at "private enterprise" should be strictly repressed.

The duty of being responsible for all data connected with design and performance thus devolves on the department. Careful records of constants, standards, specifications and dimensions employed in current design; modifications; test results; complaints received; patents taken out and pending; and suggestions, are compiled and indexed. An index of information bearing on subjects connected or allied with those under investigation must be created, preferably on the card system.

These records can only be rendered complete and therefore dependable if every unusual occurrence that bears in any way upon design is reported to the department. They also render the development staff fully capable of acting in a consultative capacity to the factory in general, and of dealing with a wide variety of technical queries. Calculations involving higher mathematics, such as the force between adjacent conductors due to a possible short-circuit, or the strength of spring required to generate a required velocity in the contacts of an oil switch, will be submitted to them. Simple formulæ or diagrams, whereby such values may be obtained by the factory staff, will, where possible, be worked out. Questions involving theory, such as the resultant current in portions of a network, the safe current density in a liquid, or the treatment of an accumulator battery, will also be addressed to the department. Test-apparatus for given requirements will be specified, designed or even constructed for the routine test-rooms. Inquiries, even of the "workshop recipe" type, may be made and answered by means of an appropriate file or index.

When a complaint is received from a customer the development department will act as an adjudicator for the firm, examining the apparatus in question and the conditions under which it failed, bestowing the blame in the right quarter and proposing a remedy.

The examination of materials comes, in reality, within the scope of routine testing; but as such work is of small extent, and requires expensive and delicate apparatus that is also necessary for development work, an exception may be made in this respect, and such routine work may be done in this department. The same arguments apply to the calibration of instruments; and those for the whole factory may, without introducing inefficiency into the development system, be adjusted and even repaired in the department's laboratory. Apart from these exceptions, routine work is out of place in a development laboratory, and its introduction is most undesirable.

From the above functions it will be seen that a very considerable burden is removed from the works and drawing office, and the result must be smoother and easier working, economy of labour and certainty of result.

VI. The Value of Suggestions.

It has already been stated that the development department is the correct place for receiving, examining and reporting on suggestions from outside its own walls, and efficient arrangements should be made for doing so. The benefit derived from this source is, however, much less than is generally imagined.

There is a popular theory that an epoch-making discovery in any branch of science may be made by anyone with a smattering of knowledge therein. A similar delusion is that workpeople and humble employees of big firms contribute largely towards the "new ideas" which help the firm to make a profit. If it were more fully realized that such discoveries can be made only by people who are earnestly searching for them, and who also know from long experience how and where to look, not only would considerable misconception be prevented but much disappointment to would-be inventors, and much loss to the investing public, would also be saved.

Some years ago the author was engaged as a consultant to report on a new reversible steam turbine, a 20-h.p. model of which had been constructed and operated under steam for demonstration purposes. The inventor was a mechanic with no training or experience to equip him as a turbine designer, but nevertheless a company was formed and registered and the shares were upon the market prior to any competent advice being obtained by the directors. A cursory examination then revealed that it was not a turbine at all, but a crude, rotary piston engine, and a brief test showed its efficiency to be in the vicinity of 1 per cent. It is interesting to note that this information led to the abandonment by the directors, not of the project, but of the consulting engineers, leaving the company to go forward and the shareholders' money to be lost without expert counsel.

The above instance, which is only typical of many such failures, has been given to illustrate the extent of the popular misconception, even among business men, as to the simplicity of arriving at valuable results. Contrary

to this mistaken view, it is practically impossible for an investigator to produce a novel apparatus unless he possesses a number of valuable qualifications. First, he must be well versed theoretically; secondly, he must be intimately acquainted with the practical conditions, and especially the worst conditions, under which the apparatus is to function; thirdly, he must be informed as to the work which has already been done on the same type of apparatus, including the failures of other workers; and finally, he must have practical knowledge of the methods of manufacture appropriate to the apparatus. The weaker he is with respect to any of these qualifications, the more the success of his efforts depends upon chance, and the more wasted work he does in a given time. These points may be strengthened by a further and more simple illustration.

One of the most attractive articles to amateur designers in the realm of switchgear is the fuse, and probably more worthless suggestions are made in connection with this appliance than any other. Its action and principle appear to be easy to understand, while the shortcomings of the standard patterns seem evident and regrettable. It is therefore inevitable that a number of would-be improvements should be designed, the defects of which illustrate the need of the qualifications that have been mentioned.

In the first place, the vast majority of their producers do not realize that a fuse has to do something more than open the circuit upon the occurrence of a small overload, up to, say, twice the normal load. If this were all, almost any enclosure containing the wire would serve the purpose. The governing condition, however, is that of a short-circuit, and the problem thus becomes much more abstruse. As a matter of fact, the standard test for a fuse is to connect it across the mains with the containing case "earthed" to the positive, and then to close the switch.

Besides familiarity with the requirements, fuse design demands a knowledge of the properties of the electric arc, as its success depends upon its power of quenching an arc stream before any appreciable damage has been done to the contacts or porcelain. A knowledge of the materials that may be involved, together with the method of working them, is also desirable, in order that sound and economical construction may be specified. Finally, all the work expended on design will be wasted if the resultant fuse is one which has been tried and discarded a number of years previously.

The fact that emerges from these examples is that the person whose suggestions are likely to prove of value is the one who is actively engaged in producing or otherwise dealing with the article in question. For example, the staff of the department itself, including assistants, model makers and juniors, become potential discoverers in their own spheres, especially if an atmosphere of research can be made to permeate the whole establishment and collective thinking is encouraged.

It is also natural that valuable proposals should emanate from the designing and drawing offices, the staff of which includes men with the necessary qualifications for at any rate the less advanced forms of invention. Here again, useful results may be few unless a certain favourable atmosphere can be created and maintained.

Such proposals from the shops as are acceptable are usually for improvements in methods of working, and for safeguarding the operators themselves from injury. The author is in favour of stimulating the workpeople by the standing offer of a monetary reward when such suggestions are used.

Outside the factory, suggestions are offered chiefly by customers and patentees. The former, as users or potential users of the firm's products, are in a radically different position from the producers with regard to the apparatus, and any comment from them affords data for design. A patentee's proposal is usually accompanied by a specification, which requires to be digested and reported upon to the management, who then take up the negotiations.

Even when a suggestion is sound it is not always possible to employ it at once, as the modification of the standard design will not always be justified for the sake of a single improvement. Such suggestions are therefore carefully filed for use in the immediate future.

VII. Staff.

The preceding section will have indicated how many people are *not* in a position to contribute original ideas, and will have emphasized the value of a development staff who are able to collaborate upon their special functions, unimpeded by commercial matters or the regular routine work of the factory.

A first great advantage derived from the segregation of the men engaged upon development is that their qualifications are largely pooled, and individual members can do original work although each does not possess all the stated qualifications. For example, an enterprising and well-educated but inexperienced junior might still bring forward valuable suggestions when helped and guided by his older and more experienced colleagues. It is necessary, however, that the senior men, and especially the head of the department, should be "all-round" men. The head himself should have as wide and general an experience as possible in the use of the articles to be developed, as it is upon him that the responsibility rests for the practical utility of the department's products. Again, the senior men, and especially the head, should have had considerable shop experience in the construction of such products.

It must not be imagined that anyone who fulfils the conditions given in Section VI above will succeed in a development department. These were intended to be the bare essentials for the making of useful suggestions, and must be reinforced by others if difficult problems are to be solved and elaborate designs arrived at.

In the first place a research man must have an analytical mind, or in other words a faculty of isolating the various components of a problem, of separating the vital from the secondary, and of distinguishing and correlating cause and effect. He must be an adept at eliminating interfering elements from his considerations, arguments and tests. In particular, he must be able to refer as many problems as possible to first principles, in order that the simplest, clearest and surest thinking may result. By virtue of this faculty, an involved and therefore a great difficulty may be broken up into a number of separate problems, the solution of which can

then be carried out in turn. Without it, the would-be research worker cannot hope to penetrate far beneath the surface without becoming confused.

Although it is probably going too far to assert that the above qualifications can be conferred by any course of study upon an individual who is not specially gifted by nature, it is a fact that they can be awakened and enormously stimulated by appropriate training. In the case of one who hopes to attain a leading position in technical research and to exercise the functions that have been described, the following preparation is indicated :—

A. General training.

(1) Training in the art of clear and logical thinking, afforded by the study of mathematics.

(2) Training in the tactics of research, afforded by a study of physics and chemistry and, if possible, of geology.

(3) Training in the art of lucid expression, afforded by the study of languages.

(4) Training for the hand and eye, afforded by the study and practice of mechanical drawing.

(5) Training in the practical application of theory, afforded by works experience as nearly concurrent with the theoretical training as possible.

*B. Special training.**

(1) Advanced study of the principal pure science concerned in the industry (electricity and magnetism).

(2) Study of the applied sciences bearing on the subject (at least applied mechanics, mechanics of machinery, theory of structures, strength of materials, and heat engines).

(3) Study of the professional subject concerned (electrical engineering).

(4) Study and practice in design (electrical design).

It will be seen that a full professional degree course has been arrived at, the pure science subjects of which the author considers to be especially valuable for the purpose in hand. Not only does a study of the work done by the great scientific investigators of the past help the student to acquire some of their ingenuity, their perseverance, their thoroughness and their courage, but the attendant laboratory practice affords the much needed ability of drawing correct inferences from experimental work.

The necessary works experience after graduation should be obtained preferably as a regular employee, and not as a privileged "hanger-on." In addition, the inspection of works concerned with collateral industries is especially valuable as an antidote to a "water-tight compartment" tendency that frequently cramps development.

A few words may be said with regard to the type of men required for various kinds of research work. For some branches, such as magnetic survey work, stolid, even-natured men are needed who can work for 14 hours a day at monotonous occupations, without complaint or desire for relaxation. But most members of a technical research staff must rather be capable of concentrating a great amount of energy upon a problem and need not have the same virtue of constancy of effort. For invention and the solution of difficulties, moreover, the qualities of imagination and enthusiasm are at a premium, and these are characteristics of the excitable, rather than the stolid, type of man. A third type, intermediate between the foregoing, includes mathematical investigators.

A characteristic of a research staff, as distinct from the components of a works organization, is that they are not only engaged entirely on brain work, but the tasks of many of them, notably of those belonging to the second type, are practically all inherently high-pressure ones, almost unmixed with work of a regular description. To avoid as far as possible the risk of mental or nervous overstrain, a few special points are worthy of note. First, a development department exists to relieve the rest of the factory of worry, and every care should therefore be taken that ordinary worries, such as "chasing" materials and plant, are spared them. Secondly, "rush jobs" should be given to them as sparingly as possible, for, although an investigator can generally rise to an occasion, the process of obtaining inspirations to order may be a very exhausting one, especially if he is already fatigued or is concentrating at the time on some other problem. Thirdly, his data should be accurate, and should, if possible, be first-hand, for these are apt to get sadly emaciated if they come to him verbally through an intermediary. Finally, due appreciation should be accorded to the work when it is done. One of the greatest incentives to an investigator is the feeling that he is about to effect a permanent improvement in the performance, manufacture or cost of some product. If, after he has solved some problem that has been set him, he sees the results of his efforts pigeon-holed or otherwise neglected, this incentive is apt to weaken considerably.

With regard to juniors, there are two types who do not require the educational qualifications that have been specified. The first of these belongs to a class of man who is not ambitious of rising to the top, and is content to go on performing the same duties almost indefinitely. It cannot be denied that such men are useful, as they can be put in charge of some specific branch of testing or other work and can be relied upon to continue doing this without further trouble after their original instruction. The author's preference, however, is to feel that every subordinate is endeavouring to improve himself, even if it means occasional temporary inconvenience through staff changes. This policy would appear to accord better with the nature of the whole department. The other type is the improver, who spends a period in the laboratory to complete his experience prior to going out to represent his firm in the capacity of branch engineer or salesman. He will already have had a secondary education, and should have followed this up by at least an evening course at a technical school. These men also have their uses as assistants in the test rooms, or in other respects, if they are conscientious ; but if they regard themselves as passengers who do not need to "make good," they are worse than useless and should be rejected when these signs develop.

The model-makers should be careful mechanics of the tool-room variety, selected for accuracy and keenness

* The subjects given in brackets are those appropriate for electrical engineering development.

rather than for rapidity. Rather more than the usual intelligence is necessary, as they will be required to work from continually changing drawings, many of which will not be fully detailed.

VIII. Buildings and Equipment.

There is no need to devote much space to the question of buildings, as this part of the subject has been very fully treated in a paper by Mr. A. P. M. Fleming.* The building with which the author is most familiar is, as a matter of fact, somewhat on the lines of Fig. 9 in that paper, but with a somewhat greater floor area. In order, however, to include the cases of small firms who may not be in a position to erect separate premises at the outset, but who nevertheless have much to gain from technical research, a few additional remarks are given especially to cover their requirements.

The most serious mistake that can be made when a research department is being instituted, and when its site and equipment are under consideration, is to adopt as a guiding principle that the proposed new section will not produce output, and that it must therefore take second place to any part of the factory that does. It is most advisable that the tendency to make this assumption be carefully borne in mind, especially when the site and equipment are being decided, and when there is a possibility of the new department being seriously handicapped from the start by unsuitable selection in these respects.

It must be made clear from the outset that the development staff are going to exercise a great beneficial effect upon production, and that anything which impedes their work is going to impede output. Furthermore, they are about to improve the quality of the work done in the factory, and anything that interferes with the excellence of their work will similarly effect the products of the shops. An inferior lathe in the main machine shop will handicap the work of one operator; but one such machine in the development shop will risk the spoiling of the design of every article made on the basis of every model for which the lathe is used.

The principal requirement as to site is absence of noise, especially spasmodic noise such as is caused by the tipping of castings. If this were to happen within close earshot of a man engaged in concentrated thought upon some intricate problem, the consequence would be not only to break the thread of his thoughts completely, but to administer a shock to his nervous system which, upon reiteration, would produce serious consequences.

A further point bearing upon the question of comfort, when use is to be made of an existing room, is the necessity for adequate heating. It frequently occurs that one of the staff will spend long periods in complete bodily inaction, and his office then needs the highest standard amount of heating. In the event of a store or workroom being converted, this should be taken into account, as a lower degree of heating is appropriate for both of these.

The author desires to endorse the stress laid by Mr. Fleming upon the avoidance of vibration for the testing and experimental section. Many pieces of apparatus such as reverse cut-outs, fuses and relays, give quite different results according to whether they are shaken or not. For example, a lead fuse passes through a pasty stage as the current through it is increased, and vibration will bring about mechanical rupture, causing the circuit to open at a much lower current than would be the case if the wire were still. The effect on delicate instruments has been dealt with by Mr. Fleming, but his recommendation of ferro-concrete for a laboratory building is not strongly supported by the present author, on account of the considerable transmission of sound through this material. For this reason, brick construction is to be preferred.

With regard to equipment, the operations involved in development will indicate what is required. These may be classed in chronological order as study and design, model making, and testing.

For the first are required offices with drawing equipment, reading and writing rooms for juniors, and a library provided with an index of literature and information.

The model-making shop does not call for much special comment. Its lay-out resembles that of a tool room, with a lengthwise strip devoted to machine tools. Vibration and noise are minimized, and cleanliness and convenience increased, by adopting individual electric drive for the machines. Provision should be made for wood-working, as it will be necessary to represent in hardwood the porcelain parts of trial designs for the models.

Most of the care and forethought will be expended on the testing laboratories, and these will vary according to the nature of the industry. A description of some apparatus designed by the author for use in switchgear development is given in Appendix 1, together with the machine tools required for this purpose.

IX. Procedure in Development.

Speaking quite generally, the method to be employed for evolving a new product for manufacture in the shops comprises study, consideration, sketching or otherwise indicating the resultant design, making the model according to this or to fuller drawings that may be advisable, and testing the model; followed by modification of the design and re-testing as required, until the desired result is obtained.

No invariable course as to the exact procedure to be followed in the development of every model can, however, be prescribed, as this will vary not only according to the nature of the development, but also according to the personal equation of the investigator. For example, one might be tempted to prescribe study or search for information of a particular kind before engaging in any practical work. Yet it may happen that the preliminary carrying out of a test upon an existing or a simply constructed model may render subsequent study easier and more profitable, owing to the ability thus conferred of visualizing the apparatus and its behaviour, and also owing to the experience so gained in the practical working of the principle involved.

One very important rule may, however, be laid down for general observation. This is a corollary to the

* "Planning a Works Research Organization," *Journal I.E.E.*, 1919, vol. 57, p. 153.

principle, already enunciated, of analysing a problem into its constituent parts and attacking these separately; and enjoins a policy of breaking up a course of development into a series of steps, each representing a difficulty to be overcome, and of performing them seriatim. It is a great mistake to expect a model to demonstrate too much at any one stage, and, except for the simplest pieces of work, the surest and, in the end, the quickest progress is made by constructing a series of models, each achieving some definite result and overcoming some difficulty of design. In some cases entirely distinct models may be required for each stage, and these may be preserved as a record of the procedure at its completion. In other cases the same model may be modified after each test or trial. In others it may be preferable to use two actual models, which are modified alternately, in order that each alteration may be evaluated by a direct comparison of the apparatus before and after this has been effected.

At first sight the above may sound over-elaborate and may appear to threaten undue consumption of time and expense, but this is far from being the case, as may be exemplified by considering the initial step of the series. The first experimental information required concerning a proposal is whether it is practicable or even workable, and the first model should, in general, be made up to demonstrate this. An examination by the various parties concerned may then reveal some fundamental failing that renders further steps unnecessary, and the whole matter can be dropped before any great amount of time and expense has been devoted to it.

For these reasons, no time should be lost and no unnecessary trouble should be taken in getting out this model, which need be neither durable nor attractive in appearance. To secure ease of construction, brass may be used instead of steel or cast iron, and wood instead of porcelain or other insulation, while soldered joints may be employed to obviate screwing, riveting or cottering. Such a model is easily modified as regards details, such as the exact size, shape or position of the parts. It is also just as good as a more elaborate one for demonstrating the worth of the original proposal, and for serving as a basis for the confident production of a more definite and finished design. These points can best be made more definite by the description of typical examples.

One of the simplest examples of development work is the electrical operation of some process or apparatus that has hitherto been actuated by some other means. In such a case the first model would, in general, consist of the original plant, to which the electrical element has been added. After this model has shown that the project is worth proceeding with, the problem would be carefully reconsidered from two opposite points of view. In the first place the reason for the various features of the original design would be analysed, in order to ascertain how these will require or admit of modification when electric operation is applied. In the second place, the advantages that can be conferred by the latter must be checked off, in order that the new design may be such as to utilize these to the full; while its disadvantages must also be realized, to ensure that they are provided against in the new design. Then, and not until then, should work proceed on the next model.

As an instance of such a type of development, the conversion to electrical operation of a belt-driven machine tool, such as a radial drill, may be described. For the first model, the machine tool, motor, and rheostat would each be obtained separately. The motor would be located where it could be easily fixed, e.g. on the floor, while the starter might be screwed on to the wall, or the column of the machine, or mounted on a pillar fixed to the floor. In this form, preliminary tests, such as those upon the power requirements, costs of running, speed control, upkeep of the motor, etc., could be made.

It would next be realized that the machine itself had not yet derived any advantages from the use of electricity, being fitted with a number of complications due to the exigencies of belt-driving upon a pulley at a fixed position and running at a constant speed in one direction. On the other hand, an extra complication had been added, in the shape of a starter placed in an inconvenient situation, i.e. away from the other operating levers, and also requiring more careful treatment than they do. In addition, the installation of such a group is by no means simple, in that locations have had to be found for three separate appliances.

In the next model, therefore, the three components will be combined into a single unified apparatus, which can be set up anywhere within reach of the electric supply and requires only about four fixing bolts and no inter-wiring to accomplish its installation. First, the motor will be mounted on the machine so as to be in a position to drive the actual drill spindle as directly as possible, thus dispensing with all, or nearly all, the usual belts, connecting shafts, mitre wheels and other gearing. Secondly, the control apparatus will be mounted in an appropriate position upon the machine, and endowed with the requisite automatic features to enable it to start and reverse the motor without requiring more careful treatment for the control handle than is accorded to the other handles of the machine. The handle will be so situated as to be convenient to the hand of the operator, i.e. among the other operating levers, if necessary. Thirdly, as much of the change-speed gearing will be dispensed with as possible, by utilizing rheostatic or other electrical speed control, due regard being had to the necessity or otherwise of using the same design of machine interchangeably for alternating and direct currents. Lastly, the complete design will be scanned with a view to simplifying and unifying the combined machine as far as possible, especially with regard to its mechanical details. For example, it may be found possible to utilize the motor as a counterweight to the radial arm and drill-head.

An illustration of a radial driller that has undergone this course of development is given in Appendix 2 (see Fig. 16).

It will be seen that this process is analogous to the life history of practically any fully developed apparatus, such as the electric tramcar or the steam locomotive. The first electric trams were simply horse cars with motors and controllers attached to them; and the early locomotive models were merely stationary engines on

wheels that were geared or otherwise connected to the driving shaft. These old patterns were the first rough models that afforded data for the more perfect types that followed them.

The production of an entirely new design differs from the above only in that the starting point is not provided and has to be decided upon before any positive progress can be made. This first step is the most difficult to describe, since the personality and the originality of the designer play a large part at this stage of the proceedings. Sometimes it is possible to evolve a design entirely original in every respect, while sometimes an idea may be obtained from some existing apparatus, belonging perhaps to a totally different branch of engineering. At other times it is helpful to know how other designers have solved the same problem. The author's opinion is that the latter assistance should not be invoked except as a last resource, for the imagination is at its best when it has a blank page to draw upon. As has already been intimated, however, this part of the problem cannot be done according to rule but must be left to the genius of the individual worker.

In this connection a distinction should be drawn between the study of another worker's solution to a specific problem in hand, and the study of works, apparatus and designs, as a part of an investigator's general training. The latter is in every way excellent in inculcating resourcefulness and a knowledge of designing methods, while the former is a not very "sporting" short cut that may actually prevent an original solution from being reached.

As an example of complete development *ab initio*, suppose that a firm which has hitherto not made contactor gear decides to do so. A member of the department who has had the most suitable previous experience is put in charge of the work and settles down to the problem of producing as original a design as possible for the most fundamental species of contactor. When he has arrived at one that he considers to be worth making up, simple working drawings are quickly got out from his rough sketches and to his instructions; and these are passed on to the model-making shop where, under his supervision, they are put into concrete shape with as little delay as possible.

The model, which at this stage probably bears only a moderate resemblance to the final design, as it must be made up as far as possible without requiring castings or stampings, is now passed into the test room of the department, where its performance is investigated as fully as is practicable. It is given a rough preliminary test to make certain that it functions as desired and that it is good mechanically. Its exact performance is then recorded in the form of curves connecting coil ampere-turns and pull-in distance, ampere-turns and spring pressure, etc. Defects made evident during this examination are reported and corrected either by modifying the original model or by the construction of new ones. The capabilities as represented by the test curves are studied and compared with existing standards, with performances of existing apparatus, and with the duty required. When the model passes muster according to these criteria, it is handed over to the works drawing office.

Here full working drawings for the final model are got out, in conformance with the data thus supplied, the design being now especially adapted to the manufacturing practice in vogue in the particular shops to which the department is attached. The intention is that the finished product shall be made in the factory from these drawings, but, before this, one model is made from them in the development workshop to check the correctness of the design. This model is given a final test, a set of coils is got out for it to suit the various voltages at which it is to work, and these are, if necessary, given heating and working tests.

The same process is then carried out with regard to the master controller, relays and interlocks that go to make up contactor installations. Finally, a complete set is assembled and connected to a suitably loaded motor, representing the most exacting duty that the apparatus will have to fulfil, and this installation is given an endurance test under working conditions. Again, any defects that manifest themselves are made good, and the tests are repeated until complete satisfaction is given, in which case the development of this particular model is complete and the shops and drawing office are notified that manufacture may go forward.

This procedure is representative of the most usual work of such a department, namely the complete development of a product, and it also sufficiently illustrates the development of a new part in an existing apparatus, or the mere improvement of the latter. In a certain proportion of cases, however, the design for a new article is evolved in the drawing office, and thus full working drawings are supplied to the development staff. The latter portion of the process just described, consisting of making up the model, testing it, amending the design, and re-testing, is then gone through, unless the last two steps are found to be unnecessary. The drawings are then returned to the drawing office, together with the model and a report detailing the tests and modifications that have been made, as well as comments and suggestions.

X. Recording and Filing of Results.

In order that conclusions that have been reached or information that has been evolved as the result of research work may be preserved and distributed to those interested in the particular subjects dealt with, an organized system of recording results is essential. It should be so arranged that the whole of the results are kept on record, in such a form that reference may be quickly and conveniently made to them by all who require to do so, without the possibility of ambiguity or misunderstanding as to any detail.

The most valuable information is usually that derived from a test, as it involves the expenditure of the greatest amount of time, trouble and expense in its acquisition. A large proportion of tests are made upon a sample or model supplied or lent for the purpose, and these cannot be duplicated without considerable trouble and delay. Many others involve the destruction or consumption of costly apparatus or material. It is thus natural that special care should be taken in the preservation of test data. A scheme will therefore be described whereby this species of informa-

tion is adequately cared for from the receipt of the inquiry to the completion of the final report upon the investigation.

There is a temptation evident in test rooms to enter figures and details relating to investigations upon loose sheets of paper, the after career of which is, to say the least, precarious. A better method is to record the data in note-books which are carefully retained, but even these form in the course of time effective hiding places for the information entered therein. Some special scheme is therefore desirable.

The system employed by the author makes use of a small number of loose-leaf binders, in which blank sheets are clipped in readiness for an investigation. When one of the latter is begun, a binder is allotted to it, in which are inserted concise instructions, together with any correspondence or other data bearing upon the matter. Full notes, test figures and other relevant details are then entered upon the blank pages, as they are arrived at. This entails that every detail of the apparatus, conditions and circumstances that may be of importance in, say, 10 or 50 years' time, must be included. No reliance must be placed on the memory of any participant, but every fact must be recorded on the assumption that it will be forgotten as soon as the piece of work is completed.

After a final result has been reached, and also, if desirable, at intermediate stages, an official report is compiled from these notes. Such reports serve the double purpose of placing the proceedings upon permanent record, and of acquainting any number of interested persons with what has been done. It should therefore be dictated to a stenographer, who can type any desired number of copies. The original notes are then removed from the binder and clipped into a folder, which is clearly labelled with the serial number of the report and a title briefly describing the nature of the investigation. This can now be filed away in a suitable cupboard. One or more copies of the reports will also be filed in the office of their compiler.

At first sight it may be thought that the notes and the reports contain the same matter, and that therefore it is not necessary to file both versions. This is not the case, however, as for several reasons the reports will not form an entirely sufficient record. First, the reports, being intended for frequent use by a number of busy men, must be made concise and readable. If they were only to be kept by those concerned in the investigation for reference purposes, they might then contain full details of all proceedings, such as the complete particulars as to tests made, and a full set of the readings taken during such tests. But since many of those who read them are interested chiefly in the results and require these to be in as lucid and graphic a form as possible, only the significant portions are included. This will nevertheless be sufficient in the great majority of inquiries. Secondly, a proportion of the proceedings are not worth placing officially on record. It is usually the case, for example, with all but the simplest tests, that one or more trial experiments are made before useful results are obtained. These serve to indicate definitely the precautions that have to be taken, and any refinements that have to be effected in the proposed method and apparatus. Results of a kind are obtained and these should certainly be kept, but they are not worth circulating. Thirdly, there is always the possibility that some part of the result may seem unimportant when a report is compiled, and hence may be omitted, but it may subsequently become significant, or a recorded result may be challenged and may require verification from the original notes.

Since the original notes must therefore be preserved, a test report should contain only a brief description as to the method employed, and a comparatively full description of the results, omitting, however, tables or figures whenever these can be satisfactorily replaced by curves. The conclusions drawn from the test should be given in detail, together with comments and recommendations. The matter should be preceded by an introduction giving the reason for the investigation and referring to any circumstance which has led up to it, and by a sufficiently detailed description of the apparatus, component or material experimented upon. It is an advantage to add to the front of the report a page upon which is a very short summary of the introduction and conclusion. This only may be supplied to those who are less intimately concerned with the matter, for their complete file, in order that they may be acquainted with the bare results and may be able to ask for the whole report if they desire it. It also serves to inform a searcher as to the contents of the report, and will thus frequently save useless perusal of the report itself.

While these reports should be concise, they should not be so abbreviated as to form a one-sided record. There is so much more temptation to dilate upon those results which are "according to plan," that the importance of others indicating failure or disappointment is often overlooked. It should be remembered that there are two limits to every phenomenon, the upper and the lower, and it is just as necessary to know the one as the other. It is therefore necessary to place on record both what cannot be done as well as what can be done, and a failure may, in consequence, be of even greater importance than a success.

XI. Indexes of Literature and Information.

An important requisite for a research department is a means to enable an inquirer to ascertain quickly what information is available upon any desired subject in current literature, and where such information is to be found. This is achieved by the aid of one of the many types of index. The author proposes to describe two of these, both of which were especially designed for aiding electrical research work. They differ in the amount of labour required in their formation, and in the amount of assistance they afford to the inquirer. The first is most appropriate for a comparatively small staff, and the second for a larger one.

The simpler scheme was designed six years ago by the author for his own department, and has since continued in use without alteration. In this case the aim has been to indicate the nature, extent and whereabouts of all information relative to switchgear, contained in the books and periodicals actually accessible in the building. All but 5 per cent of the work entailed

can be performed by a junior, or even an intelligent office boy. Each entry consists of a single line on a specially designed index card. No attempt is made, beyond about six words by way of title, to reproduce any portion of the text, but the aid of tabulation has been invoked to record compactly the value as well as the location of the abstract.

TABLE 1.

....	..	...	....	..	..	....

An example of the cards employed is given in Table 1. There are seven columns on each, of which the widest is for the title of the article, or, if this is not sufficient for identification, the matter is indicated in five or six words, the dimensions of the cards being 5 in. by 3 in. The first three columns enable the precise volume or number to be selected and the page to be found, while the date and the last three columns indicate the probable usefulness of the extract. It will be observed that the latter need not have been previously read.

With regard to classification, a list of subjects to be indexed was first got out, and a guide-card set apart for each. Distinguishing symbols of one, two or occasionally three, letters were allotted to these, and an alphabetical arrangement of the symbols determined the order of the subjects in the index. For example, "B" denotes switchboards generally, "BD" distribution boards, "BT" truck-type switchboards, "F" fuses generally, "FC" cartridge fuses, "R" research, "RH" rheostats, "RL" relays, and so on.

Extracts from one publication only are entered on any one card, a rule convenient not only for reference, but also for the work of compilation. The latter is best done from the complete volume. A junior goes carefully through the volume index, observing the references to the subjects on the prepared list. He finds all these places and marks them with strips of paper. The completed volume is then handed to a senior member of the staff, who glances rapidly through it, and removes the markers from these extracts that are not worth indexing. This done, the work of entering is carried out by the junior.

A more elaborate system, in which a short summary of each extract is filed on the actual cards, has been designed by the staff of the General Electric Company's research laboratories at Wembley. A separate card is employed for each entry, and two kinds of guide-card are used, "third-cut" for the main subjects and "sixth-cut" for the subdivisions.

A specimen of these cards, the dimensions of which are 6 in. by 4 in., is shown in Table 2. The manner in which the headings in the left-hand top corner are set out will first be noted. These are in several lines, of which the first is the heading on a main guide-card, and the second that on a "sixth-cut" guide. The remaining lines are intended to amplify the indication already given as to the contents.

Further amplification is afforded by the précis occupying the lower half of the card, which may contain up to 80 words. It may be compiled from the actual article or other extract while this is being read, but in the majority of cases there will not be time to do this,

TABLE 2.

>
> Bodies high in clay show low thermal expansion, and variations in flint for such bodies show no decided effect. As the clay content is lowered and the amount of quartz increases, its quantitative effect becomes more marked. Replace quartz by inert material lowers the expansivity. Calcined kaolin may be effective as sillimanite or other synthetic silicates. 399

and the help of published extracts, such as *Science Abstracts,* is then invoked. These will, in general, be too long for the present purpose, and not more than the 80 words are then underlined by the indexer and are copied onto the card by a typist. The practice at Wembley is to put each subject in the hands of a member

of the staff, who is responsible for keeping the index up to date in this particular respect.

The other entries on the card give the author or authors in the top right-hand corner, the references to the volume of abstracts from which the précis is compiled, and the reference to the original publication containing the extract.

Besides the subject index as described above, a duplicate set of cards is also filed according to the authors, as a search for information is frequently most easily carried out by referring to a list of publications by certain writers who are specialists in the subject of interest.

In addition to current literature, information from any other source may be filed in this manner. Test-results, patents, verbal criticisms or interviews, contents of letters, and other matter may be inscribed directly upon the cards, if the length be not too great. Otherwise the file in which it is given at length is indicated.

Card indexes are also invaluable for keeping a record of work done, by the allocation of a card to each problem and the noting of each step thereon. Ideas may also be jotted down on index cards as they occur, and filed for future use. Test-results may be tabulated on a small set of cards. The progress of patents taken out by the department, business addresses, serial numbers of reports, and lists of patterns, drawings and diagrams, are other examples of the many uses of a card index in a research department.

XII. Industrial Research Organizations.

Industrial research is carried on by a few private individuals, by firms of consultants, by universities and colleges, by manufacturing firms and by research associations. In view of the interesting and substantial improvement that has taken place in the research situation during recent years, a very brief reference will now be made to these various spheres of activity.

Owing to the change in industrial conditions referred to in the introduction, the private worker is at a greater disadvantage to-day than formerly, unless he is possessed of independent means or confines himself chiefly to philosophic research. Not only are the difficulties attending tests and experiment much greater than in the early days, but the advances in the various applied sciences are more rapid and it is not easy to maintain touch with these unless the worker is attached to a firm or other association. When a private experimentalist has developed a useful design, the further difficulty occurs of selling the results of his work or otherwise securing its adoption in practice, since firms which maintain their own research departments naturally expect them to produce as many of their new models as possible. Individual members of the staffs of electric power companies or departments, and similar organizations, frequently develop new apparatus, the patent rights of which firms are glad to purchase. These workers are in an especially favourable position in this respect. Other private inventors will probably find their cases provided for to an increasing extent by the associations established under the ægis of the Government, concerning which more detailed reference will be made below.

It is strongly maintained by some authorities that universities and colleges should not engage in any but purely philosophic research, since the prosecution of the latter is most essential and academic institutions are the proper places for this. If they are tempted to take up industrial research, university investigators will be attracted from their legitimate field by the greater emoluments that are expected to be available for utilitarian work, to the grave detriment of pure research. It is also considered that a teaching institution may not be sufficiently in touch with practical conditions to do such work effectively.

While the above opinion should not be entirely disregarded, there is no doubt that a certain amount of industrial research can and should be performed at such institutions. There are many reasons for this, of which the most direct is derived from the valuable industrial investigations that have already been carried out at many of our colleges and universities. It should be the aim of every one of these to foster a spirit of research in its students, and this is most effectively done, in an applied science department, by instituting researches in applied science. Perhaps the strongest reason of all is the great need for a closer degree of contact between the universities and the industries, for the advantage of all concerned. This is attained by anything that brings them together in the mutual endeavour to solve some pressing problem.*

The author has come into personal contact with the work now being carried out at Sheffield University in the furtherance of these various aims. Special members of the staff have here been appointed to direct research, and do not have to undertake any routine teaching. The authorities are also willing to provide the necessary facilities and staff for the performance of any industrial research that may be desirable. The work of the Fuel Technology and Mining Departments upon the safety of electrical ironclad apparatus from internal explosions may here be mentioned with appreciation. In another research undertaken in conjunction with the electrical industry it was found possible to secure to an important extent the assistance of the city electricity department. Such a comprehensive degree of co-operation cannot but excite the greatest satisfaction among those interested in electrical engineering development.

A similar type of co-operation, between the Physics Department of Canterbury University College, N.Z., and the Testing Department of the Lake Coleridge Hydro-electric System, was responsible for the solution of a most troublesome difficulty in connection with 66 000-volt transmission line insulators.†

Prior to the war, organized research was carried out by comparatively few firms in this country, although the beneficial result of their enterprise has long since been evident. The pre-eminent position of the British cutlery trade would scarcely have been possible, for example, without the research work of Hadfield and others. More recently, the vital need of developing quickly our own products in many branches of industry has led to the wide establishment of such departments, further instances of which need not be quoted.

* See Karapetoff: "Suggestions for Electrical Research in Engineering Colleges," *Journal of the American Institute of Electrical Engineers*, 1916, vol. 35 (2), p. 895.

† See C. C. Farr and H. E. R. Philpott: "Test and Investigations on Extra High Tension Insulators," *Journal of the American Institute of Electrical Engineers*, 1922, vol. 41, p. 711.

Many, if not most, items of industrial research are such as to benefit every firm engaged in a given class of manufacture, and would be most economically carried out by co-operative associations serving the needs of whole industries. The provision of these through the good offices of the Committee of the Privy Council for Scientific and Industrial Research constitutes one of the most welcome items of industrial history that has been enacted within recent years. Formed shortly after the outbreak of hostilities, the Committee issued their first annual report in the middle of 1916. In April 1918 they took over from the Royal Society the maintenance of the National Physical Laboratory, and with it the responsibility for much of the research work in connection with the war, a staff then numbering over 500 being engaged on such research. In addition, they drew up a scheme whereby research associations were to be formed in the various industries, and they stimulated the establishment of these. The result has been the existence at the present day of a large number of these organizations, actively engaged in work which has already borne abundant fruit.

By the middle of 1918 some 30 industries were in process of forming research associations, of which three, including the British Scientific Instrument Research Association, had already been licensed by the Board of Trade. The British Electrical and Allied Industries Research Association began operations shortly after this date, under the direction of Mr. E. B. Wedmore.* In addition, specific researches, e.g. those in fuel, mine rescue, tin and tungsten, timber, building materials, and industrial fatigue, were instituted and placed in the hands of special research boards.

Besides acting as an organizing body, the Council has been the medium for the subsidizing of research by the Government. The cost of the various researches is partly borne by the industry and partly met by these subsidies. For example, the investigation concerning the production of tin and tungsten in Cornwall was first conducted with the aid of a grant from the Institution of Mining and Metallurgy. The Research Department also assisted with a grant, but when it was evident that work on a larger scale was justified and desirable, they made it a condition for the continuance of financial assistance that the locality should take a more active part in the work. In a short space of time, subscriptions to the extent of over £2 500 were guaranteed by the principal mine owners and landlords in Cornwall for a period of three years, whereupon a similar amount was granted from the Government funds.

The general policy of the Department, which has remained unchanged since it was formulated in the middle of 1917, is the appointment of a responsible Director to organize each group of researches, assisted by an advisory board of distinguished men of science. The important fact has been recognized that "research work, like other forms of creative activity, will not flourish under committee rule."

The above brief notes may serve as an introduction to the subject for those who have not hitherto come into contact with these developments. Full particulars as to each year's progress may be obtained from the annual reports, published about the end of August by H.M. Stationery Office. These records of a movement that promises to be epoch-making in its scope and its results, are well worth perusal.

* See "Institution Notes," *Journal I.E.E.*, 1921, vol. 59, pp. (14) and (23), and 1922, vol. 60, pp. (3), (14), (22) and (27).

XIII. Co-ordination.

Pioneer work of any kind is exacting in its requirements as regards both talent and finance, and it is therefore important that the fullest practicable co-operation should be maintained among those engaged in such work. The organization for effecting this will, however, be very different from that appropriate to routine occupations, for which the various participants have merely to be directed along well-tried routes. For research, there are available no pilots familiar with the course, and hence sailing orders of the most general description are alone possible.

A scheme was proposed about four years ago in a paper* read before this Institution, whereby every research worker, whether in a public, university, or works laboratory, would work to the instructions of a controlling staff appointed by the Government. This staff would be partly centralized, and would consist partly of travelling inspectors whose principal functions, to put the matter quite bluntly, would be to decide for every research worker in Great Britain exactly what he should investigate, invent or discover, and to see that he did it.

This scheme, in the opinion of the present author, is merely the ordinary organizing system as employed in the Army or public services, with the research workers inserted in the lower grades. It would certainly introduce an atmosphere that would stifle research, while any benefits which it might be able to offer would be forwarded by such ponderous machinery and by such devious routes that their arrival could not fail to be tardy.

Between terrestrial and scientific exploration there is a close parallel that will assist in indicating the nature of the co-ordination required. The workers in the former may be grouped under the three headings of explorers, pioneers and prospectors, closely corresponding to the three-fold division of research workers. The very word "research" is merely "search," with a frequentative or intensive prefix to denote thoroughness.

One notable example of terrestrial search, that for gold, has from the earliest times been carried out with all the energy and resources, scientific, executive and commercial, of which mankind has been capable. Yet no comprehensive organization has ever been found possible among the gold-seekers, whose methods have been characterized by individual freedom and enterprise, and whose driving force has simply been the quest itself.

No difficulty is experienced in deducing the co-ordination needed in this case. It is that the results of all other searches should be easily available to every worker, especially those in his own vicinity. Thus the great requirement is a co-ordination of results, and this holds good whatever the object of the search may be. In the case of electrical research this need is being largely

* See H. R. Constantine: "Co-ordination of Research in Works and Laboratories," *Journal I.E.E.*, 1919, Supp. to vol. 57, p. 134.

supplied by the work and publications of this Institution, by sister societies at home and abroad, and by the technical Press. *Science Abstracts* forms one of the most efficient agencies in bringing about co-ordination among electrical research workers, while the abridged specifications issued by the Patent Office, and other publications of a like nature, assist still further. During the war the Government wisely provided a similar means of co-ordination for general use on the lines of *Science Abstracts*, by beginning the publication of the *Technical Review*. The valuable work done by the Electrical Research Association in compiling exhaustive précis of available information on various branches of electrical engineering has assisted co-operation in research in the most effective way possible.

Any useful advance in co-ordination can be effected only by a development along the above lines. For example, a central inquiry bureau might be instituted, or a complete and comprehensive card-index might be worth publishing, either of which might render available any possible information. This information should include as far as possible a record of what has not been done, whether as a result of failure or of omission; and means might be found to stimulate efforts to remedy such deficiencies. Indeed, the latter is no new attitude on the part of the Department of Research as far as well-known firms and even well-known individuals are concerned, but it is not yet accomplished generally. In the same manner, advantageous co-operation between individuals, firms, industries and countries, already brought about to a certain extent by the present organization, will be capable of yielding enhanced results as the outcome of further thought and experience. The establishment of "cross-connections" between various industries is a function fraught with big possibilities.

In particular, co-operation in research between different parts of the Empire will be especially prolific in results. The colonies have in the past accomplished notable successes in the development of industry, and are capable of further achievements in the future. In some branches of industrial research, by far the most favourable fields for work are in the Dominions; for example, the application of electricity to agriculture and non-ferrous metallurgy; the development of electrochemical and other industries requiring very large quantities of cheap electric power; hydro-electric generation; and e.h.t. transmission. A greater interchange of research workers between the Motherland and the Dominions would yield most valuable results from all points of view.

XIV. Conclusion.

An endeavour has been made in the paper to assist the carrying out of the more technical variety of industrial research work usually known as "development," for the benefit of the electrical engineering industry. The line of demarcation between the functions of the various kinds of research workers is not always sharply defined, and it is not desirable that it should be so. Consequently, much of the treatment has been made general, to cover a somewhat wider scope than that included in development pure and simple. It is the author's confident hope that the increasing use of research, especially when carried out in association with the manufacturing staff, will continually increase the successful application and the prosperity of our industry, and will raise it to a dominating position among the achievements of other nations.

The author would like to express his indebtedness to his assistant, Mr. F. R. Combes, B.E., for his valuable help in preparing the illustrations for publication.

APPENDIX 1.

Equipment for Switchgear Development.

A short outline of some items of equipment utilized by the author in the development of switch and control gear is appended. These are grouped under the headings of testing outfit and model-making appliances.

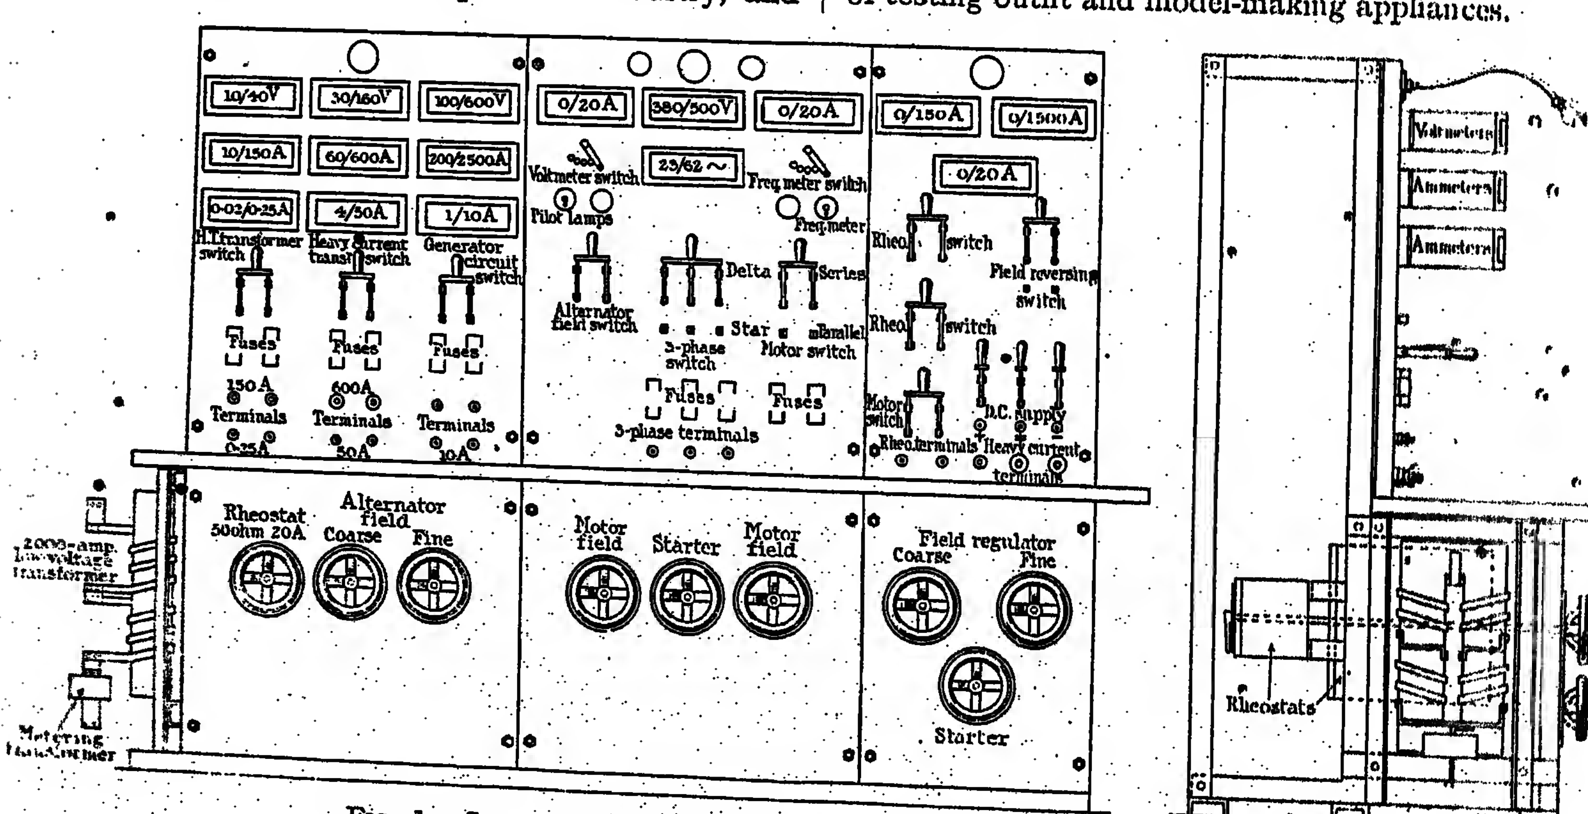

FIG. 1.—Combined test-board and bench for electrical development.

The first requirement for testing is a supply of power for operating the various pieces of apparatus undergoing test. This is effected by two motor-generator sets for direct current and alternating current respectively, controlled by the switchboard shown in Fig. 1. There are only the two machines in the d.c. set, the generator giving a maximum of 10 volts and 1 000 amperes, but the a.c. set has two motors which may be connected in series or parallel, in order to render available a wide range of periodicities from the alternator. The latter has both ends of its three-phase winding brought out, and these may be connected in star or delta. The a.c. set gives a normal maximum of 11 amperes at 500 volts, but the current may be stepped up to 2 000 amperes (single-phase) by a heavy current transformer, and the potential may also be raised to 50 000 or 100 000 volts for insulation testing by a potential transformer in a special enclosure (not illustrated). Ordinary d.c. loads are obtained direct from the supply mains.

In the board illustrated, the correct positions for apparatus under test and for test appliances have been

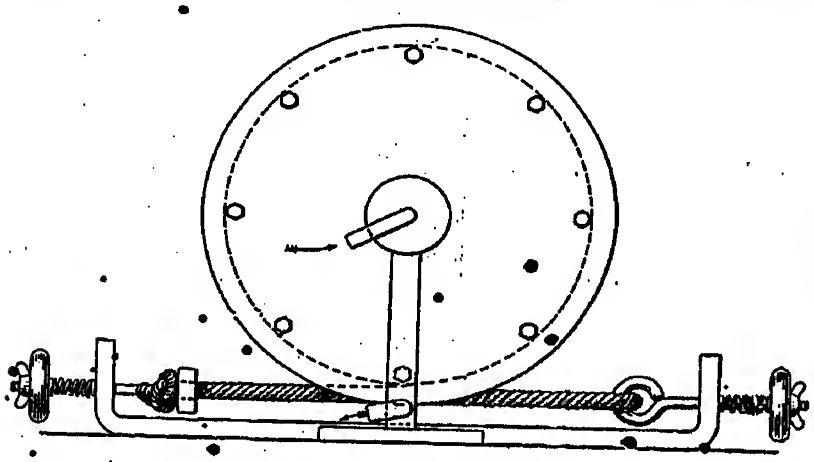

FIG. 2.—Rope brake gear for testing motor, with improved "dry" water-cooling arrangement.

secured by combining the bench with the switchgear. As will be specially evident from the end view, the former divides the upper panels supporting the meters, switches, fuses and terminals, from the lower panels, on which are the controlling hand-wheels, this portion being stepped forward of the rest in such a way that the rheostats are accommodated almost entirely under the bench itself. By these provisions everything is arranged in its most convenient position, and the crossing of the floor by cables from the board to a separate bench is obviated, and with it the feature of the more usual testing equipment that is the most conducive to untidiness and disaster.

Each ammeter is connected in circuit with its appropriate terminals, and thus one only is in use at a time. Double potentiometer rheostats are used for both generators, giving fine gradation over the complete voltage-range from zero to maximum. The heavy current transformer is at the left-hand end of the bench, where the thick low-voltage conductors can be kept short. In addition to the three switches and terminals connected directly to the d.c. mains, there are two double-pole switches and special terminals connecting the mains in series with one or both of the two largest rheostats already on the board. The pilot lamps are intended to illuminate both the bench and the board.

When a piece of control gear is to be tested, a suitably loaded motor is necessary. As far as possible, the author develops gear of this description for a 5 h.p. motor, and two of these, alternating and direct current respectively, are permanently set up, with a water-cooled pulley and rope brake in position, suitable for forward and reverse rotation and rapid adjustment of load. Rolling-mill control is represented by a 40 h.p. d.c. series motor, and by an induction motor of about the same capacity, the brake gear for both of which is shown

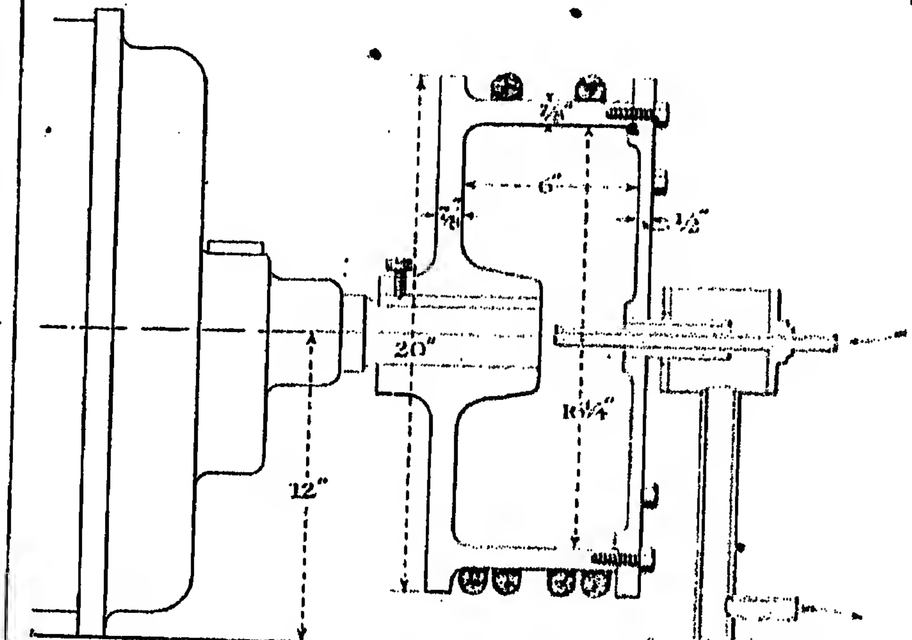

FIG. 3.—Section of pulley and water-circulation arrangement shown in Fig. 2.

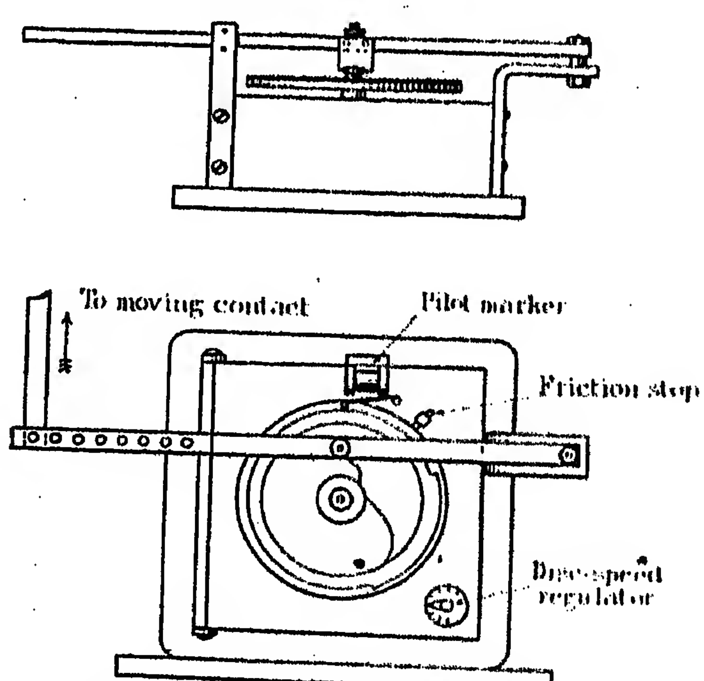

FIG. 4.—Simplified disc apparatus for measuring speed of oil switches.

in Figs. 2 and 3. It was extremely important that there should be no leakage or splashing whatever in connection with the water-cooling, and this was fully accomplished by the arrangement shown, which was specially developed for this purpose.

As will be seen from Fig. 3, the pulley is entirely enclosed, with the exception of a spout of about 1 in. in diameter. A smaller tube passing through this introduces the cold water, and the hot water overflows through the spout, from the ends of which it is thrown into the cowl. Thus it is all collected without any

possibility of splashing or leakage. About 2 quarts per minute are sufficient to dissipate 40 h.p. without quite reaching boiling point.

The smaller pulleys for the 5-h.p. motors are partly open on the outer side, the water being inserted at intervals by means of a filler and allowed to boil away. This simpler method is not safe for the larger pulleys, owing to the higher centrifugal pressures which occur in the water and cause suspended ebullition.

One of the most frequent measurements that have to be made is that of the speed of break of oil and other circuit breakers, and the closing time-lag of electrically operated switches. This was at first effected by the method already described* by Dr. C. C. Garrard. Later, the more self-contained and portable apparatus shown in Fig. 4 was made up, and has given complete

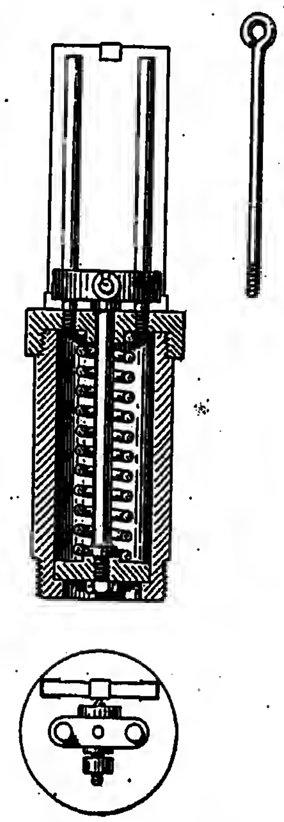

FIG. 5.—Pressure indicator for explosion tests.

success. A clockwork gramophone motor driving a 12 in. disc at a definite speed has been substituted for the drum, electric motor, and tuning-fork timing gear. A convenient part of the moving switch-contact is connected by a rigid rod to a suitable point on the moving arm of the recording apparatus, and the switch is operated when the speed of the disc has become steady. It is then an easy matter to plot the true curve of operation, similar to those given by Dr. Garrard, from the trace on the disc.

Ironclad apparatus for use in mines requires to be tested for resistance to explosion, and this is carried out by igniting in the enclosure the most explosive mixture of air and either pentane or methane, and surrounding the apparatus under test by the most easily ignited mixture of methane. A record of the crest pressure reached is simply obtained by means of the recording gauge shown in Fig. 5, which is screwed directly into the top of the casting. The piston, rod and crosshead are lightly made in aluminium, and a small graphite pencil on the crosshead marks the movement against the spring pressure. The gauge is calibrated by screwing a special eyelet on to the crosshead and directly pulling the latter by means of a spring balance until the pencil once more reaches the crest mark.

The need was felt for a simple apparatus for enabling small samples of switch oil to be flash-tested, and that shown in Fig. 6 was designed and used for the purpose. The electrodes are supported in an ebonite "cage" which can be removed from the small glass vessel for calibration. An ordinary "feeler" thickness gauge, or even a single steel plate 0·007 in. thick, is used for adjusting the separation of the spheres.

Turning to model-making equipment, the machines required for a department of small to moderate size are given in the following list. They are arranged approximately in the order of their importance, and the

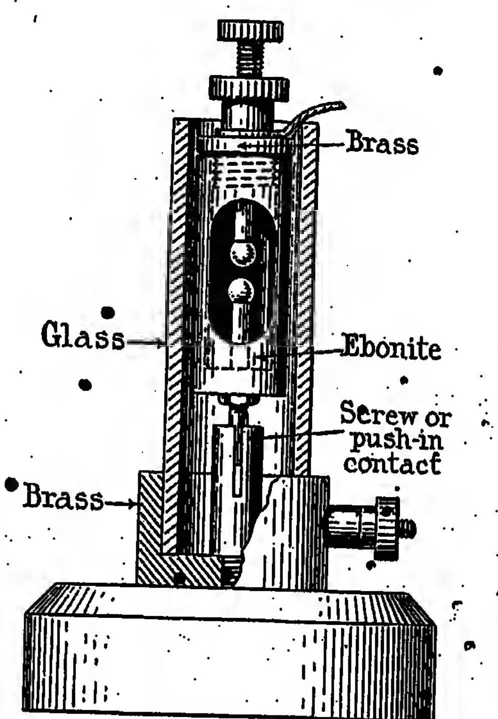

FIG. 6.—Apparatus for flash-testing small quantities of oil.

list thus indicates roughly the order in which they would be procured in the case of gradual growth from a small beginning.

Lathe, 6 in. centres, surfacing and screw-cutting.

Drilling machine, pillar type and lever feed, with ¾ in. spindle.

Grinder, to take up to 8 in. wheels.

Miller, small horizontal, with vertical attachment.

Shaper, with about 18 in. stroke.

Radial driller, with about 36 in. arm.

Small precision lathe, 4 in. centres.

Sensitive driller, high speed.

Brass workers' lathe, 6 in. centres, for rough hand work.

This whole equipment will be suitable for a staff of up to 10 or 12 model makers, in addition to the foreman, one or two labourers and two or three boys. It is supposed that the small amount of woodworking is machined on the metal-working apparatus, a course that has no marked disadvantages. It is also assumed that extra large work is sent to the main shop for planing and other machining.

* "Switchgear Standardization," *Journal I.E.E.*, 1918, vol. 56, p. 226.

APPENDIX 2.

Illustrations of Development.

As it may be of interest to make the remarks in Section IX on "Procedure in Development" as definite as possible, a few examples of the evolution of a new piece of apparatus are now described. It is typically the case, however, that a problem loses much of its interest when the solution is known. This is especially

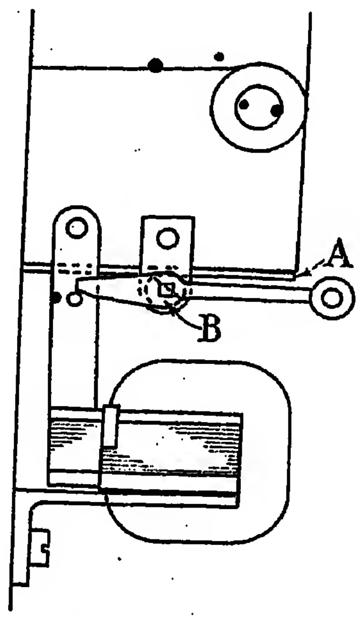

Fig. 7.—First stage of a low-voltage release.

so with the design of apparatus, for the fully developed product is almost invariably simpler than when in an intermediate stage. The great requirement is, in fact, to evolve as simple a solution as possible, and for this reason the final steps consist largely of the

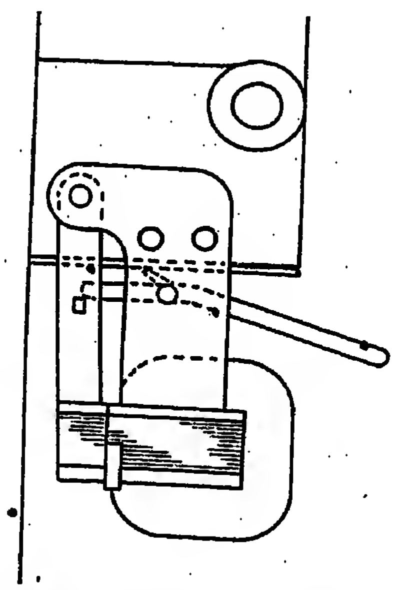

Fig. 8.—Second stage of a low-voltage release.

cancelling-out of complications. As a consequence, the result of the process is a comparatively commonplace article, exhibiting no trace of the lengthy and roundabout course by which it has reached its final state, which indeed appears to the onlooker to be the obvious answer to the original proposition. Yet it is probably true that the simplification of existing apparatus, methods and calculations, is more required at the present time than the production of new ones.

The above consideration renders it a somewhat difficult matter to choose examples of development

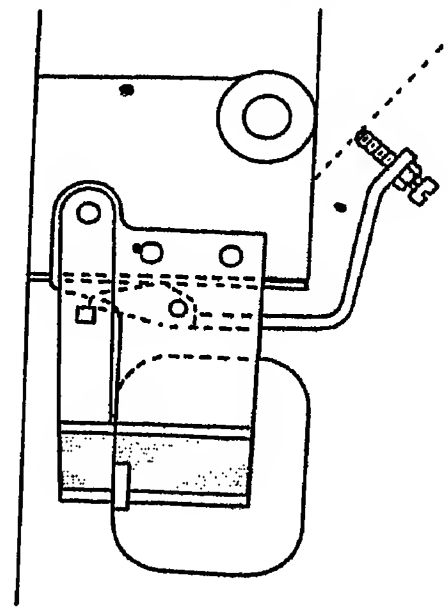

Fig. 9.—Final stage of a low-voltage release.

that are convincing without involving tedious description. The author hopes that this will excuse the apparent triviality of the three that have been chosen.

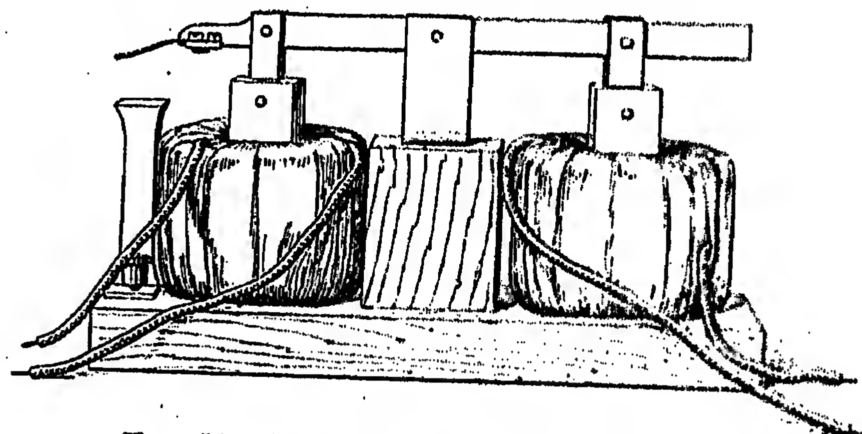

Fig. 10.—First model of a protective relay.

The first, shown in Figs. 7, 8 and 9, is a low-voltage attachment for an a.c. circuit breaker, the moving arm of which is held in by the spring plate, A. Tripping is

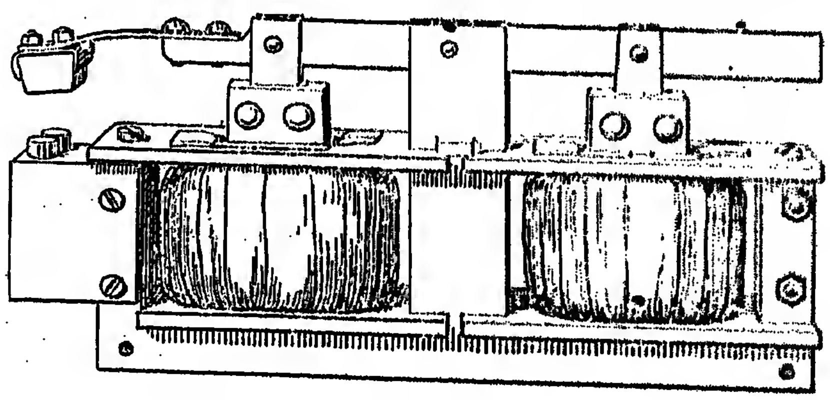

Fig. 11.—Second model of a protective relay.

effected by depressing this plate by 1 or 2 degrees, and when such a release is fitted the spring is given an original set downwards, but is kept up and in engagement by the attachment. Three different designs had been

completed, and had been unsuccessful, before the breaker was taken over, and the figures show three stages in the evolution of the fourth and successful design.

As a result of thought devoted to the problem, the idea was arrived at of forcing up the spring plate by a shaft, B, that could execute a partial rotation, but which would release the spring when a flat formed

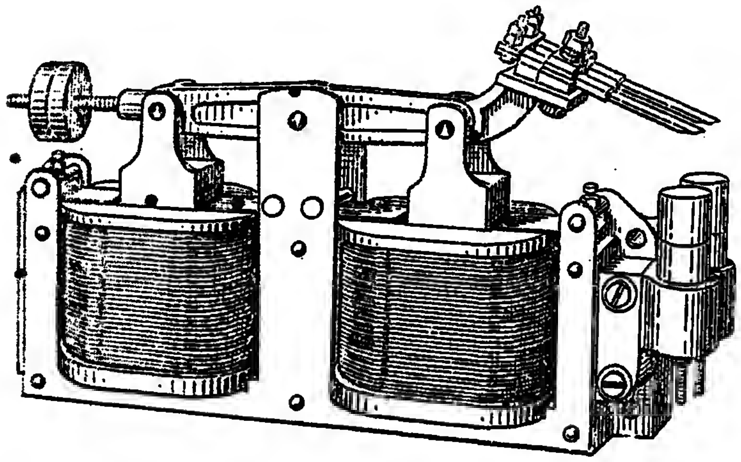

FIG. 12.—Final model of a protective relay.

in the shaft was allowed to move into parallelism. It was supported in the "on" position by two levers, the ends of which rested on a cross bar attached to the hanger of a laminated armature, which was attracted and held in place by an electromagnet.

The first model, as shown in Fig. 7, was made up with the three components independently supported, and this was modified as regards dimensions, windings, and so on, until satisfactory operation was given. In this form the release required to be set by hand after each opening of the breaker.

The principle having been shown to be a practical

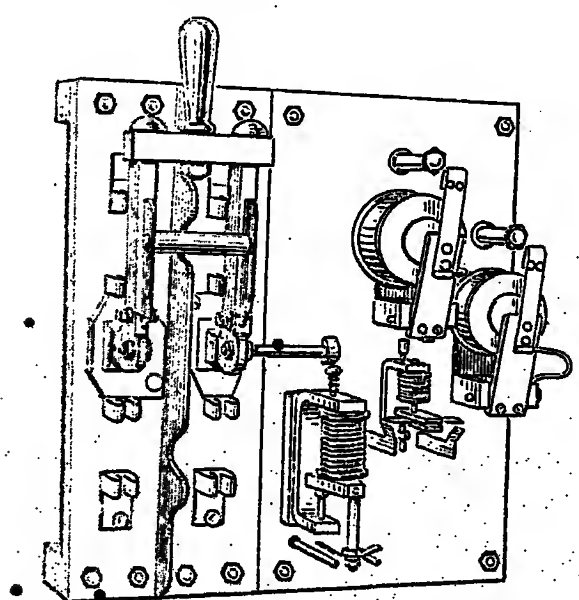

FIG. 13.—First model of an automatic reversing starter.

one, the design was unified by the contriving of a single pair of supporting plates for all three components, and improved by the use of a single lever inside the supports, instead of the two outside (Fig. 8). Finally, the release was made self-setting by bending up the "handle" so that it was now pressed into position by the open breaker arm, as in Fig. 9. The chief advantages of this general pattern over its predecessors were certainty of action and compactness, the others requiring a special swelling in the containing case to accomodate them.

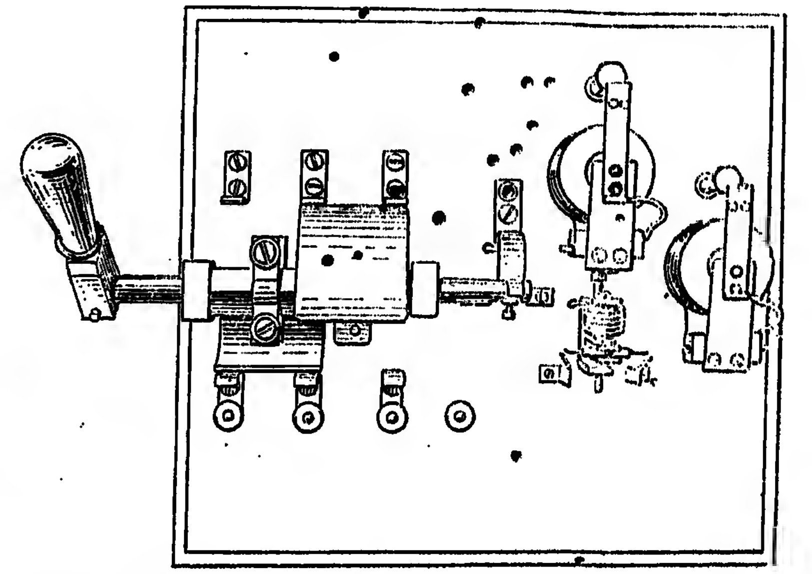

FIG. 14.—Second model of an automatic reversing starter.

The next three figures (Figs. 10, 11 and 12) illustrate the development of a beam relay for McColl balanced protection, as described in a recent paper before the

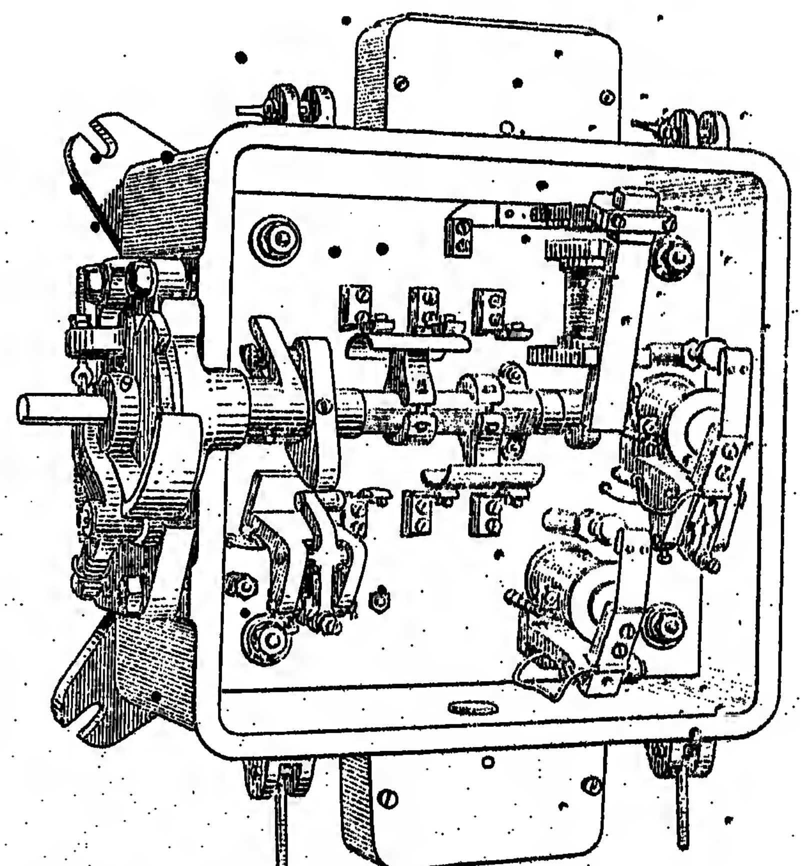

FIG. 15.—Final model of an automatic reversing starter.

Institution.* To begin with, a model was made up on a wooden framework, as shown in Fig. 10, in accordance with the details in the paper (e.g. Fig. 9, representing a parallel feeder protection scheme). After tests had

* A. E. McColl: "Automatic Protective Devices for Alternating-Current Systems," *Journal I.E.E.*, 1920, vol. 58, p. 525.

been made upon this, and the results had shown broadly the characteristics of the relay and the respects in which improvements were desirable, the model shown in Fig. 11 was constructed, having a nearly complete laminated iron circuit, and other improvements rendering it a more practical design. Exhaustive tests were now made until the relay was technically sound, whereupon the drawing office brought it to the form shown in Fig. 12, employing the necessary castings and moulded-insulation parts.

A final example, of a more elaborate collection of apparatus, is the reversing starter for machine tools, already mentioned on page 68 as having been evolved for controlling a radial driller. The analysis of the problem indicated that the connections from the line to the

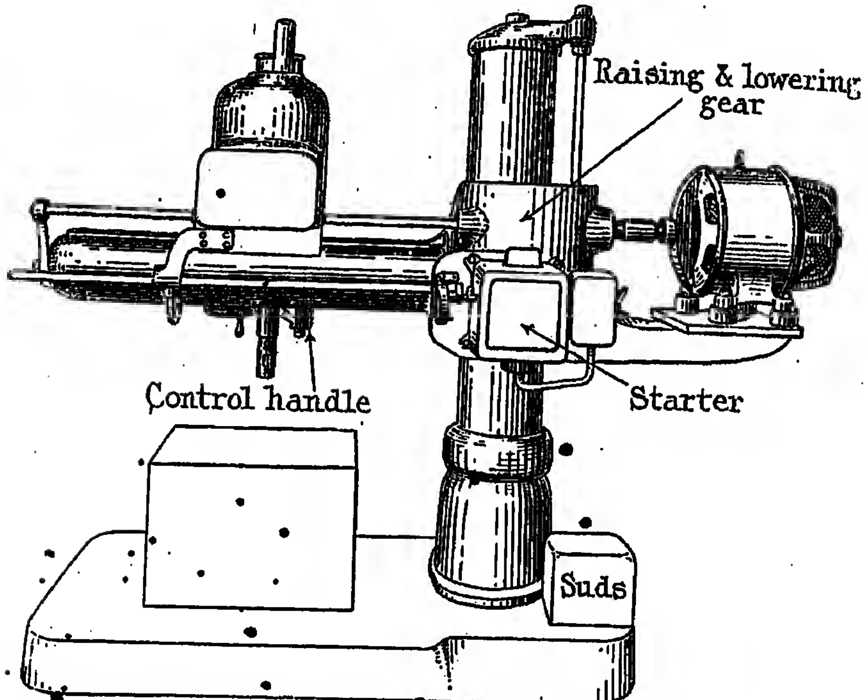

FIG. 16.—Final model of an electrically operated driller.

motor armature would be most appropriately dealt with by a direct reversing switch, and the acceleration by contactors and automatic relays interlocked with this. The first model, illustrated in Fig. 13, was accordingly made, in which a standard throw-over switch was roughly mounted in conjunction with simply constructed contactors and relays.

This was tested upon a motor, and its performance warranted the construction of a more practical model, shown in Fig. 14. The switch was now replaced by a reversing drum, especially designed for the apparatus, and the whole was brought approximately to the form and dimensions required in practice; but still the contactors and other parts were made up without the use of special castings. In this form the starter was mounted on an actual driller, and its operation was demonstrated to the machine-tool designers who had inspired the development.

This trial and inspection having been satisfactory, the final design was drawn out and manufactured, as in Fig. 15. In Fig. 16 it is shown in place on the actual driller for which it was developed.

The above are instances of a course of development continued until a saleable product has been evolved. The development does not, however, stop here; in fact, it can never be said to be complete, as tests and modifications still go on upon the latest pattern, resulting in continued improvement throughout the life of the apparatus.

The beginning of the whole process is the original idea, and a few additional words may be said as to how this is come by. The first essential is to concentrate upon the problem, until it has been thoroughly grasped in all its aspects by the imagination; and all possible assistance to the latter, such as the inspection of surrounding conditions, should be given. It is quite the usual experience for the actual solution to come after the matter has been temporarily laid aside; for example, when on the way home or during relaxation in the evening. Describing the problem to an associate is one of the best methods of stimulating the mind and inducing the desired response. Success is rendered almost impossible by mental fatigue, and this provides a further reason why the research worker should be safeguarded from unnecessary worry.

APPENDIX 3.

BIBLIOGRAPHY.

It is not proposed to add a complete bibliography upon the subject of research, since this has been excellently done by the English authors of two books that have appeared recently. These are:—

"Organization of Industrial Scientific Research," by Dr. C. E. K. Mees [McGraw-Hill], 170 pp., 7 ills., and "Research in Industry," by A. P. M. Fleming, C.B.E., M.Sc., M.I.E.E., and J. G. Pearce, B.Sc., A.M.I.E.E. [Pitman], 244 pp., 30 ills.

Both these works can be confidently recommended for their matter and their lucidity; and since they present the subject in American and English settings respectively, both text and bibliography are to a certain extent complementary.

The appended list of references (see pages 80, 81 and 82) relates to works that are likely to be already in the possession of, or accessible to, members of the Institution. They are indexed as for the first filing system, described in Section XI above.

Discussion before The Institution, 1 November, 1923.

Mr. A. P. M. Fleming: The author has brought forward a most important subject at a very opportune moment, in view of the competition from overseas that electrical manufacturers are likely to have to face, and I am sure it is more than ever important for them to bring their products up to date and set their house in order. I wish to bring forward two very important reasons for having a development department or a research department, whichever it may be called. One is the need for consistent development, in place of the very spasmodic attempts at development often made in works. The other reason is the importance of removing from the factory every trace of experimental work. This is not by any means sufficiently realized by manufacturers even of the most modern school. I think that we all sometimes forget the very hampering effect that experimental work in the factory has, and one can fully sympathize with the author's complaints as to the tendency for foremen, toolmakers, draughtsmen and others, to experiment for themselves. The tendency is not at all confined to these particular kinds of employees; it is a natural tendency for engineers and others to carry out experimental work and thereby hamper manufacture. I think that no manufacturer will nowadays oppose the need for a development department, but I am not quite sure as to the functioning of the department as the author describes it. He indicates that the functions of such a department are to produce new designs as the result of representations from the sales, design, works or other departments, to study and observe electrical practice and then to remove technical burdens from the shoulders of the staff and works. Figs. 10 to 16 in Appendix 2 illustrate more clearly much of the work he has in hand, but I think it might be a little confusing and difficult if one were to try to apply this method of development organization to all kinds of electrical manufacture. I should be glad if the author would say whether in his opinion this department should actually function, as he describes it, with regard to all kinds of general electrical manufacture, or only for certain kinds of manufacture or certain sizes of works. In the electrical manufacture with which I have been associated both in this country and abroad, the functions which he describes would have to be dealt with by at least three, or possibly four, departments. For instance, the engineers would deal with calculations and the control of drawings for the manufacturing departments; the research department proper would deal with fundamental and applied research in connection with domestic problems as they arise in the works and the recording of data as the author describes, and the provision of new data for designs to assist the engineers in cases where they require those data. The development department would then consist of a department in which new designs are actually made up by hand or in which new tools, jigs, etc., would possibly be tried out and models or completed apparatus would be produced, fully tested and suitably processed and planned. In that sense a development department functions simply as a very great assistance in the economic development and manufacture of the apparatus, but it does not quite fulfil the function which the author has in mind in regard to relieving the engineers or in superseding the engineers' and draughtsmen's work. We may, of course, be looking at the matter from two quite different angles and have in mind two different kinds of apparatus, one of which might be suitable for the development department which he describes. I can quite understand, for instance, that it may be suitable in the case of switches and control gear, but less so in connection with other electrical apparatus. I am greatly interested in the author's remarks in regard to the staff. That is the most important feature of any organization, and perhaps particularly so in the case of research or development. An organization tends to centre itself round personality; if one has a strong and suitable man, the component parts of an organization will grow round that personality as a nucleus. As far as my experience goes, I have as a rule taken university-trained men and, whether they be physicists, metallurgists or engineers, have put them into the works for experience before they proceed to do research work. I think that such a plan is very desirable in a works organization, because the men get accustomed to the atmosphere of the works and its requirements, and learn the run of the works and so gain experience in dealing with the operatives. With regard to the question of suggestions, I had some experience a few years ago in setting up a system for obtaining suggestions from work-people. It was enthusiastically received at the beginning, but it did not work very well. I hope that the author's experience was more satisfactory than my own. The methods he suggests for recording data, and for organizing what is sometimes termed the "general intelligence system," are very interesting. It is very much a matter of opinion and experience how to deal with the vexed question of keeping up to date with the vast amount of scientific and technical data that becomes available. I have gained the impression that the author rather tends to depreciate the idea of foreign designs. I am not sure whether it is not quite a good plan to have a system of interchange with designs of foreign engineering concerns; it brings in a new view and, I think, can be utilized very satisfactorily. I should like to have the author's view as to the amount of money that should be spent on this kind of development and the complete functioning which he describes. As far as I have been able to ascertain from the figures of various companies, it would appear that a sum of from 3 to 5 per cent of the turnover should be allocated to what I should call complete development and research, or at any rate covering all the functions described by the author. If manufacturing firms would definitely set aside such a sum it would maintain a very regular and consistent, and much needed, attempt at development.

Mr. E. B. Wedmore: The whole trend of the paper is to support and advocate greater attention being given to the work of the development engineer, that is, to work directed to the conversion of ideas into commercial

models and products. In writing up development it is almost inevitable that there should appear to be some disparagement of the intellect required in other branches of the industry. In an engineering business it is, however, engineering which distinguishes the business from any other and which must be given first importance. One would look with suspicion at any engineering business which had no engineer upon its directorate, and which had not development engineers amongst the most highly paid members of its organization. Theirs is the work that puts profits into the shareholder's pockets, or, looked at from a higher standpoint, the service that the manufacturing concern is doing for the community is very largely measured by the work of the development engineer whose business it is to convert ideas into useful products, and this after all is surely the business of an engineering concern. I feel that the author lays insufficient emphasis on the engineering, as distinguished from the high scientific, side of the business. The boy who will be an engineer will, from his childhood upwards, show the engineer's gift of constructive ingenuity; and surely, if one has to choose, in adding to one's staff, between a man who has this gift and a man who has only a scientific qualification, no one would hesitate which of the two to select. It is a difficult gift to develop, but its development is all-important, and I agree with Mr. Fleming that every development engineer should be given the opportunity of becoming thoroughly familiar with the works point of view. The essential business of the work is to manufacture, and no one on the engineering staff can know too much about manufacture. One should place before the development engineer the detailed cost sheet of the piece of apparatus upon which he is to work. If he does any good at his work it will show in that cost sheet a year hence. The money value is not a bad measure of the value of his work to the community. By studying the cost sheet he can find directions in which there is room for real commercial improvement of the product with which he has to deal. The most vital part of development work is the experimental side. The development engineer whose services are not properly appreciated, when he asks for money for experimental work is regarded as being even less desirable than he was before, and yet the experimental side of the business is the vital part. Far too much material is made and sold in large quantities which has never been properly tested before it is put into production, and that is because the development engineer is not encouraged or given sufficient facility for making real tests; he has to guess far too much; he has to assume far too much for want of recognition by others of the importance of the experimental side of his work. The author goes on to speak of co-operation. Co-operation, in the sense in which he uses it, appears to be a co-operation of persons of diverse gifts who work together for the development of apparatus; it is what we call "team work." There is another aspect of co-operation which has been made possible by the work of engineers, and that is co-operation between competitors, which showed marked development during the war. Some of us have been trying to keep it alive ever since, and not without some success. There is no doubt that co-operation is one of the movements of the day which we shall see carried much further. We do not know what direction industrial reconstruction will take, but we shall see better co-operation as a feature. If any one country neglects this co-operation it will be left behind by the countries who develop it. Its advantages are obvious to anyone who will take a broad view of the situation; its difficulties are sufficiently obvious in particular cases. At the same time, if we can get particular men concerned in any manufacturing industry to meet round a common table, give them something innocuous to discuss, and then gently lead the conversation, we shall find that they have certain problems in common which they are all attacking, which they are all attacking inadequately, and which, if they can only be persuaded to join forces, they will be able to attack much more adequately with better facilities and to greater advantage. That has been the experience of the Electrical Research Association. It will be readily appreciated how directly most of the work of this Association bears on commercial development, and how much more it could have done if it had been started earlier. Consider the way in which various methods of laying cables have been developed without the help of the sort of experimental test which we have now carried out. After cables have been laid for many years and very heavy expenditure has been incurred, we find that some of the methods employed are wrong and should never have been used, notwithstanding that contractors and users had used such facilities as they had, and made such tests as they were able to make with their individual facilities. The same thing happened with regard to power companies and the development of poles for overhead lines. Now we get a sufficient number of persons together and make investigations and we find that poles for overhead lines ought to have been developed in a different way. Take switchgear for another example. I speak with feeling on the matter; one has had to make and sell, on a large scale, apparatus which one could not test because individual firms had not sufficient facilities. Recently the Electrical Research Association has spent a large sum in testing under working conditions, and I know that the author of the present paper will speak appreciatively of the sort of information which the individual manufacturer has been able to get from an adequate test carried out under proper conditions on a co-operative scale. Our work on insulation is also very largely development work, and it is safe to say that the larger part of the money of the Association is spent on development engineering. I hope the discussion to-night will be in the direction of commending that work, and indirectly the work of the Association, because the Association is the servant of the industry.

Mr. W. B. Woodhouse: The division of research into this so-called section of development is of great interest. There is a general feeling, I think, that all one wants for research is a laboratory and a staff of experts. I think the author rather indicates in the paper, but does not bring it out fully, that what is really wanted for research is an incentive, and that the real incentive in all this research work is reward. He speaks of the difficulty of getting co-operation. That difficulty is, I think, very largely due to a feeling on

the part of individuals, and perhaps of manufacturers, that they may not get their fair share of the reward, in money, in reputation, or in any other form that they expect it. If research is to be developed in this way and if manufacturers come together, no doubt a strong association of manufacturers is very beneficial because they can control the home market and they can be sure that each of them will get a share of the reward. If they have a good home market I suppose they can, to a certain extent, control the foreign market by dumping, but only to a limited extent; therefore they must progress and appreciate the essential necessity of working together. I think that the author has brought out this necessity very clearly in the paper. The expectation of reward may be a commercial incentive, but it is one which is necessary if co-operation is to be obtained. There is one other aspect that appeals to me, and that is that the electrical manufacturer has a class of customer who is, so to speak, an expert user of his products. The electricity supply industry uses the products of our electrical manufacturers and criticizes those products. The user is concerned to get a simple, cheap, reliable and efficient apparatus, and—perhaps because I am on the user's side—I believe that a great many developments are due to suggestions made by users who find out the troubles. Perhaps some of us on that side feel as a class that we do not get quite a fair share of the reward. Whether there should be a preference to the home user, or how the reward should be given, I cannot say, but we should like to feel that we were getting it. Ultimately, of course, we do get it in the improved product. I believe that the work of the Electrical Research Association of which Mr. Wedmore has spoken will help very much in that direction. There are many problems which we can all wholeheartedly tackle, feeling that the general reward is sufficient. There are some special problems, such as the development of particular pieces of apparatus, in which I believe the user might very advantageously be taken into consultation. During the past year or so I have been very pleased to find that our Electrical Manufacturers' Association has consulted with bodies representing the users as to specifications and forms of requirements, all of which tends to this proper sort of co-operation. I believe also that we ought, as far as possible, to take the universities into counsel. The teachers have a great deal to do to keep up with the times. Progress is very rapid; they have perhaps their own special research work and research interests and they are in some cases a little out of touch with manufacturing requirements or practice. If we could bring them in, I believe it would not only help the teachers in their own special researches, but also be most beneficial to the present generation of students.

Mr. C. C. Paterson: The author expresses his opinions very readily and fearlessly, and I am in cordial agreement with a great deal of what he says. I think he sums up the real object of the works development laboratory when he describes it as removing from the production shop everything which is not strictly productive work. I am afraid that the problem of establishing the principle which he lays down is one in human nature rather than in system, because one so often finds that the production manager whose energies could be usefully devoted exclusively to obtaining efficient production is very reluctant to devolve what he feels to be a large sphere of his work to an independent department which will be responsible for development. I think with Mr. Fleming that the author tries to prove a little too much in the paper. When he describes the development laboratory relating to a factory manufacturing electrical apparatus such as switchgear, electrical measuring instruments, telephone apparatus and the like, it seems to me that he is on very safe ground in the organization that he proposes, although one would like a little more information as to the manner in which he correlates the work of the development department with the usual works drawing office and production section. He gives an indication in the paper, but it seems to me that liaison must be a little difficult to arrange, and when he seeks to apply his scheme of works development laboratory to all sections of the industry—and, after all, the sections of the industry which do not manufacture appliances are very numerous indeed—it seems to me that he is stretching his case too far. I do not think that there is any universal rule which can be followed in deciding what is the right system and what is the right size and scope of a development laboratory; I think that every section of the industry and every section of manufacture must be considered on its own merits as to what is the best organization to apply. Let us consider the case of the thermionic valve. It appears to be just the sort of case in which one would require a development laboratory to work out designs and so forth, but actually in that particular branch of manufacture one finds that what the author would call the pure research man has to be responsible right through production and on to the finished product—to such a very great extent does a very slight deviation, quite unexpected and quite unknown to the production man, affect the quality and performance of the final product. Then on the other hand we have the kind of organization that the author describes, i.e. the second class, in which it may practically be said that, having worked out a model satisfactorily, the development department can release themselves from further responsibility. But there are many branches of the industry where works processes rather than models have to be investigated, and those may require a great deal of thorough-going research. There are other branches of work, such as chemical, metallurgical and mathematical investigations, at which the author hints. He suggests that these are functions of the development laboratory. I do not say they are not, but I think that the type of man who is suitable for the kind of work described in the paper is not usually the type of man who is best at that sort of investigation, and I do thoroughly disagree with the author as to the sequence of events in which he describes the genesis and application of any idea. We have heard a great deal about "pure" research. I should like to suggest what is the difference between research and development: Research is a search for knowledge and principles and laws, whereas development is the application of that knowledge. Now this search does not acquire any very special quality of purity, because the motive actuating

the worker is mere curiosity as distinguished from the motive of the worker who hopes that ultimately the knowledge he finds may prove to be of some benefit to the community. In our experience at Wembley some of the most ordinary works problems yield material for the most "pure" research. Industry will, I think, produce only very ordinary and mediocre results if it restricts itself to reliance upon the universities for the supply of its original ideas. For instance, we should never have had the gas-filled lamp or the dull-emitting valve—to take only one branch of industry—if we had relied entirely upon universities for our new knowledge. I feel that the pursuit of knowledge as an end in itself will have to form a very integral part of our industrial system. I should like to repeat that while I join issue with the author in such generalizations as this, I do congratulate him on having urged the importance of segregating this sort of organization and research work from the production work itself. If he would only discriminate a little more clearly between research and development, I feel that the paper would even gain in value. Every industrial research laboratory does a certain amount of development, and every development laboratory does a certain amount of research; we should not like to segregate all research in one department and all development in another, because the research worker with his knowledge and enthusiasm must father the application of his work if success is to be assured, and obtain from it the inspiration and ideas for further work. An organization of industrial research workers which spends all its time in development work and does not use part of its energies in seeking for knowledge of the principles and the real scientific basis of the industry with which it deals, is merely living on its capital. It will soon become sterile and unproductive. It is by a judicious mixture of the two that a healthy industrial research organization is maintained.

Mr. E. T. Williams: It is well known that during the late war many new problems had to be faced, and though they were thoroughly discussed by scientific men it was usual to resort to experiment and development in order to produce practical and reliable apparatus. As a result of this, research, experimental and development work assumed a new importance in the annals of this country, and though its extent has necessarily been reduced to meet the financial stringency of the times, it is now established that such work is essential to progress and efficiency. Scientific advancement generally makes this phase of progress of even greater importance than in pre-war days. In the laboratory connected with the Electrical Engineering Department of the Admiralty, research, experiment and development are treated as separate sections of one organization, and the plan works very successfully. It can be stated that the great value of such work is due to the fact that it enables the designer or inventor to see in a practical form what he has in mind, and present-day laboratories in which organized development and organized research are carried out constitute a scientific method of making advances, as against the more haphazard methods of other days. The paper refers to the question of individuality and co-operation. All who have been associated with this class of work realize how very important is the question of staff. The very individuality of the British people is at once a benefit and a disadvantage in this kind of work, which must necessarily in many cases be team work. What the head of such an organization should endeavour to do is to reap the benefits of this trait of individuality but secure at the same time the benefits of team work. This is largely a personal equation, and my experience has shown that if one will only take the trouble it is possible to obtain men who will work together without losing their individuality. To effect this it is essential to see that every man gets due credit for his work. If a man feels he is getting the credit of his work, whether it is team work or not, he has a new inspiration to go on, very often against great odds. In arranging the staff the aim should be to secure a balance, i.e. all the members should not be highly scientific, or alternatively, all practical men, but there should be reasonable proportion between the scientific men and the practical men and those who have organizing and administrative ability. It is, I think, important to keep work of this kind away from routine work, otherwise one is bound to suffer and this is usually the development side. On the other hand many valuable suggestions can be made by those employed on routine work. In this connection there is, in the Naval Service, an organized system of considering any suggestion which any workman may desire to make, however seemingly unimportant such a suggestion may be. Each suggestion is carefully considered on its merits and in many cases awards are made. This system has inspired workmen to take a greater interest in their work and develop improvements. In any experimental or development work it is a great advantage for some man, other than a designer, to be engaged upon it, as this brings a separate mind to bear on the same problem and enables valuable suggestions to be made. One of the most important functions of such work should be the reduction in the number of parts and ease of manufacture of any piece of apparatus. In conclusion, I consider that discussion between the designer, manufacturer and user should be encouraged in every possible way.

Mr. S. W. Melsom: The author states that the standard method of testing fuses is to connect them straight across the circuit, and then to close the switch. This may be quite a suitable test for the particular fuses which the author has in mind, but it can hardly be called a "standard" test. Very much more information is generally required, and in particular it is essential to know the current which may pass when the circuit is closed. The specification of the B.E.S.A. actually requires that the resistance of the circuit shall be so adjusted that the current may rise only to certain values. There are few matters which present so much difficulty as the definition of a reasonable test for a fuse. The type of organization laid down and the direction from which suggestions for improvement may come are apparently suitable to one particular case but are scarcely capable of general application. The exact type of organization depends so much on the individual worker, and suggestions for improvement should be entertained from whatever quarter they come. In practice it is found that the research worker is frequently

able to make suggestions for improvements, and in a number of cases it has been found beneficial to transfer the design section or parts of it to the research department—a very sound arrangement if the calibre of the research men is sufficiently high. The author is perhaps not altogether fair to scientific workers in his suggestions as to their qualifications and limitations. One feels that the general air of "nerves" and aloofness with which the scientific worker is held to be enveloped is frequently due simply to affectation often fostered by those with whom he has to deal. It is, of course, agreed that research work cannot be turned out on the lines of mass production, and also that some men possessing ability of the highest order are at the same time blessed with a somewhat peculiar temperament. For a works laboratory, however, if the work of the individual is to be fully effective, he must, as far as is possible, absorb the spirit of the works and, like everyone else in the organization, recognize that times of stress have to be met. A great deal might be said as to the author's suggested qualifications of research workers. Like others, he insists that a university degree is a *sine qua non*. What is actually required in a research laboratory is good men with a *flair* for research. The number of men really capable of doing good research work is very limited, and it is a curious fact that some of the most successful, aye really brilliant men, in works research laboratories to-day are without the paper qualifications without which the author appears to think they are incapable of doing such work. The author has omitted one section of staff which I should have thought to be indispensable—I refer to the skilled mechanic. One at times finds a mechanic who is almost if not quite a genius in the origination and development of new ideas. Such men are rare and require encouragement, but it is probable that they could form one of the most valuable sections of the staff of a development laboratory.

Mr. F. Creedy: The previous discussion appears to me to show clearly that if we are to avoid confusion we urgently require a definition of what is meant by "research" and what is meant by "research workers." I was surprised to hear Mr. Fleming tell us how he prefers to train research workers by a certain combination of theoretical and shop training. Surely if "research workers" are produced by such a training, then this is only a grandiloquent name for a superior type of test-room assistant. That it is possible by any course of training whatever to produce genuine research workers out of average human material and then set them to work at a bench to discover regularly for 8 hours a day, seems to me a grotesque conception and I do not suppose for a moment that Mr. Fleming believes it can be done. Hence I must suppose that by research he simply means such ordinary testing as it is not convenient to make in the commercial test-rooms. If so, I think this ought to be made plain. The author's is the first sound paper on the subject to be read before the Institution, because, unlike other writers, he realizes that research is not a business and cannot be reduced to routine and that novel and useful ideas cannot be produced to order. Not that the power of producing potentially novel and useful ideas is rare. It is, on the contrary, fairly common, as is evidenced by the fact that some 30 000 patents are applied for every year, two-thirds at least of which represent technically sound inventions. We all know brilliant inventors who are, three or four times every year, close on the track of some new invention, frequently quite sound. What is rare is the power of persevering in the development of a single idea, ignoring side issues and overcoming all the difficulties which stand in its way, until it becomes a practical success. I think that it would conduce to a great deal more clarity if we divided research into three grades. The first, which it would be better to call "precision testing," is apparently what Mr. Fleming has in mind, and simply consists in making tests to a higher degree of accuracy or of a more refined character than is possible in the production departments. It is confusing to call those who conduct such tests "research workers," useful and important though their work is. On the other hand, their work may be inspired and directed by a true research worker, who certainly cannot be trained in any such manner as Mr. Fleming suggests. A second grade of research appears to be what the author has in mind, namely, the production, modification and development of existing types of apparatus as described in the latter part of the paper, in order to enable them to fulfil a modified function or their original function in a more satisfactory way, and the actual working out of these modifications so as to ensure that the design shall give no trouble in operation. This may be called "development of known principles." The third grade would be the production of radically novel types of apparatus which shall solve some industrial problem in a new way. Examples of this type are: (*a*) The development of the phase advancer; (*b*) the development of means of varying the speed of induction motors by cascade commutator machines as associated with the names of (for instance) Scherbius, Kramer and others; (*c*) the development of the cascade motor and other variable-speed a.c. types; (*d*) the development of a.c. commutator machines for variable and constant speeds; (*e*) the development of the motor converter; and many other instances that will readily come to mind. This may be called "development of new principles." If these distinctions between different grades of research are borne in mind, I think it will be found that the apparently conflicting remarks of different speakers, both on the present and on previous papers, can be harmonized by bearing in mind that they are made in respect of different grades of research. I should now like to draw attention to a rather different aspect of the subject, which may perhaps throw some light on what has already been said in the discussion. The author assumes that there is in existence a development department continuously engaged in working out new apparatus. Two questions arise with respect to this: (1) Who decides what new apparatus has to be worked out? And (2) having developed the apparatus to a state of technical perfection, can we be quite certain that it will not prove a commercial disappointment? From the author's point of view both these questions are irrelevant, but the fact is that someone must decide these two matters if a development department is to yield the advantage which it should yield. In this

respect the position of a firm of consultants is rather different from that of the head of a development department who regards such matters as being outside his province, since such a firm must be able to offer their clients advice on the commercial aspect as well. I should like to ask the author how the first of these questions is dealt with in the organization with which he is familiar. One of the functions of his development department is to cure troubles arising during manufacture, on routine tests, or after installation, and so far his work is provided automatically by the production departments; but it is usually found that the decision as to what development shall be done must be referred to the business heads of the firm. Now I have not found that business men are unfavourable to research; on the contrary, I have found them most eager to benefit by it whenever possible. The real cause of their reluctance to spend large sums, and the reason why the development engineer is regarded in some organizations as undesirable, is not that the business heads are unwilling but that they are puzzled as to whether the development will really pay. It is almost impossible to say whether it will pay, but the man who is best able to give a valuable opinion on the subject is the development engineer himself, and if he shelves questions of that sort, in my opinion he shelves the biggest part of the problem and performs only half the function which he should perform if he is to deserve the confidence of those who have to find the money. I have for some years held the opinion that a development department should work in close touch with the commercial side. The development engineer should first of all be a close student of applications; he should be constantly viewing the operation of all sorts of plants, studying their defects and considering how these may be remedied. On the other hand, one must not be deceived by statements which users sometimes make without a due sense of responsibility. One often finds that a user states that some improved apparatus would be of such enormous benefit to him that he would give almost anything to get it, but when it is offered at a price ever so little above the stand rd price he will have nothing to do with it. Now comes the second question, which the author is wrong to neglect. Supposing a new development has taken place and is technically a perfect success, will it be a disappointment to the commercial man or not? Here we must distinguish between the different grades of research. Many people may suppose that all that is now necessary is to send to the selling agency a leaflet describing the new apparatus, and all will be well. This will often be true as regards the development in what I have called the "second" grade of research, but where a development is of rather involved character, in what I have called the third grade of research, our difficulties are only just beginning. We have it on no less authority than that of Mr. Henry Ford, that there is never any demand for a new thing, and the ordinary salesman, unless he has been specially instructed, cannot sell such apparatus. He does not possess the technical knowledge to enable him to explain its new features to the customer in a convincing manner. How is the development engineer to bring home to the user the pains he has taken to overcome the preliminary difficulties? This is a problem which cannot be shirked, and he is the only one who can solve it. Let us look at matters from the customer's standpoint. Here is a new apparatus which, it is alleged, produces some novel and marvellous result; it is not true that the user has any prejudice against it; in fact he is anxious to benefit by any advances in knowledge, though as a rule he does not expect it to cost him anything. The development engineer must be prepared to go in the minutest detail into the user's individual requirements, to understand his business sufficiently to appreciate what those requirements really are and to make it clear to him that he really does benefit. Pamphlets and other advertising literature go only a very small way in this direction; nothing but a personal discussion can carry the matter through; and this is a very heavy burden upon the development engineer during the first few years of the new apparatus. At the same time it is of the very greatest possible benefit to him. In my own experience I have frequently found that a really thorough discussion with users of the way in which the proposed new apparatus can be applied to their work, has entirely changed my ideas and shown the necessity for developments in design which, previous to taking into account the user's point of view, had not been at all apparent. The development engineer who cuts himself off from this source of inspiration makes, in my opinion, a very great mistake. After the first few years a good class of sales representative will relieve him. In certain other cases the business heads, in starting a new development, have not realized the sales difficulties and are consequently rather appalled when they are faced with the fact that while the standard apparatus sells over the counter, so to speak, because the user knows quite as much about its uses and capabilities as the manufacturer does, novel apparatus requires a long and patient explanation.

Mr. P. M. Baker (*communicated*): Present-day conditions in the industrial world call our attention in a very urgent manner to our own position in the world's markets. It must be remembered that we were the pioneers in the huge manufacturing development of last century, and that fact, together with our national resources in raw materials and the native ability of our people, gave us a pre-eminence which had been severely challenged by other nations; notably Germany and America, before 1914. The war has simply served to accentuate the struggle, and we have now to realize that not only must we so produce the goods which we export that they will sell in foreign countries in competition with the products of the other manufacturing nations, but that our very life depends upon our success in so doing. With our diminishing stores of raw materials there remain only two directions in which we can cheapen production for export, viz. (1) by improving the efficiency of our production processes and appliances, and (2) by increasing the skill of the personnel of our shops, so training the workman that he will acquire a higher and more useful type of skill and greater effective speed than ever before. The author, in discussing industrial research, is directing our attention to one of the main divisions of the former of these matters of which the national importance cannot be over-

estimated, and is thus rendering the Institution and industry at large a service. Turning to the paper, while agreeing with the author that the head of a research department should have had university training (otherwise why give anyone such training?), I think we must realize the importance of the "works experience" component of his qualifications. It is not impossible for the holder of a university degree to be a fool in some directions, but, if our university training means anything at all, the chances are that he will have acquired greater ability to think clearly and broadly than those of his colleagues who have only had the training of the shops. I am in favour of the second man in the organization being selected mainly for his outstanding knowledge of shop processes, as I think the combination of a Head having first-class "college" training and some shop experience, with a second who is intensely practical but has some theoretical knowledge, is an easier solution than that of finding the "superman" described in the schedule of qualifications. In somewhat parallel circumstances I have known the combination to work very satisfactorily. The author seems unfortunate in his choice of examples to illustrate the work undertaken by the research department. Those selected are scarcely such as call for the "high university" type of worker; some indeed could have been entrusted to any intelligent artisan. Again, the special apparatus referred to scarcely shows special ingenuity or novelty. To quote one example, the brake pulley described (see Figs. 2 and 3) has been extensively used. I myself used it in Bombay in a "Joule's equivalent" apparatus fixed on a 4-h.p. motor. It was designed and made by students from sketches supplied and was not considered novel, although we were rather pleased with ourselves at the convenience with which results could be obtained with a "Soames" or a modified "Prony" brake either for determinations of J or when, purely as an exercise, it was used in brake tests of motors. The strong point of the paper seems to me to be the careful organization of records which is demanded. This is a most important matter; records *must* be complete, showing failures as well as successes, and handy, and in this direction the paper, by detailing an organization, should be very useful. There are two aspects of the case for research organizations which do not, in my opinion, receive the attention which they deserve. (1) Our manufacturers —with some brilliant exceptions have, until recent years, starved research. They had no use for the highly technical man, if we may judge by the salary they were prepared to pay him, for accountants and secretarial men usually received much more than the engineers. (2) Modern research calls for much more expensive and elaborate apparatus than the individual worker can generally afford, so that organized research seems bound to replace individual invention to an increasing degree as time goes on.

Mr. P. Dunsheath (*communicated*): I feel that the author's conception of industrial research is altogether too narrow. The title of the paper certainly suggests that he is dealing with only one part of industrial research, but the impression one gets on reading the paper is that this part equals the whole. Possibly in the particular branch of electrical engineering represented by the author, development is the whole story, but this is not so in all branches. More usually, large calls are made on a research department in connection with factory difficulties, the control of materials and processes, and many other matters which do not come within the scope of the author's "development." Possibly the reason for the different outlook lies in the fact that the author is engaged in a branch of the industry where the product can be represented by models and where technical processes are of less importance than actual design. The question of the relationship between the research department and the factory organization is of vital importance. Wherever the two come into contact there must be fusion and not a fence, and in this connection I feel that the policy of the last few lines of the first paragraph on page 64 is rather too autocratic to be entirely successful in operation. The author says that the production staff should be instructed to communicate their proposals, and that any attempt at private enterprise should be strictly repressed. While I agree that experimental work should, as far as possible, be carried out away from routine production, I do not think that the author's method will be found very helpful. In hydrostatics a vacuum will often achieve a result where pressure fails. In dealings with men much the same principle applies, and my advice to industrial research men is to get the interest of the production staff. Remember that a man who is doing a job all day and every day probably knows a good deal more about the details than you do, and let him see that you appreciate this. Do as much to advance an idea put forward by the production staff as if it were an idea emanating from your own department, and you will soon find that under the "vacuum treatment" of personal interest the ideas will flow in without any repression. One might say that this treatment helps to weld the research department to the factory organization at all points and is, as a matter of fact, the only path to successful operation. On page 64 the author shows how epoch-making inventions do not come from the uninitiated. Few of us have the courage to say as much in the face of popular opinion, but how true it is! The invention of the buffer spring by the carpenter playing with a shaving is typical of what may happen in the pioneer days of an industry, but as the industry becomes organized great changes do not come about in this way: they have to be worked out. In the early days of a goldfield the digger unearths valuable nuggets alone; but thousands of pounds' worth of machinery is necessary and thousands of tons of rock must be treated to produce the same result as years go by. The author's condemnation of slackness in the recording of research results is very necessary. A certain type of research worker, otherwise quite well-balanced mentally, cannot be brought to see the necessity of placing his findings correctly on record. To me it seems purely a question of honesty that when a man has spent £50 or £100 of his employer's money on an investigation he should place on record everything found, even if he has only discovered that a certain thing will not work. It has been claimed, I know, that the value of a piece of research is sometimes inversely proportional to the length of the report, but, admitting this, the argument in favour of complete records still holds. The

author's suggestion for recording ideas on cards is very sound. In a busy research department new ideas are so prolific that it is quite impossible to follow up any but a small proportion. Unless recognition is given, however, the springs dry up, and a definite system by which the ideas are preserved is most desirable. I find that such a record kept personally by the head of the department is a good incentive to the staff. It also forms a gold mine for future digging. The correct selection of research workers is of vital importance. The author refers to collective thinking: this is absolutely imperative and the man who is secretive, withholds his co-operation from his colleagues and is for ever watching for an opportunity of thrusting himself forward, is better out of industrial research. The mental advantages accruing from membership of a well-developed and well-equipped research organization are, after all, considerable and demand in return full and hearty cooperation from every member of the staff. As to the type of mind desirable, the author makes some useful comments on pages 65 and 66, and it seems to me that the whole matter can be summed up by saying that a research worker should be highly skilled in the theory and practice of the weighing of evidence. In this respect the scientific investigator may learn a good deal from the lawyer, who first ascertains what facts are proved and then decides what can be deduced from these facts. As an example of what I mean, electrolysis does not occur where a lead cable is laid in a dry pipe, and if a report states that electrolysis was caused by water in the pipe it may be assumed that the writer has mixed his known facts with the inferences deducible therefrom. This is perhaps a rather bald example, but it illustrates a type of confused thinking which is by no means uncommon. In conclusion, then, I would suggest that the two most important factors in the success of industrial research are the mental training of the research worker and the extent to which fusion is successfully accomplished between the research department and the factory organization. These two ends can only be attained by selection of men with character, and if the personnel is chosen with these points in view nothing can limit the value to industry of industrial research.

Mr. J. G. Pearce (*communicated*): The author has performed a valuable service in drawing attention to development work and its relation to research and production. It is not clear from the paper whether the development he describes is a function of the engineering department, but development is undoubtedly an engineering function. Designing engineers, however, are frequently overloaded with current commercial work, and it may be an advantage to devote a small staff to co-ordinate and encourage desirable development in conjunction with specialist engineers. The paper takes a rather limited view of development work, being concerned with the evolution of new or fresh, but not necessarily novel, types of electrical apparatus of small size. The paper is concerned specifically with design, but the author does not even mention the development of new materials and the methods by which these materials may be produced and applied in the shops. The slides shown make it clear that the work done is principally experimental development, which has to be differentiated carefully from manufacturing development. A considerable amount of manufacturing development will be required after the model leaves the development department, whereby the design is prepared with due regard to the commercial materials, shop equipment and tools available. Development procedure also varies according to the motive with which it is undertaken, to reduce manufacturing costs, to meet the requirements of a client, to introduce a new line of manufacture or to meet competition. It also depends to some extent on the source of the original idea, i.e. whether it comes from inside or outside the works. Valuable as models may be in some cases, their use is subject to limitations; thus the performance and characteristics of a machine can only be satisfactorily obtained from a full-size sample. The author would add to the value of the paper if he would define the relationship, either as it exists or as he conceives it desirable, between his development department and the engineering, works and research departments, and indicate how much time is required, on an average taken over many varied developments, for a piece of experimental development, and how much for the subsequent manufacturing development. The references to indexes of literature and information are scarcely full enough to permit adequate criticism. The first system is suitable for a small office index, but there is considerable risk in leaving the work to an untrained junior. Working from annual volumes introduces a considerable time-lag. In the more ambitious Wembley scheme there is again the apparent lack of a skilled indexer or librarian to arrange the all-important key words in the titles, and to deal with the classification generally. It is also difficult to persuade specialists to maintain up-to-date indexes of their fields of inquiry. An active library or intelligence service would aim at keeping the specialist informed of matters likely to interest him, and so relieve him of the trouble of examining quantities of periodical literature, or of doing translations, abstracts, etc. Much work best done by a library staff is also involved in seeking information relating to new subjects for inquiry. The suggestion that the most effective method of co-ordinating research is the more complete dissemination of data for the benefit of research workers was advanced by me in a Faraday Society discussion in 1919, and is amplified in "Research in Industry" referred to in Appendix 3. The appreciative references to the value of co-operative research through research associations are thoroughly justified, and the electrical industry should note that it is concerned not only with its own peculiar materials but also with materials covered primarily by other associations, for example the Non-Ferrous Metals and Cast-Iron Research Associations. Considered broadly, the paper is a contribution to the problem of the effective utilization of new knowledge in industry. This transcends in difficulty the question of promoting research itself, and the paper should assist considerably the movement towards the "functionalization" of development work.

Mr. E. Kilburn Scott (*communicated*): I want to see a research institution where anyone can carry out technical research, have use of testing apparatus and instruments of precision and be in an "atmosphere"

conducive to creative engineering work. This can best be done in an organization on some such lines as Prof. Kennedy Duncan had "the vision to organize" at the Mellon Institute, Pittsburg. Fellowships at this Institute are for one or more years and cover the salary of the research worker and expenses of materials, but the use of building, light, power, standard apparatus and instruments, etc., is free. In the course of time much apparatus has been accumulated from hundreds of researches already carried out, so a newcomer is supplied with apparatus and instruments very quickly. Just as industrial operations require carefully planned buildings and special apparatus and tools, and the co-ordination of many factors, light, heat, power, voltage, kind of current, etc., so also does technical research require a suitable environment or atmosphere. The main idea underlying the Institute is service to the whole community, and therefore the results of all researches are published after a certain period of time. Also there are clauses in the Fellowship agreement to protect the research worker regarding rewards. As one who has lived overseas for some time, I am very glad that the author has drawn attention to the importance of this country initiating inventions and improvements because of the prestige it gives abroad. Our people overseas look to the homeland to keep in the van of engineering progress, as was the case in the last century.

[The author's reply to this discussion will be found on page 101.]

North-Eastern Centre, at Newcastle, 12 November, 1923.

Mr. B. H. Leeson: As an alternative to reading the paper, the author has given an interesting lecture describing the experimental stages in the manufacture of certain apparatus. The title of the paper, however, covers rather a larger scope than this and I think that the choice of the name "Development Department" to denote an industrial research organization is hardly a happy one. The word "development" in its usually accepted sense only implies one particular branch of such an organization's general work. Why does not the author adopt the broader title of "Technical and Research Department," to which he makes a reference towards the beginning of the paper? The principal function of such a department should be to act independently in a consultative capacity, upon technical matters, to every branch of the firm's activities and not merely to development work in the factory. This calls for the closest co-operative working with all the various departments concerned, not necessarily to relieve them of "all technical burdens" (which I think would be as impracticable as it would be undesirable), but to relieve them of the more difficult problems and to assist them in the lesser. As a guiding principle, the technical and research department should deal essentially with all problems involving "unseen" phenomena, leaving the purely visible and constructive problems for co-operative working with the design staff. The laws of dielectrics, the physical properties of materials, and the high-frequency resonance phenomena which occur upon a high-tension distribution system under an arcing fault or atmospheric conditions, may be mentioned as common examples of "unseen" problems. Fig. A shows diagrammatically the general principle of one piece of testing apparatus that we use in connection with these. With the bank of condensers charged up to 85 000 volts, a discharge current of the order of 8 400 amperes at a frequency of 100 000 is "spilt" upon the apparatus under test. This corresponds to a momentary maximum of over 700 000 kVA. To reproduce service conditions, a power transformer is employed to supply the necessary "follow-on" power current. The paper does not deal with the commercial side of the question. A customer can only consider the price of a commodity in relation to its sound construction and technical qualifications. The ability of the vendor's engineer, or agent, to effect a sale from this point of view, depends entirely upon his faith in the particular article. There is therefore need for an organization to provide him with expert knowledge of the principles involved, the tests which the apparatus has satisfactorily complied with, and the conditions under which it can be most efficiently employed from the customer's point of view. I should like to know whether the author employs such an organization for

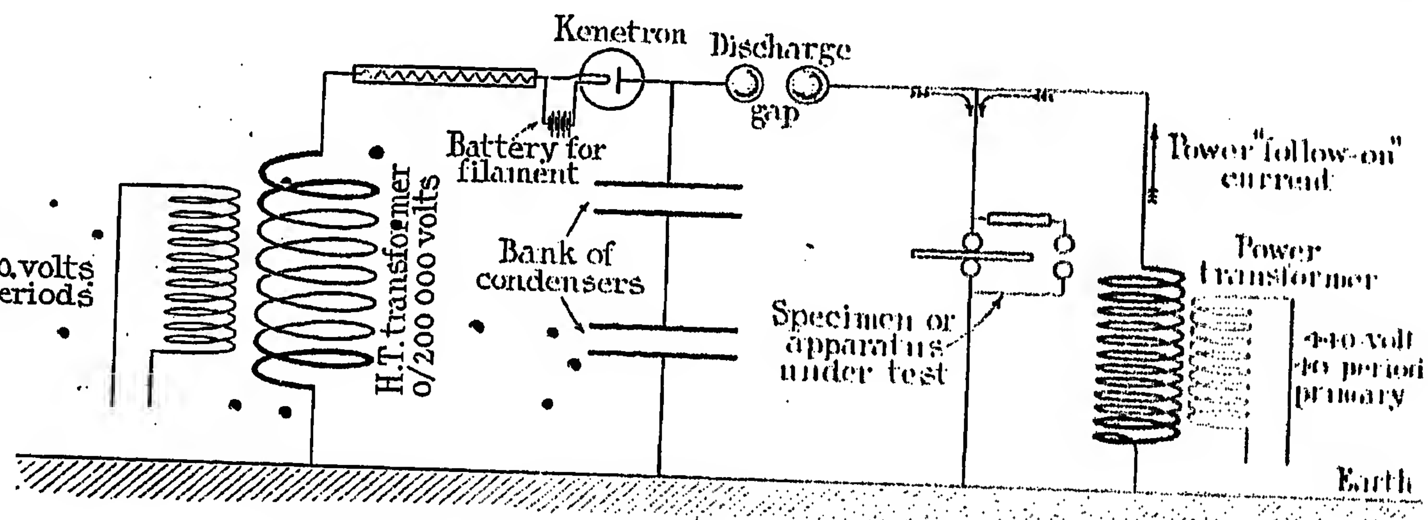

FIG. A.—Schematic diagram of connections for high-frequency surge tests.

the dissemination of the knowledge accumulated in his development department. The employment of a staff engaged upon technical and research work to embrace this purpose, in addition to the productive and other functions dealt with in the paper, becomes a sound commercial proposition and an actual necessity to any progressive firm. What, in the author's opinion, is the monetary limit (expressed, for example, as a percentage of the annual turnover) which may be economically expended upon purely research work? I think that every encouragement and the fullest consideration should be given to any suggestion, from whatever source it eminates. A suggestion on first acquaintance may appear small and possibly nebulous; its true value, however, should not be judged by this, but rather by its potential worth when transferred to the expert investigator. The manner in which a workshop suggestion is received and considered may prove, in many cases, as successful an encouragement for another to be forthcoming, as a monetary reward. As a technical and research staff consists, more or less, of a collection of experts, team work, for the good of the department as a whole, is essential. The qualifications of common sense, power of analysis, a keen sense of discernment and proportion, broadmindedness and the gift of application, are fundamental, and without these the possession of pure technical knowledge may lead to little practical attainment. I fully agree with the author's insistence upon every investigation and test being properly recorded and filed—a point which many investigators are apt to underrate. Regarding the question of national, collective, or individual research, I think that each one is equally essential in its own particular sphere, and that neither can dispose of the others. A closer liaison between these should be encouraged. No co-operative effort, however desirable on certain grounds, can dispense with a firm's individual need for an organization to deal exclusively with its own particular problems and developments. I witnessed the first official "flameproof" tests upon mining switchgear made at Sheffield University, and I can therefore endorse the author's appreciative remarks in regard to the work that has been carried out by that institution. I should also like to record my appreciation of the work carried out by Dr. Thornton, at Newcastle, upon the "Electrical Ignition of Gaseous Mixtures," as being another example of the assistance rendered by a university to industry. The switchboard described in Appendix 1 is very useful for repetition testing, but I should like to know how the author arranges his circuits and controls when making precision tests. Will he also state the degree of accuracy that can be obtained with the pressure indicator shown in Fig. 5? The last thing that I should expect this device to indicate would be the "crest pressure." I should be glad if the author would state why he employs an oil-testing apparatus which does not conform with the requirements specified and standardized by the B.E.S.A. The apparatus shown would give no reliable indication of the electric strength of the oil under test. With regard to the particular examples of research development work illustrated in the paper, I would suggest that in many instances certain stages in the development could have been either eliminated altogether or carried out by the design staff irrespective of the aid of any research organization.

Mr. E. Fawssett: I agree that it was an unfortunate national characteristic that we were prone to abandon enterprises just where they began to be profitable. Due to abnormal conditions this tendency disappeared in war time, but in some directions I have observed signs of its return. Co-operation between firms as well as between departments was largely assisted by war conditions, and while that incentive has passed and the national characteristic of individualism tends to reassert itself, the trend of development renders such co-operation increasingly necessary. That this is an accomplished fact may be judged from the number of co-operative research associations now at work. The current issue of the Privy Council Committee's report gives a list of 24 of these, nearly all of which have received substantial help from the Million Fund. As, however, this grant may be terminated after 5 years' work, manufacturers and users (especially the latter) will have to make greater efforts in the future if the industries are to benefit, as they should, from a properly ordered programme of research reasonably unfettered by financial considerations. The author sets out a training scheme for research workers which is probably ideal in theory, but unfortunately men trained on these lines are often unpractical and erratic. I agree that this is the fault of human nature rather than the type of training, but I consider that research workers for the higher positions (as distinct from mere intelligent observers) are born and not by any means made. I should say that the equipment of a research organizer would be a large portion of that rare gift "common sense," another of "tact" to deal with a diverse and probably unusually temperamentally "difficult" staff, and an excellent knowledge of first principles. I think that the training suggested by the author is hardly "human" enough, and in this connection I would mention that one of the questions asked of young engineers seeking positions on a large concern with which I am acquainted is: "What success had you at games at school?" The training and experience so gained is most valuable in "team work," and in acquiring that outstanding British characteristic of "playing the game."

Mr. H. Parry: My experience of research is more from the user's point of view, so I propose to confine my remarks rather to detail than to general organization. I agree with the author that buildings should be as free as possible from vibration; much time can be lost due to this trouble, particularly if one is doing ballistic measurements or using reflecting instruments. Books of foolscap size are, in my opinion, much better than the loose-leaf system; there is always the possibility of a leaf being lost in the latter system. Referring to the author's abstract cards; if abstracts are too condensed the information is sometimes misleading. I should like to make a plea for greater support for *Science Abstracts*, which forms a very complete abstract of the current published science and engineering data of the world. It seems to me that instruments on the author's switchboard may be affected by heat

from his rheostats, and magnetic fields from his heavy-current circuits. I have found iron-cased instruments to be in error to 1 per cent or more due to a lead about 1 ft. away carrying a current of 700 amperes. I think that an oscillograph or an instrument of that type is preferable to the one described by the author for studying switch motions. In general, these motions or their rate of change can be transformed into electromagnetic effects to work an oscillograph.

Mr. T. Carter: While we must all agree that the author advocates a useful, indeed a necessary, adjunct to the activities of manufacturing firms, I think it must also be agreed that the setting up and the maintenance of a research department presents varying difficulties in varying types of firms. In a very small firm, for example, the head of the firm, personally active in directing it, will probably usually have to be himself the research department, which is a satisfactory solution of the problem, or the opposite, according to the temperament of the man; in a larger firm, but one still comparatively small, there must be a separate staff for research, and the cost of such a staff may conceivably be a serious item in the bill of expenses, making the firm hesitate before taking any elaborate steps in this direction, and perhaps compelling the combination of the research department with some other department, which is not always a satisfactory solution. Generally, the larger the firm the less will the expense of research be felt, which leads to the conclusion that research establishments common to a whole industry, or at least to a section of the industry, and supported in common by the members of that section or of the industry, are most likely to be fully useful. I am inclined to think that "investigation" would be a better word than "research" to describe the process dealt with in the paper. The pursuit of knowledge by pure scientific research has in view merely the discovery of something for the sake of discovering it, its nature being often altogether unspecified and utterly unknown; but industrial research, so-called, does not appear to be a lurking-place for surprises calling for review and revision of fundamental things such as may be encountered with exciting frequency by anyone undertaking the more ideal kind of research. Someone, in fact, recently described it as a rather belated realization of the truth that business is business; and it was only ten days ago that I heard several examples of the calamitous effects of neglecting to investigate before new things are made. It is a fresh testimony to the wisdom of the counsel: "Look before you leap." Industrial research on the lines described in the paper is the systematization of what goes on in every factory that is not a mere machine for belching forth undigested articles on the turning of a handle; and the value of the systematization is that, under it, ideas once conceived are less apt to be strangled at birth than they are when there is no one to nurse them skilfully. The scheme is for the ordered materialization of an idea by means of an investigation starting from a known point to reach an end that will fulfil a predetermined purpose. I value the reminder that ideas may come anywhere but in the ordinarily expected and set-apart places; for myself, I find a crowded street sometimes as useful a place as any in which to let my thoughts take shape. The author is right when he indicates that though we as a nation produce great initiators—great men, that is, with the power of revealing great things that have been hidden until their time—we are often weak in applying their new ideas to practical ends, particularly when the stimulus of the immediate presence of the initiator is withdrawn; and sometimes we have even failed to realize the greatness of the new work and have allowed the man of vision to starve. We have been called a nation of shopkeepers: is it that we are so busy with our buying and our selling that we will not risk a little of the present to win a finer future, not to say a more lucrative one? It is often said that a certain political creed, if put into practice, would stifle initiative; but it could not do that, for what is in a man like Newton will come out of him somehow in any sort of circumstances. What is thought of as likely to be stifled is really the imagined desire of the ordinary man to leave things a little better than he found them; I sometimes think that the alleged fear is expressed only to keep us a little longer from realizing that the great majority of people have no such desire, and that it could not exist in the dreaded circumstances because it does not exist now. Our nation does not usually look at things from the same point of view as that in the paper; perhaps it ought to do so, and perhaps persistence in the end will teach it; but let us realize the problem to be faced and the battle to be fought. There are too many instances in commerce and trade and industry of deliberate refusals to do insistently needed things; there is too much of the tendency, inborn and inherent, to travel in the old rut, even when the better way is pointed out. "Compromise"—"Good enough"—"No harm in it"—these are common but fatal watchwords against opposing nations with characteristics that naturally make them pick up ideas anywhere, internally, externally, on the right hand and on the left, and build up something out of them. I refer members to an example of this sort of thing that was mentioned in the technical Press only a week or two ago. Inertia, the refusal to change the ancient way, is a horrid sin when it grows into a habit. We are individualistic; we do not readily co-operate; sometimes, even yet, things are kept secret and apart when they ought to be widely known—things that would add to the national efficiency and prosperity and so in the surest way to the prosperity of every concern and finally of every individual in the country. Unless we prosper in every unit, any show of prosperity is a hollow thing. All this is proper comment on the paper, which is a plea for the sort of work that will bring us more closely together for our mutual good. Those of us who have already been trying to go in the way it points out will be stimulated to greater efforts by it; and no one can read this record of actual achievement without feeling that it is worth while to go on, and that not only in manufacturing, but in every branch of the industry, the ideals that underlie the proposals of the paper are somehow capable of being realized.

[The author's reply to this discussion will be found on page 101.]

SOUTH MIDLAND CENTRE, AT BIRMINGHAM, 14 NOVEMBER, 1923.

Mr. F. R. Combes: It would seem that greater co-operation in research work is most urgently needed in this country. This applies particularly to the period following the "philosophic" research stage. With greater co-operation between the universities and industrial concerns, for instance, each would attend to the work best suited to its resources, the universities undertaking work requiring the expenditure of much time, by thoroughly qualified men, while the manufacturing concerns would carry out research requiring the use of large quantities of power and apparatus. The final development can only be carried out efficiently by the manufacturers themselves, through the medium of suitably trained men with the necessary practical experience. The necessity of taking full notes of all relevant matter during the test has been mentioned and cannot be too highly emphasized. During a test the operator is steeped in his subject, but on changing over to a fresh piece of work the mental notes of the last test vanish with remarkable rapidity. The author stresses the necessity of highly trained men, and it is interesting to note that practically every important discovery has been made by a man who has devoted his life to the work. The half-watt lamp was made possible by the discoveries of Raleigh and Ramsay. The telegraph was the result of a series of discoveries starting with that of Oersted; this was carried on by Ampère, and his results were investigated and continued by Gauss, Weber and Henry, and their researches resulted in the first workable telegraph. All these men were highly trained investigators, and these examples might be continued indefinitely. To extend the author's analogy of the gold-seekers; it is technical training that enables an investigator to distinguish between pyrites, or as it is more commonly called on the goldfields "new-chum gold," and the desired mineral.

Professor W. Cramp: The paper arrives at an opportune moment, for the advent of the Research Associations and research departments in works renders it necessary that a discussion should take place upon the functions of these establishments as compared with the research departments at universities and technical schools. It seemed at first as though, between philosophic research in the physics departments of the universities and these new works developments, all research in the applied science schools would be squeezed out, but it is perfectly clear from the paper that the work undertaken by a development department is of an entirely different character from that which we do at the University. In this connection, one cannot overrate the importance of "atmosphere." In a works the conditions are always certain to be subject to limitations of time, and the atmosphere is unsuited to the conditions of concentration and leisure that are required for inquiries into fundamental matters. Thus in the universities that research which has taken the form of the complete development of a new apparatus will gradually disappear, as will also those tests of completed machines which are much better carried out in the works. The function of the applied science research department, therefore, will be to take hold of the basic principles as the physicist leaves them and show how such principles can be usefully applied; and to reduce the laws governing them to a form that can be utilized by a development department. To take a concrete instance, the principles underlying Kapp's phase advancer would be worked out in the university, but the actual form would be developed in the works. Or, again, and as a converse case, such a research as that carried out by the author in connection with liquid rheostats would have been much better performed in a university, since he was obliged, from limitations of time and opportunity, to omit important considerations and to announce general results which are only roughly true. It is obvious that co-ordination between the works and the universities is much to be desired. Another function of university research departments, and perhaps their most important business, is the training of men to be capable of undertaking works' research and development on thoroughly reliable and scientific lines. Each year I am more and more impressed with this necessity and with the immense amount of training required, and I do not think that the summary on page 66 is by any means adequate for this purpose. I find that, although ours is a four-year degree course, research men in their fifth year still need advanced lectures and training in the application of mathematical functions, as well as development of the attitude of mind to be adopted in regard to any research problem towards which their attention may be directed. In this connection it is much to be regretted that when such men have been trained there is no works in this country which has an adequate organization for giving them the practical specialized training by means of which they may be made fully efficient in a development department. I think it is high time that works' directors should consider this problem. In conclusion, I should like to thank the author for outlining the methods of filing information, which have been a source of trouble to so many heads of technical departments.

Dr. M. Kahn: Industrial research has in recent years reached a new stage as the result of the progressive specialization and the tendency to subdivide work, namely, that special departments, concentrating entirely on this work, have been created in many manufacturing concerns. Such an arrangement improves the efficiency of a manufacturing organization, as it frees the bulk of the staff and works to concentrate entirely on production, the development department dealing with new designs, improvement of existing types, troubles in manufacture, testing of new materials and new processes and other matters, which are outside the scope of the daily routine work of manufacturing. Such an arrangement presupposes a subdivision of work such as is usually only found in large organizations, and this fact should not be forgotten, as an explanation why such organizations have been more numerous in other countries, especially in the United States. Whilst this subdivision allows a greater amount of specialization and concentration in the purely manufacturing side of the works,

which is in itself desirable, it introduces on the other side a number of workers, who can take a broader view of the questions that arise, thus counterbalancing the narrowing of outlook which specialization often brings about. This consideration shows how important it is to choose for the development department men with a training on a comprehensive basis who can look on a subject from several points of view. Such men should be, if at all possible, those having experience outside the particular scope of the work. Such men can introduce new ideas and keep in touch with developments in other factories and other trades. In this way the advantages of specialization can be combined with those of versatility.

Mr. W. F. Higgs: The author refers to the fact that we have grown accustomed to abandoning our enterprises just where they begin to be profitable. Unfortunately, this is a failing of an engineer. He naturally has an inventive mind, and one must not expect him to convert himself from an inventive to a productive being. The author uses the term "mass production." I cannot remember the use of this before the war; it implies to the uninitiated new methods, and to most people methods evolved during the war. Without reviewing the whole history of production, what better example is there of "mass production" than the printing press invented six centuries ago? The author implies that there is not so much scope for industrial research and repetition work as in other classes. I disagree with him; finality is never reached, as the more one knows of repetition work the more scope there is for industrial research. He refers to limit-gauging, but in my opinion gauging is useless without applying limits. When we refer to a dimension, limits are implied, but that is not sufficient; they should always be stated. The author refers to the university degree in engineering. It is very important that young men about to enter the profession should take this degree. The great advantage of university training is that it teaches people how to learn. The author points out the importance, when investigating a proposition, of finding what has already been done in that direction before commencing work, and his method of indexing is of great assistance in that direction. He says that the private worker is at a greater disadvantage to-day than formerly, but I doubt if this statement is correct. He implies that the particular testing apparatus necessary is not at the worker's disposal, but he must remember that formerly this apparatus was not in existence. I am of opinion that a modified form of such a paper as the present should be brought to the notice of financiers. Research costs money, and before it can be done money must be found. On what does the success of a nation depend? A banker will say finance; a merchant will say foreign trade; politicians, at the present moment, the tariff question. I say it is combination, and the smallest component is not industrial research. Our success during the last century is to a large extent the result of industrial research carried out by Watt and others.

Mr. W. Lawson: The author's contribution to the subject of industrial research is of great value as it is based on a bold and apparently successful attempt to put the idea into actual practice. Notwithstanding all that has been said, and the evidence of research activities given in the paper, one has serious doubts as to whether the average British manufacturer is yet wholly convinced of the necessity of adopting such measures as are advocated by the author. There is indeed absent from many standard lines of electrical products that appearance of finality in design and construction which can only be achieved by those possessed of the requisite equipment, knowledge and technical skill. Moreover, instances are not lacking of misdirected development whereby successful designs have been altered to their detriment for the purpose of cutting down weight of material and cheapening the method of manufacture. What usually results in these cases is a diminished reliability in service which in consequence increases the cost of maintenance. The attitude of the British manufacturer towards technical research, and his reluctance to pursue his enterprises to ultimate completion, are not explainable by national decay, conservative outlook or temperamental inability to co-operate. Possibly the explanation is to be found in the peculiar trade conditions existing in this country, but this leads to considerations which are outside the scope of the paper. It may, however, be confidently expected that with the spread of the spirit of research this problem will in due time be susceptible of solution. I agree with the author as to the impossibility of epoch-making discoveries coming from untutored sources, but would go further and add that it is improbable that any such discoveries will have their origin in the development departments of industrial concerns. The author attaches insufficient value to suggestions and ideas from outside sources. It should be remembered that many of the articles in common use have been brought to perfection through suggestions from users, and one of the signs of the times is that the general public are rapidly acquiring what I might term the "electrical sense." The growing use of electrical appliances is bound ultimately to open up sources from which valuable suggestions for improvements may be looked for. In this connection, and also in its attitude to those employed in a works who are not specifically engaged in development work, the author's outlook is perhaps too exclusive.

Dr. C. C. Garrard: I think that the author's remarks on page 64 relating to "private enterprise" might be misunderstood. It is very important not to suppress initiative anywhere within an organization; many valuable suggestions emanate from the workshops, for example, and it is desirable that these should not be discouraged. It is important to distinguish between industrial research and industrial development. Take, for example, oil switches. An industrial research might concern itself with the phenomena associated with breaking electric circuits under oil. The development department, however, deals with the production of an actual piece of apparatus which can be illustrated and priced in a catalogue. This kind of work is especially necessary in connection with switchgear and the like, the designs of which are not amenable to pre-calculation as are, for example, those of electrical machinery. This work, however, entails just as high a class of man to carry it out as does research work. The function of the drawing office is

to produce designs which are mechanically feasible and capable of being made in the works. The drawing office must also embody the tradition of the organization and be the repository of experience gained in all parts of the works. When it comes, however, to breaking new ground and developing a new piece of apparatus, generally speaking, something more is required than is available in the drawing office staff, and it is here that the development department comes in. Of course, there are many draughtsmen who are original and quite capable of making developments. If they show themselves to possess this capacity then they should certainly not be repressed but should be allowed free play. Hence, I do not think that such a hard-and-fast line as is set out in the paper can be drawn. Originality, inventiveness and initative are the things that keep a works going; they must be welcomed and encouraged wherever they occur. By this I do not mean that the functions of the development department as outlined by the author are superfluous. On the contrary, it is because in the ordinary working of a factory we do not have sufficient of the qualities just mentioned, that a development department is necessary and is organized primarily as a vanguard of the forward progress of the works. It is the business of a development department to develop new ideas, to make new designs, and to produce data upon which new designs can be based. There is no doubt that development departments have come to stay. For their efficient management and operation they need men of considerable intellectual and educational attainments, and they should receive as high acknowledgment from industry as does, for example, the commercial department. Progress and evolution in engineering affairs have to be organized, and a necessity to this organization is a development department. Money spent there is in the long run the best investment, as, without this department, stagnation and retrogression speedily assert themselves.

[The author's reply to this discussion will be found on page 101.]

Discussion before the Mersey and North Wales (Liverpool) Centre, at Liverpool, 19 November, 1923.

Professor E. W. Marchant: The subject of industrial research is one that it is very fitting should be discussed by the Institution, because the Institution has had no small share in promoting such research during the past 10 years. The Research Committee of the Institution was founded many years ago, and out of that arose the Electrical Research Association, which later became connected with the Department of Scientific and Industrial Research. The part of the paper which interests me most is that dealing with co-operation between the industry and the universities in research work. In connection with any scheme of research the chief function of a university is the training of research workers, which has been referred to in the paper. The author points out on page 66 that it is necessary for research workers to be trained in the art of clear and logical thinking, then in research by a study of physics and chemistry and, if possible, of geology, and lastly, in the art of expression and languages. The latter is, I think, very desirable, but at the same time one is bound to point out that it is a quality very often not possessed by some of the most brilliant research workers. It is unfortunate, because the fact that a man is not a good expositor tends to depreciate the value of his work to the outside world. It is very often difficult for a research worker to express himself clearly, and it is very difficult indeed to train him to do so. At the same time, clear expression is a very important matter, and he should certainly be trained in the art as far as possible. Again, the author refers to the necessity for training in the practical applications of science. I entirely agree with that, and I think that research workers undergoing training should be encouraged to make things for themselves. It was my good fortune to be associated with the late Mr. Duddell in some of his early work, and I think his extraordinary success was largely due to his mechanical skill. We always lay great stress on that in the training of research workers in the University of Liverpool, and there is no doubt that it is of great assistance to them afterwards. In the second part of the scheme of training I should also like to suggest that more stress should be laid on the study of applied science. The author does not, I think, attach sufficient importance to the necessity for studying applied electricity. I am very strongly of the opinion that the advantage that is to be gained by a research worker by spending a considerable amount of his time in studying the appliances which make use of electricity, is very great. Scientific training can be given quite as effectively by a detailed study of an electrical machine as by the study of an experiment in pure physics. "Massed research" is a method which has been largely used in America and which developed rapidly in this country during the war. By having a group of men engaged on a problem, much more rapid progress is often made than by the same number of men working independently on the same problem. This method of attack is bound to develop as industrial research progresses.

Mr. J. G. Pearce: I would suggest that development work should be regarded as a "load equalizer" for the engineering staff during slump periods, as then the time and equipment are available. During prosperous periods when money is available for development work it does not get proper attention. This involves a regular and continuous development policy. I should be glad if the author would deal with the following questions in his reply: (1) What relationship exists in his works, and generally what relationship does he consider desirable between the engineering, manufacturing, research and development departments? (2) Where a progressive firm pursues a continuous development policy, what annual sum expressed as a percentage on profit and loss or turnover should be set aside for research, experimental development and

manufacturing development? (3) What average time does the author find is required for experimental development of the kind he describes and for the subsequent manufacturing development? And (4) what method or system can he recommend in a works for determining development policy, bearing in mind that suggestions for development come from outside inventors, from engineers and salesmen in the company, or from clients?

Mr. J. H. Collie: While I agree that a research department is a very necessary adjunct to manufacturing firms, it appears to me that only the larger firms can afford to run a department of this kind. I think it would be a good scheme if there were some public research department which would for a fee carry out tests on apparatus manufactured by smaller firms, and which would issue a certificate that such apparatus had been duly tested and found satisfactory. Such a certificate would assist users in getting reliable apparatus, and afford some guarantee that it would function satisfactorily under all conditions. This might remove some of the shoddy apparatus at present on the market.

Mr. B. L. Myer: Mr. Pearce has raised the question as to who and what should determine the particular line of development or research to be undertaken, and I suggest that usually under commercial conditions the economic factor determines it. In other words, will the result be a profitable one? The person or persons generally responsible for determining whether new developments should be embarked upon must of necessity take this responsibility. I think the economic factor is one which the author should examine closely in connection with this matter. The point raised by Mr. Collie is also of interest from an economic standpoint, because it appears to me that such research laboratories as have been indicated in the lantern slides are only within the reach of such concerns as have vast resources of capital. Perhaps it would be useful if the universities were in some way provided by means of Government funds to enable them to act for the smaller firms, who could submit their problems to the specially skilled people in the university, to be dealt with on their behalf.

Mr. O. C. Waygood: The chief work of any research organization should be to search for knowledge or information concerning manufacturing processes, the selection of materials and the utilization of waste by-products, leaving the actual development to the engineering staff, who by their training and experience are best able to deal with such problems. What in the author's opinion would be the chief work of the development department? Does he mean that an employee anxious to put some new scheme forward should pass it on to the research department for them to develop? Surely, the right place for this idea to germinate is in the mind of the originator. On the other hand, would employees be willing to divulge their secrets if such a system prevailed, especially if they knew that it was not for them to carry on with the idea? Does the author suggest that this department should take charge of every possible branch of the products of an industrial organization? Apart from the impossibility of organizing such a department, the only place for the development of any new idea is in the environment of the department set aside for that particular product. The author on page 64 points out that draughtsmen and foremen are exposed to a natural temptation to experiment for themselves. There is no reason why this should not be encouraged, provided it is confined to senior and trustworthy employees, and to hinder or prevent it in any way would be fatal. New developments are not being evolved every day and so would not unduly disorganize the work of the department. On page 69 the author suggests that a firm desirous of making contactor gear, for example, and not having previously done so, should put this in charge of some suitable member of the staff. A close study of the advertisement columns of the technical Press suggests otherwise. On page 73, under "Co-ordination" the author criticizes a scheme proposed some years ago whereby every research worker whether in a university or works laboratory would work under a staff appointed by the Government. He condemns this scheme and suggests that it would stifle research. I quite agree with him, but if he does not like this particular Government scheme, why suggest its application in a smaller degree in industry? It is for the industrial concerns to encourage their employees in development and suggest, in the interest of each, ideas which will eventually benefit the whole and so keep electrical engineering development in the forefront. Adam Smith in "The Wealth of Nations," remarks: "The wages of labour are the encouragement of industry, which, like every other human quality, improves in proportion to the encouragement it receives."

Mr. W. Holttum: The author states in Section IV, in reference to the causes of the present position, that much of the pioneer work of British scientists is built upon by foreign nations rather than by our own, and points out that while individual work succeeds up to a point, beyond that point co-operation and co-ordination of the results of different workers are a necessity for progress. In Section XIII he comments rather cautiously on the means of co-ordination made possible by societies, the Electrical Research Association, publications, etc. Nevertheless, the fact may as well be recognized that a large proportion of the useful research work done is carefully guarded from publicity for competitive reasons, and there must, therefore, be a great deal of overlapping of endeavour and inefficiency of utilization of the sum total of the results obtained. It is hard to see how this state of affairs is to be rectified, since the needs of individual firms can in many cases be best met by their own individual research work, and they are naturally loath to give away the results of their experience. It seems evident, however, that a system of free interchange of knowledge would benefit industry in every way, and it is probably a fallacy to think that undue prosperity would attend the business of the selfish manufacturer who tried to profit by utilizing the brains of others. If it were not that a great deal of the information which is attempted to be hidden leaks out or is unavoidably given away by the manufactured product, progress

would be far behind its present position. I think that a system of free interchange of information might be initiated by the more reputable manufacturers in each line of business, and it would be a step fraught with great possibilities.

Mr. J. A. Morton: The author mentions that progressive standardization has opened the way for quantity production: he might also have added, "and development." This is well illustrated by the British Standard Specifications. The formulation of these Specifications gave manufacturers more time to devote to other problems. For instance, before electric light cables were standardized, different makers employed different thicknesses of insulation, lead, etc., consulting engineers had their own pet specifications and consumers their particular fancies. The Cable Makers' Association took this question in hand and standardized the most common cables, which was a great gain to everyone concerned. Later on, the British Standard Specifications were produced, and these provide a solid basis for further development. It is not clear to me how the head of a development department (though he must obviously be some sort of superman to perform all the duties which the author lays on his shoulders) can himself deal with all sorts of suggestions made from the selling side of a big business, from consumers and from workpeople. He needs to be a man of university status, as the author says—meaning, I suppose, exceptionally well educated and not that a university education is a *sine qua non*. There are many men who have done good research work without a university education, although there is no doubt that the grounding in first principles which such an education gives is very useful; still, this does not necessarily give a man an adventurous and initiative mind such as would be required for the head of a development department. Professor Marchant has referred to the question of the necessity, or otherwise, of the research engineer knowing several languages. My own feeling is that the most important thing in these days is for the engineer to know thoroughly his own language and be able to express himself clearly in it, if not by the spoken word at least by the written word. The quality of the English employed in many engineering reports and specifications is extremely poor. The author's arrangements for the recording and filing of engineering matter are very good indeed, and his suggestions seem to me to be one of the most useful parts of the paper. As an instance of the value of research, I can speak from experience of the great usefulness of the research work carried out under the direction of Mr. Wedmore on the heating of buried cables. Before this work was put in hand all information on the subject was scattered and chaotic, it being the result of uncoordinated efforts made by various individuals all over the world. The two reports issued on this particular piece of research have helped both consumers and engineers even more than cable makers, and have given us definite conclusions put forward by an independent authority whose findings have a standing that no private conclusions could be expected to have.

Mr. R. G. Devey: I feel sure that the introduction of research and development departments in manufacturers' works will assist greatly in the manufacture of really first-class materials and plant. A few years ago, the designer in a works produced what he considered to be a suitable design of a piece of apparatus or plant. This was sent in to the works to manufacture and then passed on to the test department, the apparatus being despatched to the user after obtaining trial runs with certain results. It appears now that by the introduction of a development department a piece of apparatus is made up in a rough form and afterwards modified and reconstructed to give as near as possible ideal results, these results being returned to the drawing office. The final designs are then evolved from known results, after which the apparatus is tested and sent to the user. As I am mainly interested in the use and operation of electrical plant, I feel that it will be a great advantage to the user to receive plant which has been thoroughly tried out before and after the final design and before it is despatched and put into commission. The results should be very much more satisfactory when the plant is put into commission, as it must be remembered that failure of any plant in power stations, works or factories results in loss of output. I should be glad if the author would give his opinion in regard to the control of a works development department, as unless this is properly controlled it is quite possible that apparatus may be developed and a good deal of money spent on it, and when finally finished the article is not required on the market. I can quite understand there are many officials in works who might consider that the control should be theirs. The company with which I am connected control their developments by means of a development committee. A useful and broad development committee appears to be necessary and might be formed of an electrical engineer, a mechanical engineer, a steam engineer, a chemical engineer, the technical manager, the production manager and a chairman with a very wide experience and not too young, but with a committee formed of energetic, well experienced younger men. One of the previous speakers in the discussion referred to the system of passing technical papers through various offices in works; if a busy engineer is in the habit of receiving about ten per week he finds it impossible to read them through, with the result that they are generally passed on. Perhaps a more satisfactory method is to circulate abstracts taken from the technical papers. These can be obtained by means of a suitable man who can make abstracts from all the leading technical papers both English and foreign. It is then a simple matter to look through the abstracts and select any particular subjects which might be of interest to each official of the company. The author appears to be very uncertain as to the value of suggestions. I agree that although it is difficult to get the whole of the works employees interested in a scheme of sending in suggestions, this can be done provided the matter is properly handled by the company. When a suggestion is put forward, it should be carefully considered and if it is of no value then the reason should be explained to the suggester. I am informed by the company with which I

am connected that they have received during the past 4 years approximately 2 000 suggestions. Out of these approximately 22 per cent were adopted. The success is in my opinion due to the fact that for all suggestions adopted a suitable monetary reward is granted, the amount being commensurate with the value of the suggestion to the company. Whilst a large proportion of suggestions are useless there is bound to be a large number which when investigated must have some real value. In one case which came to my notice an alteration to the shape of a piece of metal in a particular machine was suggested. This resulted in the output of the machine being increased owing to the number of "spoils" being reduced. The cost was a matter of a few shillings but the company was saved £100 per annum. In another case a suggestion was put forward to make a certain improvement (not a costly one) which enabled the work to be carried out in one operation instead of two. In this particular case the output amounted to several millions of articles per annum. Suggestions of the latter type are most valuable to companies, as they lower the working cost, reduce the capital outlay, improve the efficiency of a works and play a useful part in the balance sheet. I should like to suggest to the author that whilst better work and results can be obtained in a development department, there appears to be little hope of obtaining results such as are obtained in works using plant continuously after it has been installed. Results obtained in a development department must of necessity be only short-period results, and whilst apparatus is probably tested to destruction the results in ordinary use may be considerably different. It rather points to the fact that there should be some form of co-operation between manufacturers and users of plant, and I have in mind that most large power stations and large works keep a history log of each important item of plant in which the working results are entered from time to time.

Mr. A. E. Malpas: The opening statement in the paper emphasizes the changes that have taken place in electrical development in the past 40 years. Reference is made in the paper to Faraday's work, and it happens that exactly 100 years ago he produced chlorine and liquefied it in a closed glass tube, using the chlorine hydrate as a carrier. It has taken almost 100 years to develop liquid chlorine, which has had to wait for the employment of electrical methods in the chemical trade for its application in industry to become a practical and paying proposition. A few figures relating to the German production of chlorine by electrolytic methods may be of interest. Ten leading German works last year produced by electrolytic methods 6 600 tons of chlorine per month, of which quantity more than 33 per cent was liquefied, so that the daily output of liquid chlorine in Germany is probably over 80 tons per day, which shows that their industrial population must to a large extent be fully employed. With reference to the remark on page 72, in the case of a particular installation working at 60 000 volts the insulators were fixed to their pins with litharge and glycerine, which in course of time expanded and caused the insulators to crack. Can the author state what was the particular trouble in the case of the transmission lines of the Lake Coleridge system ?

Mr. C. Rettie: The recommendation that the knowledge of foreign languages should be cultivated is very important. The late Silvanus P. Thompson was a great linguist, and we owe much to him to-day for the knowledge which we possess in more than one scientific branch. I do not wish to question the work done in the laboratory, but it is only by the study of work done by others that any real advance can be made and in this connection the knowledge of at least one or two foreign languages is essential. I should like to add to the author's Bibliography, "Record of Science," by Wm. Warner Bishop, published in *Science*, 25th August, 1922.

[The author's reply to this discussion will be found on page 101.]

North Midland Centre, at Leeds, 27 November, 1923.

Mr. W. M. Selvey: The paper deals with the link between what is ordinarily known as "research," and the process of producing a finished article. For years I have had experience in that kind of work, and have generally found it to be quite unorganized. It is only of late years that an organized system has been employed. The workshop staff in the past have often met with difficulties in translating the ideas of the drawing office into practice, and the result has been the development of what was often known as the "trouble engineer." The experience of this engineer was then fed back to the drawing office. Now it is beginning to be realized that in many classes of smaller apparatus such trouble can be anticipated and corrected before the article leaves the works. Those of us who have been connected more particularly with "Supply" than with "Manufacture" may feel entitled to claim that industry has largely borne the burden and heat of the day, and will, I think, continue to carry some of the load, even if organized research on the author's plan becomes common. On large generating plant and switchgear the supply industry alone can provide the necessary conditions under which important research can be carried out at all. I have in mind the recent experiments at Carville. There is a little difficulty in the author's idea of linking research and development. Sir John Dewrance, in his presidential address to the Institution of Mechanical Engineers, expressed the view that most patents are worthless. Yet the modern stimulus to individual effort often lies in the idea of a sudden discovery and a successful invention that will change the inventor's position rapidly and completely. However idle this idea may be, yet it often remains a fact that even after many co-operative workers have produced by their efforts a fairly satisfactory article, some brilliant suggestion is made which turns it from a qualified to

a complete success. What is the proper reward for such work? If it is nothing beyond the steady salary and the satisfaction of self-sacrifice in research laboratories, then I think that the most individual and brilliant man will still endeavour to work independently. To offset this difficulty there is, however, certainly the asset of preventing the production engineer from dabbling in petty research on his own account, thereby wasting time and money, as has far too often been the case in the past.

Mr. W. H. N. James: It seems to me that if the engineering industry is to make progress in the future we must employ technical and scientific men and use technical and scientific methods to a much greater extent than we have done in the past, and I feel that the importance of this point of view is not often realized. Further, I think there is need to educate the public mind in regard to the value of technically and scientifically trained men. I was very interested in the author's remarks in regard to the qualifications of the research man, particularly in connection with the statement that the man should have the ability to refer matters to first principles. I think that a good many engineers do not realize how very helpful first principles are; a knowledge of first principles, combined with the necessary faith in them, often saves much work or doubt. Occasionally, of course, we may find that the first principle is not effective, but that means that a new discovery has been made. I wish to endorse the author's remarks with regard to the need for completeness in the recording of observations. Definiteness is important, and in this connection the author states that the standard test of a fuse is to connect it across the mains with the containing case connected to the positive, and then to close the switch. This is an example of indefiniteness; the test would be very severe if made near the power house, but much less so if made a considerable distance away. The author states that pure research has been largely done by workers in university and similar laboratories, and I think that technical research also can be done there to some extent if the requirements are made known. In that case, of course, co-operation between the works and the university laboratories is essential, and I feel that there is room for much greater co-ordination between the two classes of workers than often exists at the present time. With regard to the method described by the author for obtaining the time of operation of switches, I had occasion some time ago to test an overload relay. This relay worked off a current transformer, the full secondary current of which was 5 amperes, so that 10 amperes on the relay corresponded to 100 per cent overload. The test was made by taking a double oscillograph and connecting one strip so that current waves through the relay were shown from the moment of closing the switch, the other strip being connected to give a movement when the d.c. trip circuit contacts were closed on the relay. The load on the alternator was very small compared with its total capacity, so that no appreciable change in speed took place on closing the switch, and by taking photographic records and counting the number of waves occurring between the closing of the switch and the closing of the tripping contact, the time of operation was found with considerable accuracy. The lantern slide exhibited by the author showing a galvanometer room, prompts me to ask if he can recommend a type of galvanometer lamp which, while not being too expensive, will permit of use without making it necessary to darken the room materially.

Mr. A. F. Carter: I should like to ask the author what is the relation between the drawing office and research departments. The paper appears to imply that the drawing office has the final word in design, and this may not be advisable. Much could be done by the research department guiding the drawing office in such a point as accessibility. If the draughtsman had to spend, say, a fortnight per annum on practical work in the pit bottom, boiler house and such places, he would no doubt remember the difficulty and would design accordingly.

Mr. S. D. Jones: The building up of the finished apparatus as shown by the lantern slides is a striking illustration of common sense applied to the operations of science. The author lays great stress upon the research engineer, but I feel that a great deal of the success in the examples shown was due to the draughtsman, who would often be still more successful if he were more in touch with the men who had to operate the apparatus. One is often impressed by the simplicity of the final result as compared with the initial design. The plan of perfecting a design before putting it on the market is, I think, the right one, and is the method employed at the Ford motor works. I think that one great secret of success in making plant and apparatus lies in all those who have to handle it being thoroughly familiar with its working; and I consider that Ford's method of training his apprentices is the right one. They enter his training schools at 16, and everything they do in calculations or model- or pattern-making has some direct bearing on the work of motor making and is utilized in the works. Though at school, they are paid for the work which they perform, and thus a sense of reality is given to everything that they do. It has been said that ideas are evolved in England but that very often the Germans develop them and bring them to commercial success. For instance, aniline dyes were first brought out by Sir William Perkins, but chiefly the Germans have developed them. One reason for this state of affairs is that the Germans have a more orderly mind and a greater power of organization for working out things in detail. There is, however, another factor. The author makes a great point of co-operation. In the past the practice of obtaining expert workers at a low salary has been too prevalent; and I once heard the manager of a large works remark that when he wanted a designer for his plant he engaged a "tame mathematician." This ungenerous spirit towards the man of a "brainy" type, who in many cases is not so capable of looking after his own interests as the commercial man is, militates against true development of design in machinery and apparatus. Every type of intellect is required to bring our industrial operations to a higher pitch, and even the ordinary fitter at a bench can give ideas to the research engineer. I think that the author attempts to define too closely the different types necessary to carry out the work of development. This is not practicable with the British type of mind, which refuses to be put into cast-iron compartments. Any suggestion,

no matter by whom it is made, should be tried for what it is worth and, if useful, should be recognized, not necessarily in money, but in some fitting manner. If that were more often done, a greater advance would be made in the industry of our country.

Mr. R. M. Longman: With reference to suggestions from workmen and members of the staff re improvements in method, etc., I have heard complaints from various works of suggestions being adopted without the slightest acknowledgment to the authors of the same. I think that some acknowledgment, whether monetary or merely verbal, would be much appreciated. The author refers on page 64 to a new reversible steam turbine, and I wonder whether it is the same idea that was mentioned to me some years ago. The device would probably work, but undoubtedly with a very low efficiency. It is essential to get the views of those who have to operate the apparatus, as the latter must not only be correct electrically but also of correct mechanical design. It is also essential for research engineers to study both the failures and the successes. The correct idea may be present in the failure, and it may only require proper details to convert the failure into a success. I was very interested in the author's views regarding the keeping and indexing of notes; this is most essential, for although a subject may be fresh in one's mind while one is actually engaged upon it, with so many things supervening it is impossible to carry the details in one's head. I agree with the author as to the use of brick foundations instead of concrete. In some cases it is even advisable to insert a thick layer of rubber.

The Author's Reply to the Discussions at London, Newcastle, Birmingham, Liverpool and Leeds.

Mr. W. Wilson (*in reply*): Before considering the points raised during the discussions, I should like to express my appreciation of the support that the paper has received from the many authoritative speakers in London and the Local Centres. Quite a number of statements and arguments had been included in the expectation that they would meet with considerable opposition, and the sympathetic hearing which they have received has been the more gratifying on this account.

I propose to deal with the discussion under various heads, as follows:—

Scope of the subject.—A number of speakers have criticized the scope of the paper as being either too wide or too narrow; a note as to the former was, however, made in Section XIV ("Conclusion"). It should be pointed out, first, that the intention has been to appeal especially to those manufacturers who have not employed organized development or research, to supply them with arguments why they should do so, and, as far as possible, to provide the information and data needed for such an undertaking. In this, a firm of moderate or small size that would require or prefer to start in a small way was particularly borne in mind. Thus the scope has been made much more comprehensive than will be in order for a larger and more experienced firm that may subdivide and specialize, as indicated by Mr. Fleming. Secondly, the arguments and principles have been illustrated by examples of development from my own personal experience, which has included shell fuses and switchgear, as was explained and set out on page 63. I entirely agree that the exact scope, curriculum, and procedure of development vary according to the type of product developed, as has in fact been clearly stated by Mr. Paterson, and indicated by Mr. Fleming. It will be to the benefit of the industry if this paper is followed by others on the development of specific types of apparatus, of a different nature from switch and control gear. The latter, however, forms a useful example in that full-size models are in general readily made and modified, and thus the full course of development is possible in the laboratory itself.

Nomenclature.—Several suggestions have been made as to the definition of terms employed in connection with research. In addition, minor disagreements have been expressed with statements in the paper, and these have in a number of cases been due to differing interpretations of the terminology. For example, Mr. Paterson objects to my account of the genesis of an idea; but, nevertheless, I find myself in cordial agreement with his statement of the case. Vagueness in the meaning of terms is inevitable in connection with a comparatively new subject, and confusion at this stage is the usual experience. With a view to clarifying matters somewhat, therefore, I venture to express my preference for the terms "Primary or Fundamental," "Secondary or Applied," and "Tertiary or Technical," for the three orders of research as described in Section II, leaving the compact but unsatisfactory term "Pure" out of the list. Scientific research I would define as research in science as distinct from research in history, law, etc.; industrial research as that carried out in association with industry; philosophic research as that undertaken purely for the extension of knowledge; and utilitarian research as that having for its object the acquisition of knowledge of direct benefit to mankind. It will be observed that the last two terms are antithetic, but none the less they differ essentially in motive alone. According to these definitions it is actually possible for a research to be both industrial and philosophic; for it is conceivable that an industrial organization may on occasion permit a research worker to satisfy his own personal inclination in pursuing an investigation along a by-road that promises no immediate financial advantage. It will also be noted that I have used "Development" in Section II, to denote only the "Tertiary" order of research, and do not at all intend the "Primary" to be restricted to non-industrial establishments, the procedure in Section II having indeed been qualified as merely "typical." It is, however, impossible for an isolated works research

department to confine itself to one of these three orders of research, whatever may be the principal object of its existence. I must confess that I do not care for the term "grade" employed by Mr. Creedy, although he has not imparted any ulterior meaning to it. I have, however, heard a speaker stigmatize research connected with a works as "low grade," as compared with "high grade" work done in a collegiate institution. It should be recognized that the whole process of producing a new article, wherever it may be conducted, is carried out by the application of the same principles, by the same type of men, and, as Dr. Garrard has pointed out, by men requiring the same standard of intellect. For these reasons I cannot help regarding this use of the work as offensive, and would prefer to substitute "type" for "grade." Apart from this point I am quite in accord with Mr. Creedy's classification, which amplifies my remarks on this heading.

Relationship between development department and factory organization.—I have been asked by two speakers to formulate the relationship between the development department on the one hand, and the drawing office and other parts of the factory on the other. The general principles should be intimate contact, willing collaboration, and absence of red tape; and the general attitude of the development staff should be that of consultants, who afford advice, information and data when requested to do so. The exact nature and scope of the inquiries depend on the individuals and on the staff organization at the particular factory, but definite rules may be laid down for all cases. These are, first, that communications should be as direct and informal as possible; secondly, that any suspicion of a "superior" or "highbrow" demeanour on the part of the research men must be carefully avoided; thirdly, that problems should, as far as possible, be solved in collaboration with the inquirers, and due credit carefully given to each participant; and finally, that the conversations should be such as to encourage the originating talents of all parties. The last is of especial importance, as has been stressed by Dr. Garrard, for it should now be possible to stimulate such originality and turn it to greater advantage. Section leaders in the drawing office, foremen in the shops, and higher staff members, should be permitted to apply directly to the department, without other formality than the issue of an official report by the latter after the conclusion of the work.

Freedom of communication is of especial benefit to the development staff themselves, for they cannot hope to solve difficulties beyond the powers of the men that are actually doing the work, unless they are completely in touch with this in all its aspects. As has been aptly expressed by Mr. Dunsheath, "where there is contact, there must be fusion and not a fence"; and the same principle has been stated by Mr. Leeson. It is necessary, however, to determine a boundary line, even if it be not rigidly observed, between the functions of the drawing and designing offices and those of the development department, to ensure that the former do not transfer much of their own work and responsibilities to the latter. There are various opinions as to where the distinction should be made, but my own contention is that all routine designing should be done by the factory staff, the word "design" being intended to mean the production of an article from data in hand. Thus a development model is not a design to be merely transferred to paper by the draughtsmen, but is the embodiment of data from which this design can be and should be produced. On the other side of the line, the provision already laid down in the paper and strongly endorsed by Mr. Fleming and Mr. Selvey may be repeated, viz. that all experimenting must be carried out by the development staff. The reasons given in the paper for this rule have not been controverted by any speaker, although the conclusion seems rather to have surprised some members.

A specially close relationship of the same kind is necessary with the routine test-room, for the reason that valuable data as well as inspirations are derivable therefrom. The development staff may be made responsible for the nature of the tests, but, as Mr. Williams has stated, must not be responsible for the carrying on of this section. Development and routine work require different classes of men, and the two functions do not blend. The procedure involved in a typical case would thus be as follows:—The request for information or assistance is made directly by the member of the factory staff requiring this, to the development department, preferably in the form of a note, a duplicate of which may be forwarded elsewhere if so stipulated. Unless the matter is sufficiently simple to admit of a straight-out solution, the appropriate research worker gets into touch with the inquirer and, after discussing the matter fully, carries out the necessary investigation, inviting the inquirer to be present whenever an experimental result is being obtained that would be likely to interest the latter. Upon a conclusion being reached that satisfies the original request, the report embodying this is compiled and sent in. Finally, the drawings (if any) that are got out in accordance with the data supplied are submitted to the development department for endorsement before being proceeded with. This last step complies with Mr. A. F. Carter's opinion as to the drawing office having the last word.

As to the line of demarcation between development and "pure" research, I think this has been stated very clearly and broad-mindedly by Mr. Paterson. I do not consider a development department in general to be the right place for the carrying out of long mathematical investigations; for although I would specify for item $A(1)$ in the training scheme on page 66 a course in mathematics including analytical conics, differential and integral calculus, and elementary differential equations, yet the development worker would ordinarily have too little of this work to do to retain sufficient facility in carrying it out. Hence, when a "pure" research department is available, such work should typically be forwarded to it for solution.

Finally, it must be made clear that the promotion and maintenance of co-operation and concord between the various departments is in the hands of the management. The whole success of a research department in particular depends upon the maintenance of correct relations with the rest of the works, and if this matter

be neglected by those in high authority, efficiency and harmony are impossible. The ideal state of things is for each component to contribute its own share to the work without trespassing on the domains of others, and firm direction alone can bring this about.

Control and jurisdiction.—The question as to who will decide whether any particular item of development shall be undertaken, and whether the resulting product shall be manufactured, has been raised by Mr. Creedy and Mr. Devey. There is no doubt in my mind that the decision as to these points must rest with the management, on the principle that he who pays the piper can call the tune. But the control as to the first point should be of the most elastic possible description, as a research worker is at his best when he is given free rein. With regard to the second, commercial considerations play a great part in the matter. If, however, the development man has gone about his work thoroughly, he will have qualified himself to speak with a considerable degree of certainty on this question, and his opinion should be treated with due respect. For psychological reasons, the shelving of the results of an arduous and successful investigation should be avoided as if it were an actual loss, although the attention of a busy manager may be required when his interest is attracted elsewhere. Mr. Ford's statement that "there is never any demand for a new thing" is widely applicable, and its truth should be borne in mind even by those who will actually profit by the adoption of new proposals. We have it on the authority of Dr. Mees that "It is by no means easy to prevent work which has a real bearing on practical questions being ignored by the practical man to whom it should be of value. The mere filing of a report is not always sufficient, and some method of following up the application of the work is desirable."

With regard to administration, I agree generally with the scheme described by Mr. Devey.

Relationship with the user.—It is natural that the presence of so many supply engineers at the various discussions should bring about many references to the user's point of view. The purchaser is concerned with both ends of the process, for he must be satisfied before he places an order, and he gives the final verdict upon the product after it has been put into service. The great amount of development work carried into effect by users is readily acknowledged, and the establishment of closer relations, to enable greater co-operation to be attained in the future, is hoped for. The sales organization of an engineering firm is the usual medium whereby contact is established and maintained with users generally, and liaison with the former is promoted by the regular supply of information from the development files. Many of the reports are specially written for circulation to them, and most of the rest are indexed in a monthly list, which is circulated to the various branches and from which they can be selected and asked for as required. This will answer Mr. Leeson's query. The close touch advocated by Mr. Creedy, Mr. Devey and others is a most advantageous state of things. It is my own practice to visit users personally in order to secure at first hand the data so obtainable. The valuable nature of suggestions from users has already been mentioned in the paper; and the assurance can be given to Mr. Lawson and other speakers that no criticism from this source is ever treated lightly under my own auspices.

Invoking and dealing with suggestions.—A considerable amount of discussion has been caused by the reference in the paper to the value of suggestions. Like Mr. Fleming's, my own experience of suggestions from the works has not been a very favourable one, as although there is a standing offer of a reward for suggestions adopted, and although such rewards have been given in the past, yet the number of suggestions, useful or otherwise, is very small indeed. This coincides with the experience of the various public Suggestion Boards instituted by the belligerent nations during the war. It has, however, always been my own opinion that the man who is in the best position to make novel suggestions regarding a given operation is the man who is actually engaged upon the work. For example, the machinist should be more likely to discover an improvement in the method of machining than the tool setter, and the tool setter more likely to arrive at an improvement in the tools than the foreman, and so on. Consequently, I was particularly glad to note from the remarks of Mr. Williams and Mr. Devey that it is possible to obtain better results than I have hitherto heard of. I have now no doubt that an atmosphere favourable to invention can be created in the workshop, just as in the design and drawing offices and the development laboratory itself. The system has one or two minor drawbacks, as, for example, when a workman makes a suggestion as to an obvious measure in connection with a new product, which would have occurred to practically anyone and will have almost certainly been already acted upon by the drawing office. Upon the appearance of what appears to be his idea in a concrete form without acknowledgment to himself, he is likely to feel aggrieved, and consider himself badly used. Mr. Devey's method of submitting suggestions to a committee which includes representatives from the workmen themselves would appear to overcome this trouble.

The existence of the development department offers a new means of putting into effect suggestions from various parts of the works. In the past, there is no doubt that would-be inventors have been discouraged, because the trying-out of their suggestions would involve trouble to people who are already loaded with routine duties. Now that the extra work will not fall upon the factory officials but upon the development staff, it should be possible to increase the number and the value of suggestions from the factory generally. With regard to the nature of these suggestions, Section VI of the paper has not been strongly challenged, and I adhere fully to what has been stated therein. Mr. Baker's expectations from "any intelligent artisan" need not, I think, be taken very seriously.

Qualifications and training of staff.—Many speakers have referred to the section dealing with qualifications and training, and have given additional opinions upon this important subject. Mr. Wedmore's preference for a youth who has from his boyhood shown signs of a creative mind and has been accustomed to make things for himself, appeals to me very much, and I consider

this aptitude to be a sure sign that the youth is of the right material. The value of making things has also been mentioned by Prof. Marchant. Like him, I consider this to be one of the most promising traits in the character of a budding engineer, and one that will also stand him in excellent stead when he goes into the works to obtain his real experience.

Mr. Melsom and one or two other speakers have stated that a university degree is not essential, and I would draw their attention to the wording of the paper on this subject, especially the use of the expression "of university status," and also the deduction that "a university degree *or its equivalent*" is indicated, in Section VI. I should be far from attempting to show that a degree is the only reliable proof of a research worker's fitness for his duties, or even that a university is the only place where the qualifications stated in Section VI can be obtained. What I do say, however, is that a youth of to-day who considers that his talents lie in the direction of research, and who wishes to fit himself for this work, should by all the means in his power endeavour to secure the necessary training by taking such a degree. Mr. Higgs's support of this standpoint is especially appreciated. It should not be overlooked that, in Section V, I have laid down stringent rules for the practical experience a research man should have, in addition to his theoretical training.

Prof. Marchant has referred to the language training which forms part of my curriculum, and mentioned that some famous investigators in the past have not been gifted in the direction of lucidity of expression. However, in the functions which a development worker has to fulfil, I consider that this qualification is of special importance, as he is there largely to afford useful information to the staff of the factory and its outside organization. This he cannot efficiently do unless he is able to put his meaning into easily understood language. Mr. Rettie has also pointed out the great practical advantage of having access to information which may have been published in foreign languages.

In my curriculum I had intended "Applied Electricity" to be included under "Electrical Engineering."

Facilities and conditions for research.—The great facility required for development is, as Mr. Wedmore has said, that for making real tests. Some of these may appear to be unduly expensive or troublesome when proposed, but all my experience goes to prove that it is far cheaper in the end to make them in the laboratory than to suffer for their omission afterwards. The value of incentive and credit to research workers has been rightly emphasized by Mr. Woodhouse and Mr. Williams.

Mr. Selvey has referred to the importance of anticipating trouble before an article leaves the works. This policy of anticipation is the great feature of technical research work, and is most valuable when it prevents trouble before the articles reach the routine test-rooms or even the drawing office. This can be readily accomplished when the development work is continuous, as distinguished from "hand-to-mouth." If no communication is made with the development staff until trouble arises, and if the whole case has then to be inquired into and digested, the necessary data secured, and the investigation carried out, under these conditions all has to be done in the shortest possible time, and thus at the greatest possible inconvenience and at the lowest efficiency. If, however, the department is continuously supplied with manufacturing data and details of performance by the rest of the works, as laid down in the first column of page 64, then these panic conditions are very largely obviated; probable defects are anticipated and their remedies proposed, probable wants are foreseen and satisfied, and, in general, most of the trouble is intercepted before it has caused waste of time or materials.

Remuneration of research workers.—The question of payment for research was not dealt with in the paper, but has been broached by quite a number of speakers. While agreeing in the main with what Mr. Selvey and others have said regarding payment by results, I do not think that anything resembling "piecework" remuneration is practicable in the case of investigators, or even desired by them. On the one hand, they are not a mercenary class, and the most powerful incentive that can be given them is practical appreciation of the results of their work, in the shape of utilization and verbal acknowledgment. On the other hand, they recognize that it is their function to make discoveries and inventions, and that this is covered by their salaries. The appropriate way, then, of paying by results, is to adjust the salaries from time to time as their value to the firm increases. This scheme should not, however, prevent the award of an occasional bonus when a piece of work of special advantage to their employers has been effected.

With regard to the amount of the salaries, I welcome Mr. Wedmore's statement that an engineering business should have development engineers among the most highly paid members of its organization. The practice mentioned by Mr. Jones of referring to their kind as "tame mathematicians" is comparable with the traditional refusal on the part of a successful manufacturer to send his son to college, because he could "buy all the brains he wanted in his business for three pounds a week." Such an outlook is a suicidal one, for an investigator is utterly incapable of exercising his mental faculties efficiently if his mind is already occupied with financial worries or discontent, or is not afforded adequate relaxation. There are few other professions in which the output is so directly influenced by the input as in the case of industrial research, and generous treatment is therefore a matter of policy as well as of ethics.

Industry and the universities.—It has been generally agreed that greater co-operation between the universities and industry will be productive of nothing but good. Each has its special sphere for research work. The calmer atmosphere of a college laboratory, and a liberal provision of philosophical instruments, conduce to thoroughness of consideration and of experimental proof; while the activity of a factory and the accessibility of large apparatus and supplies of power induce enterprise and practicalness. As has been pointed out by Prof. Cramp and Mr. Combes, there should be no fear of harmful overlapping on this account. It is not, in general, possible for a college to carry out

development work for a manufacturing firm, partly because this species of research chiefly deals with those features of the firm's products that are peculiar to itself, and which it would therefore be least willing to share with competitors. A certain amount of secrecy is therefore necessary, which under ordinary circumstances would not be practicable in a teaching institution. This is, however, actually carried out in the United States by the Mellon Institute's scheme of industrial fellowships, described in some detail in "Research and Industry" (see Bibliography), and briefly by Mr. Kilburn Scott in his contribution to the discussion.

In reply to the inquiry of Mr. Malpas, the insulator trouble in connection with the Lake Coleridge hydro-electric scheme, overcome at Canterbury University College, was due to porosity of the porcelain, which was only made evident by subjecting the material, while immersed in a dye, to a pressure of 1 500 to 2 000 lb. per sq. in. for a period of 7 days.

I am much interested in the question raised by Prof. Cramp of providing works experience for students as I have twice formulated schemes for this, under radically different circumstances, both of which gave results entirely satisfactory to the parties concerned. My convictions are expressed in the following conditions. On the part of the students, there must be a real determination to play their part in the works, by identifying themselves for the time being with their fellow workers, laying "swank" on one side, doing, if anything, more than their share of the work, and not asking for any privilege that is denied to their companions. On the part of the firms, there must be a greater willingness to take in men who agree to the above, to give them the highest justifiable responsibilities, and to afford them an interest in the work by paying them something of what they are worth. I am not overmuch enamoured of the usual "pupil" course, on account of the large element of privilege inseparable from it, which not only reduces the value of the experience but also largely cancels the value of the youth to the firm. Thus the number of such appointments that an undertaking is willing to make is seriously limited; and an appointment tends to become a favour to be conferred on those having special claims on the firm.

The principle of putting newcomers to a works laboratory into the shops for preliminary experience I regard as being sound in every way.

Co-operation and co-ordination.—The value of co-operation and the need for its fullest possible extension have been generally endorsed, and I particularly welcome Mr. T. Carter's remarks in this connection. Speakers in every Centre where the paper has been read have expressed appreciation of the work of the Electrical Research Association, not only in carrying out valuable research work on its own account but more especially in promoting co-operation between manufacturers, universities, and power supply authorities. In numerous fields of electrical work, economy and increased reliability have already resulted directly from its work, notably in the safety of mining apparatus, underground and overhead transmission, insulating materials, and high-tension switchgear. I was particularly impressed with the success of the negotiations with the supply authorities at Carville, and with the thoroughness, care and ingenuity that characterized the tests upon makers' own oil switches there. The data cannot fail to be of great assistance to designers, and it is to be earnestly hoped that these tests will be proceeded with on an increasing scale as regards breaking capacity. The Association is rapidly becoming essential to the whole electrical industry, and deserves the full support of every constituent member.

When the co-operative principle is pushed to its furthest limit, it includes co-operation between engineers of different nationality. I see no harm, but good, in the interchange of designs as mentioned by Mr. Fleming, as long as it does not lead to deterioration of initiative on our part.

Secrecy versus publication.—Where the motive for the abandonment of secrecy is the furtherance of co-operation, I am in agreement with those speakers who advocate publication. That the firm with which I am connected is not ungenerous in this respect is made evident by my having been enabled to write the present paper, as well as that on liquid rheostats and several articles in the technical Press, publishing data that had been obtained at considerable expense; and I think their generosity deserves this acknowledgment. One cannot help suspecting, however, that the desire to get something for nothing sometimes actuates those who denounce secrecy. I have remarked above upon the impossibility of giving away all the results of development.

Small firms and research.—As Dr. Kahn has pointed out, development was assisted abroad by the earlier organization of industry under the auspices of large firms. But I think that Mr. Collie and Mr. Meyer exaggerate the position when they assert that research is only possible for a big concern. A numerical instance may help to make this clear. Let it first be supposed that a small firm risks putting a new development upon the market, and manufactures a batch of 50 articles; and, further, suppose that their judgment was at fault, the market absorbing these only with difficulty. In this case the firm has incurred no other loss than the abandonment of its design. But if a larger firm be supposed to have turned out the same article, to the extent of 500, then if only 100 were sold (the market being the same for both firms) they would now incur an additional heavy loss due to the serious amount of dead stock that must be written off. Thus the smaller the firm, the more flexible and enterprising it can be, and therefore the more it is likely to gain from development. The cost of the latter can be borne like any other overhead charge. It is the rule in such cases, as Mr. T. Carter has pointed out, for one of the heads of the firm, such as the chief engineer or even the managing director, to superintend development work personally, and in this way the financial conditions are met.

Research work during slump conditions.—There is no difficulty in proving that development work should be carried on when trade is good, but opinions are certainly not unanimous as to its furtherance in times of slump. The natural tendency on the part of financiers would be to reduce it then to a minimum, in common

with other overhead expenses. But if it is of advantage, when times are good, to remove all non-standard work from the shops, and worry and uncertainty from the designing staff, it is surely more necessary to do so when times are bad, and when not only is economical working in the factory specially desirable, but also many special orders have to be entertained, each requiring individual attention. These arguments would seem to indicate that development work should be increased during slump conditions, and this is actually what Mr. Pearce's suggestion of "load equalization" amounts to. Surprising though it may be at first glance, the latter policy is the correct one. It should be realized that the effect of development work is lasting, and does not vanish when the articles that originally called for the particular investigations are sold. Research is thus equivalent to the putting by of capital, and capital that will return a high rate of interest. A slump should therefore be regarded as a time of storage, and a fund should be reserved for this special purpose. In addition, an extra value is attached to slump research, as it is carried out under conditions of stringency and therefore when the research workers are on their mettle. It is well known that other originators, such as poets, musicians and artists, often do their best work in times of stress, and it may well be that a slump is in reality a period of opportunity instead of misfortune.

Standardization, mass production and research.—Mr. Higgs has laid stress upon the necessity for industrial research in connection with repetition work, and Mr. Morton instances the facilitation of research by standardization. It is of advantage, when dealing with any one of these three principles, to realize that all are phases of the same movement. It is most important that research and standardization should go hand in hand, and the introduction of the further principle of specialization results in mass production. I had endeavoured, in the first part of Section V, to prove the importance of development in a factory where nothing but repetition work is carried on, although it might seem to the uninitiated that such a works would not need any form of research.

Cost of research.—The question of research costs has been mentioned by Mr. Fleming, Mr. Pearce and Mr. Leeson, the first of whom gave an estimate of 3 to 5 per cent of the turnover as a fair proportion to be devoted to research. It is a necessary feature in the organization of a department that the cost of upkeep should be placed on a proper basis, and I consider that these figures are about correct.

General.—A few points have been raised concerning accessory details in the paper.

The soundness of getting down to first principles has been endorsed by Mr. James, while Mr. Jones has referred to the frequently surprising simplicity of the final result as compared with the initial design. One learns to value the attitude expressed in both of these opinions the more in that it is not in accordance with human nature. A layman tends to undervalue an investigator's more successful work because of its greater simplicity; his reasoning because it is too childish; his explanations because they are too lucid, his calculations because they are too elementary, his designs because they appear too obvious. Yet the facts are as indicated by Mr. Paterson in "The Physicist in Electrical Engineering" (see Bibliography), that "The better the physicist, the simpler the terms of the explanation."

Mr. Melsom has provided some intimate details for testing fuses, and the same matter has been mentioned by Mr. James. I think they will realize, if they refer again to the context, that the fuse test was introduced merely to illustrate the requirements in design, and consequently it was not in order to dilate upon an unimportant side-issue, when the matter could be summarized with sufficient accuracy by the three lines that I employed.

In connection with examples of development shown in Appendix II, Mr. Baker should note that, as I have already indicated in introducing them, their insertion was not intended to display ingenuity but to illustrate the principles laid down. The feature of interest in connection with the brake pulley in Figs. 2 and 3 is again not this method of absorbing power (which was familiar to some of our grandfathers) but the device employed for injecting and ejecting the cooling water with the certainty of avoiding a mess.

In reply to Mr. Leeson, the oil-testing apparatus in Fig. 6 was designed for dealing with small samples of oil received by post from distant clients. When a sufficient quantity of oil is available, the more usual apparatus has always been employed. It should be noted that this device was designed and used before the B.E.S.A. dealt with the matter, and was actually included in the paper before the present standard apparatus was published. None the less, I dissent from Mr. Leeson's opinion as to its unreliability. The pressure recorder in Fig. 5 has hitherto been employed principally for obtaining comparative results, and it can be regarded as being perfectly accurate for such readings. Used in this way, the pressures developed by various explosive mixtures, in various pieces of apparatus, employing various relief devices, and with other variations, can be accurately compared with one another, and, if necessary, with the pressure required to burst an apparatus. However, there are no more factors introducing error in it than in the steam- and gas-engine indicators, which are regarded as precision instruments. Consequently, I estimate its absolute accuracy as being within about 5 per cent.

Mr. Leeson and Mr. Parry have commented on the possibilities of error in the instruments on the test board of Fig. 1, due to heating or stray fields. The meters are situated so far from either rheostats or conductors carrying a heavy current that these effects have been found to be quite negligible in practice. The high-reading ammeter is supplied from an instrument transformer at nearly floor level, none of the heavy-current wiring being above the height of the bench top. The accuracy attained with this set is fully equal to the requirements. Instruments are, however, checked on a special bench in a test room provided for highly delicate work, and containing the oscillograph. I agree with Mr. Parry as to the utility of the latter, but in its present forms it is hardly convenient enough for factory work that can be adequately carried out by such apparatus as that shown in Fig. 4.

Mr. Leeson's example of technical research, shown in Fig. A, is very interesting.

In reply to Mr. James's inquiry regarding a galvanometer lamp for daylight work, the practice I am familiar with is to employ a translucent scale, and a gas-filled lamp of the motor-headlight pattern, of 24 watts' capacity and working at 12 volts.

I was interested to find that Mr. Longman had come across an instance of futile development similar to mine in connection with steam turbines. It may, in fact, have been the same case, though the turbine seems strangely susceptible to such misdirected enterprise, and the two are probably distinct examples. Another case almost identical with my own experience was recorded at about the same date in the American publication *Power*.

THE WHIRLING OF SHAFTS.*

By Julius Frith, M.Sc., Member, and F. Buckingham, B.Sc.

(*Paper first received 14th August, and in final form 29th October, 1923.*)

Summary.

The paper is an attempt to explain the phenomenon of whirling by proving that it is essentially a case of vibration and obeys the laws of vibration, especially those relating to the phase change between the disturbing force and the resulting displacement.

Whilst acknowledging that the critical speed of whirling is usually calculated by the same expressions as those which give the natural time of vibration, it is maintained that the identity of the two phenomena is not sufficiently recognized. To prove this, the case of the spring-controlled governor is cited, which, according to the ordinary treatment of whirling—equating the centrifugal and the elastic restoring forces—should come in again above a certain speed.

A description is given of experimental verifications of the theories put forward.

Introduction.

In spite of all that has been written on the whirling of shafts, it is doubtful if the mechanism of the phenomenon is generally understood, and this paper is put forward in the hope of clearing up certain points which may remain obscure after a study of the more elaborate but in many respects inadequate treatments.

Some years ago one of the present authors, in conjunction with Mr. E. H. Lamb, read a paper on the torsional oscillations of shafts.† We now wish to extend a similar treatment to the whirling of shafts, as it has been impressed upon us very forcibly that the usual treatment is inadequate in that, whilst giving correct numerical solutions, it quite fails to explain the mechanism by which the results are obtained.

A very simple example will serve to illustrate our meaning. In Fig. 1, AB represents a vertical shaft carrying a mass M at its centre and supported in spherical bearings at A and B. The shaft is very slightly bent so that on being *slowly* revolved, the above mass would rotate in a circle of radius r. Let the stiffness of the shaft be defined by saying that it would require a force F applied to the mass M to displace it 1 foot.

Exactly the same effect is produced if the shaft is straight and the mass M is slightly eccentric. The distance r would then be measured from the centre of rotation to the centre of gravity of the mass.

Now let the shaft be rotated at a speed of n revolutions per second ($= 2\pi n$ radians per second $= \omega$). The usual textbook treatment of this would be to say that the mass M will now fly out and revolve in a circle of radius, say, $d + r$, and to write

$$M\omega^2(d + r) = Fd$$

from which
$$d = \frac{M\omega^2 r}{F - M\omega^2}$$

and
$$(d + r) = \frac{M\omega^2 r}{F - M\omega^2} + r$$

If the value of this expression is plotted against n, it increases until $n = (1/2\pi)\sqrt{(F/M)}$, when it is infinite, and if the curve is further extended on the assumption that the expression still holds when $M\omega^2$ is greater than F, the value is reduced and ultimately becomes less than r.

In actual fact it is found that the whirling shaft has its maximum displacement when $n = (1/2\pi)\sqrt{(F/M)}$, and that at higher speeds the displacement diminishes to something less than the initial eccentricity. The shaft therefore runs truer at speeds above the critical than at those below. These are results to which those obtained from the foregoing expression bear a superficial resemblance, but it will be shown that at no speed does the expression give the true displacement, and the

* The Papers Committee invite written communications (with a view to publication in the *Journal* if approved by the Committee) on papers published in the *Journal* without being read at a meeting. Communications should reach the Secretary of the Institution not later than one month after publication of the paper to which they relate.

† J. Frith and E. H. Lamb: "The Breaking of Shafts in Direct-Coupled Units, due to Oscillation set up at Critical Speeds," *Journal I.E.E.*, 1902, vol. 31, p. 646.

method of its derivation does not justify its application to the problem of whirling at all.

To those who uphold the treatment let us put this question: The expression as derived being perfectly applicable to half of a very common type of steam-engine governor, is it contended that such a governor would, beyond a certain definite speed, close in again and allow more steam to pass? If so, then here is a most interesting explanation of many flywheel accidents. We have, however, tried the experiment and have ascertained that, for such a governor, the mass M moves further and further out for speeds up to *and beyond* what would be the critical value, so that this handling of the problem, as far as the running of shafts above their critical speed is concerned, is utterly discredited.

Some authors take refuge in some such phrase as "above the critical speed the system tends to rotate about its centre of mass," which, although true as a statement of fact, by no means constitutes an explanation.

It has long been recognized that the critical speed,

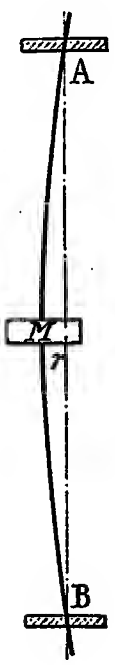

Fig. 1.

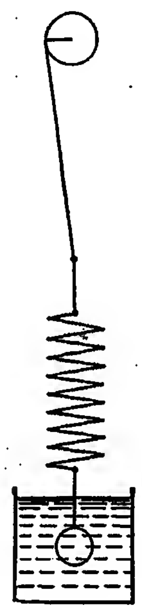

Fig. 2.

as given above, is also the number of oscillations per second at which the shaft would vibrate if plucked like a fiddle string, and this gives the clue to the correct explanation of the facts. For imagine the above shaft not to revolve but to be subjected to a periodic disturbing force of gradually increasing frequency. At frequencies much below the natural frequency of the shaft, these disturbing forces would produce little effect; this would be so until the frequency of the disturbing force nearly equalled that of the system composed of the shaft and its attached mass. When the two frequencies were equal, the amplitude of the motion of the mass M would increase until, if there were no friction, sufficient energy at that frequency would be stored up to break the shaft, or otherwise until the resulting friction absorbed all the available energy.

If, however, the frequency of the disturbing force were still further increased, the amplitude would gradually decrease until, when the force had a frequency many times that of the shaft, the latter would again be practically at rest.

But this description leaves out of account some other very interesting facts, an understanding of which is essential for the other problem. There is, for instance, a change in phase between the disturbing force and the motion produced, and this can be better illustrated by a slightly different example.

Imagine a mass suspended in oil by a spring, as in Fig. 2. If the other end of the spring is moved very

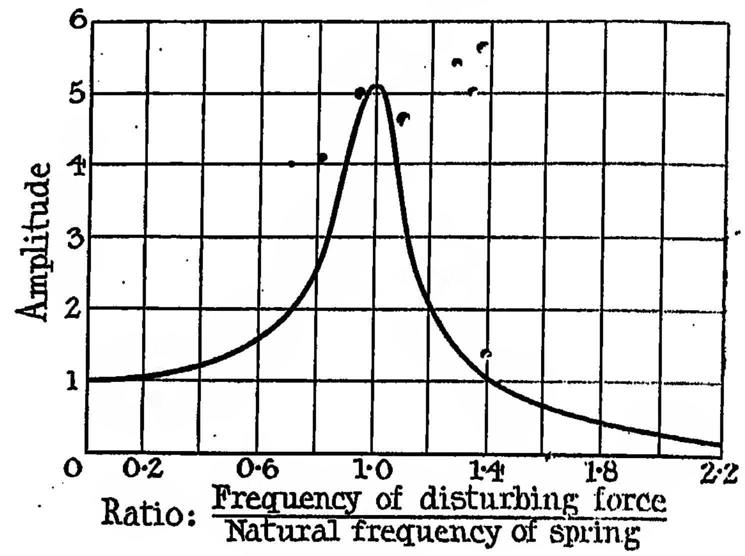

Fig. 3.

slowly up and down, then the mass will move up and down, not only with the same amplitude but *in phase with* the force acting on the other end of the spring. As the frequency of the motion becomes greater, the amplitude will increase and a change of phase will take place between the top of the spring and the mass. If the motion of the top of the spring be caused by the

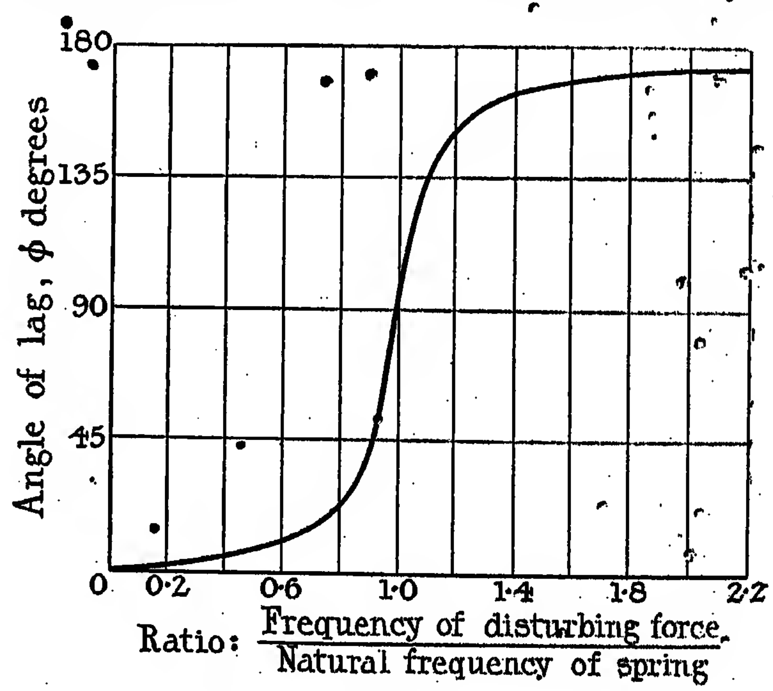

Fig. 4.

rotation of a crank, then the motion will be harmonic and the crank will indicate its phase.

The resultant motion of the mass will also be harmonic and may be considered as the projection of a revolving vector, which will in turn indicate the phase of the motion of the mass.

If the stiffness of the spring be defined as the force F required to extend it by unit distance, then at a

critical speed $(1/2\pi)\sqrt{(F/M)}$ the amplitude will be very nearly a maximum but will not be infinite owing to the friction of the oil. The phase difference between the force acting on the top of the spring and the motion of the mass will now be 90° and will approach 180° as the frequency of the disturbing force becomes greater than the critical value.

The value of the amplitude for a particular case is plotted in Fig. 3 in relation to the frequency of the disturbing force, taking the motion of the crank as unity. This figure cannot represent the gradual change of phase, and it is best, therefore, to neglect sign altogether in this figure and take it from the curve in Fig. 4.

It is generally recognized that there is a resemblance between whirling and vibration, and the usual method of obtaining the critical whirling speed is to calculate the natural frequency of transverse vibration of the system. We propose to show that this coincidence is not accidental, that the phenomenon of whirling is essentially one of vibration, and that only when whirling is so regarded is the stability at speeds above the critical satisfactorily explained.

The Shaft in Transverse Vibration.

Let us set the shaft AB vibrating *in one plane* by applying to it a periodic disturbing force of maximum value x, and study the various quantities involved. The shaft will, of course, vibrate with the frequency of the disturbing force. Call the time of one complete vibration T, the half amplitude A, and the coefficient of friction μ.

The whole state of vibration is maintained by the disturbing force, which has therefore to provide for several different things. It has first to provide a component to overcome FA, the stiffness of the shaft. This component must have a maximum value equal to FA but acting in the opposite direction, i.e. outwards, and the maximum would occur at the ends of the swing, when A is a maximum. Having overcome the stiffness of the shaft, it must provide a component to give the mass M its acceleration. The maximum value of this would be $4\pi^2AM/T^2$, which would also occur at the ends of the swing but would act inwards. Lastly, the disturbing force must provide a component to overcome friction. Not knowing what law the friction obeys, we will write the force to overcome it as $\mu \times$ velocity, which is probably very near the truth. It will have a maximum value of $2\pi A\mu/T$ at the centre of the swing.

Knowing all its components, we can now add them together and find x, the maximum value of the disturbing force. Below the critical speed the vector diagram will be as Fig. 5 (*a*). In this figure the values represent the maximum values of the various quantities, ω being written for $2\pi/T$. The one marked x is the maximum value of the disturbing force. It is seen resolved into its three components, FA, $M\omega^2A$ and $\mu\omega A$, which are all jointly necessary to keep the shaft vibrating.

FA is in phase with A (the displacement) and therefore points to the actual position of the shaft in space, which is seen to be out of phase with the disturbing force by an angle ϕ, the tangent of which is $\mu\omega/(F - M\omega^2)$. This is the angle shown in Fig. 4.

At the critical speed the vector diagram would be as shown in Fig. 5 (*b*) when $FA = M\omega^2A$ and $\mu\omega A = x$. In fact, the amplitude increases until this equality is effected, when equilibrium is established; but for μ, A would be infinite.

At speeds above the critical, conditions would be as shown in Fig. 5 (*c*). It is here seen how far the motion has got out of phase with the disturbing force.

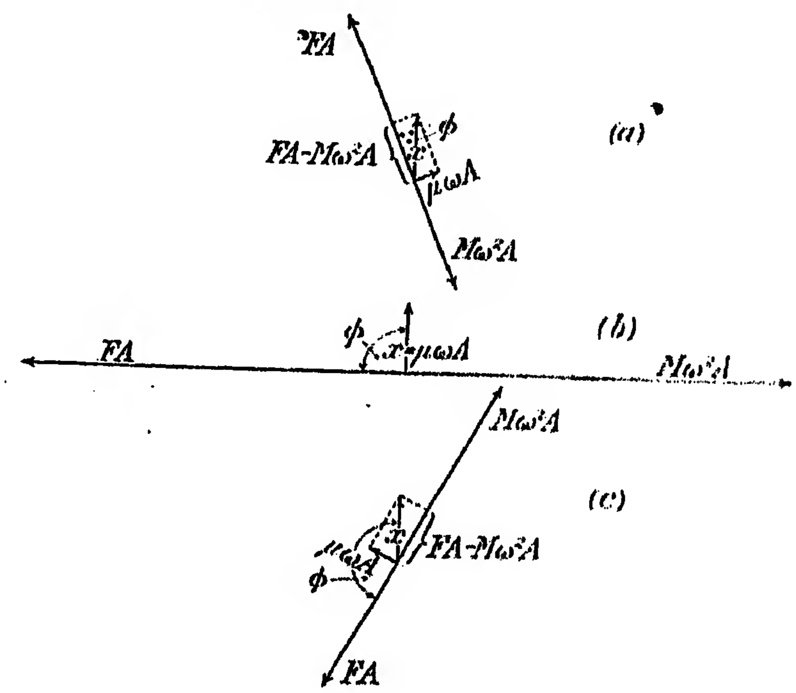

Fig. 5.

If μ is comparatively small, A is a maximum when $\omega^2M = F$, i.e. when $T = 2\pi\sqrt{(M/F)}$, which is of course the time of natural vibration of the system.

From the figures it will be seen that in all cases the following relations hold:—

$$x = \sqrt{[(FA - M\omega^2A)^2 + (\mu\omega A)^2]}$$

$$A = \frac{x}{\sqrt{[(F - M\omega^2)^2 + (\mu\omega)^2]}}$$

The Shaft in Whirl.

If the same shaft AB is now revolved, $M\omega^2r$ will supply the disturbing force, the maximum value of which we have called x.

As the speed is varied, this force varies only as ω^2, r remaining constant. It is the existence of the original eccentricity r which is the whole cause of the whirl; further elastic deflections take place under the combined actions of centrifugal force, the stiffness of the shaft and friction, but all this happens over and above the original motion in a circle of radius r. This is made clear in Figs. 6 [(*a*), (*b*), (*c*) and (*d*). The action of the crank moving the top of the spring in Fig. 2 is now represented by r in circular motion. The motion of the mass is sometimes greater and sometimes less than r, but r is always present in it, even though M ceases actually to revolve at that radius.

The value of the disturbing force due to r is $M\omega^2r$ and increases as ω^2. This force will give the shaft

a circular vibration which may be resolved into two rectilinear vibrations at right angles. In case this circular motion cannot be recognized as a vibration, a very simple experiment will be convincing. Fix a hatpin by its point in a vice or drive it into a bench; it can be set into rectilinear or circular vibration at will, but the rectilinear motion will often end in being more or less circular. If, when vibrating in a circular path, its shadow be projected by two lights on to two planes at right angles, the two rectilinear components of the vibration will appear. As the inverse of this, a harmonograph will combine two rectilinear vibrations into circular motion.

We can therefore write the same expressions as before for each of the two components at right angles of the whirling shaft.

All the quantities which varied harmonically in the case of rectilinear vibrations now become revolving vectors of constant length, pointing to the various positions of the shaft in space. The vector $M\omega^2 r$ points to the original position of M on the bent, unstrained shaft, and Fd to the actual position of the shaft in space.

Regarded from the point of view of the elastic displacement alone, all these vectors revolve from a centre where $d = 0$, d being the elastic deflection of the shaft caused by the rotation—as distinct from the permanent set r. The starting point of d in the actual combined whirling motion is on the circumference of a circle of radius r. Then

$$d = \frac{M\omega^2 r}{\sqrt{[(F - M\omega^2)^2 + (\mu\omega)^2]}}$$

ω is equal to 2π times the revolutions per second and is sometimes called the "circular frequency" of the disturbing force. It is sometimes useful to write α for 2π times the natural frequency of the system, of which the time of one complete vibration, $T, = 2\pi\sqrt{(M/F)}$, M being as before the moving mass and F the restoring force per unit displacement.

The natural frequency $= 1/T = (1/2\pi)\sqrt{(F/M)}$, from which $\alpha = \sqrt{(F/M)}$ and $F = M\alpha^2$.

Making this substitution in the above expression for d, we obtain :—

$$d = r \times \frac{\omega^2}{\sqrt{[(\alpha^2 - \omega^2)^2 + (\mu\omega/M)^2]}}$$

If $[(\mu\omega/M)]^2$ is very small, as it is likely to be in most practical cases, then $d = r \times \omega^2/(\alpha^2 - \omega^2)$.

The actual motion of the shaft in whirl is a circular vibration compounded of two of these rectilinear vibrations at right angles, plus the rotation in the radius r due to the shaft being bent; the radius R of the path of M through space being compounded of d, the half amplitude of each of the two vibrations, and r, the original eccentricity, which causes the disturbing force, these two being at the angle ϕ to each other, as shown in Fig. 6.

The application of the various forces is of course on the mass M, the restoring force of the shaft along the line d, the centrifugal force which is compounded of the disturbing force $M\omega^2 r$ and the acceleration to the centre of vibration $M\omega^2 d$ radially along R. Similarly, the total frictional force is circumferentially at right angles to R.

The frictional resistance is $\mu\omega R$ and has a moment $\mu\omega R^2$ round the centre of turning, this moment being counteracted by the torsional stiffness of the shaft. If we express this as the torque required to twist the shaft through 1° and call it f, then the friction will cause the shaft to twist through an angle

$$\frac{\mu\omega R^2}{f} = \theta \text{ (say)}$$

This angle will, in general, be very small.

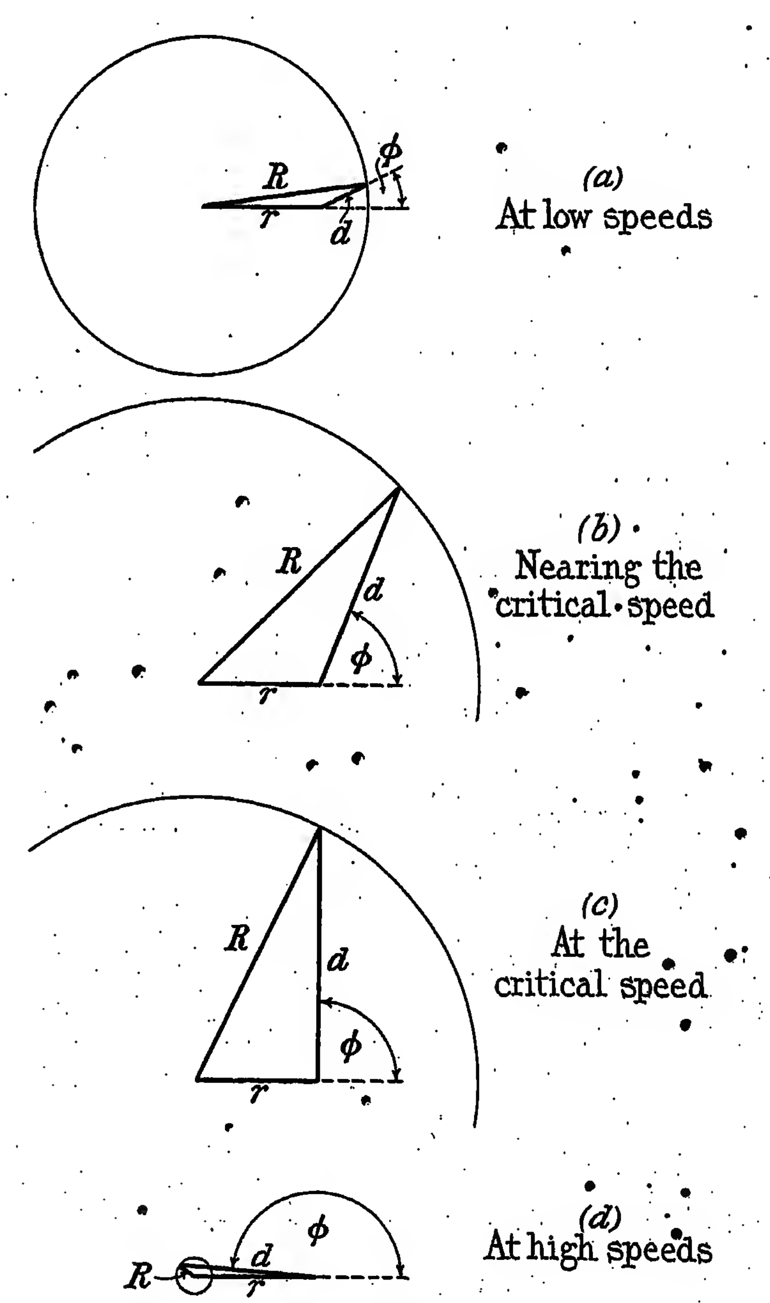

Fig. 6.

The energy to overcome the friction will be derived from the prime mover, as from it comes all the energy to maintain the state of vibration.

We can now represent in a figure the shaft in whirl at various speeds, all at the same angular position, say, when the disturbing force $M\omega^2 r$ (which is due to, and in phase with, the original eccentricity) acts in one particular direction (see Fig. 8).

A numerical example may help to make this clear.

Let $M = 100$ lb.
$F = 10\,000$ poundals per foot of deflection.
$r = 0\cdot01$ foot.
$\mu = 500$, i.e. it would take a force of 500 poundals to move M at 1 foot per second.
$f = 1\,000$ foot-poundals per 1° twist.

Then d, the elastic deflection due to being revolved at ω radians per second, would equal

$$\frac{100 \times \omega^2 \times 0\cdot01}{\sqrt{[(10\,000 - 100\omega^2)^2 + (500\omega)^2]}}$$

The critical speed will be when

$$\omega = \sqrt{\frac{F}{M}} = \sqrt{\frac{10\,000}{100}} = 10 \text{ radians per second}$$
$$= 95 \text{ r.p.m.}$$

ω	Speed	d	ϕ	R	θ
rads./sec.	r.p.m.	ft.	deg. min.	ft.	degree
1	9·5	0·0001	2 52	0·0101	0·00005
5	47·5	0·0032	18 26	0·013	0·0004
7	67	0·0079	34 37	0·017	0·00102
9	86	0·0166	66 57	0·022	0·0023
10	95	0·02	90	0·022	0·0025
11	104	0·0205	110 53	0·019	0·0021
15	143	0·0155	149	0·009	0·0006
20	190	0·012	161 34	0·004	0·0002

These are plotted on Fig. 7, from which is drawn Fig. 8, which is a combination of Figs. 6 (a), (b), (c) and (d).

Fig. 6 will explain why, when balancing, say, a rotor by running it in spring-controlled bearings until it runs out and marking the place with chalk, the correct position for the balance weight is not opposite the chalk mark but is behind this position. The chalk mark will be at the end of the radius R, while the correct position for the balance weight is on a radius opposite to r.

A knowledge of the angle ϕ would certainly help to determine the correct position for the balance weight, and so save time over this operation.

One of the reasons why the expression first given fails to represent the behaviour of the centrifugal governor now becomes apparent. The forces Fd and $M\omega^2(d + r)$ are not mere scalar quantities but are revolving vectors. It is because the governor works in rigid guides, which prevent the various forces taking up their correct relative phase relationships, that it fails to show the peculiarities of a whirling shaft.

Another way in which the first expression was quite at fault was in assuming that if the original permanent set of the shaft was r and the bend due to the fact that the shaft was rotating was d, then the total bend of the shaft was $(d + r)$ and the restoring force $F(d + r)$. In actual fact d and r are seldom in the same direction and the restoring force may be anything from $F(d + r)$ to $F(d - r)$, and only in these two extremes (which occur at zero and infinite speeds respectively) does it pass through the centre of rotation.

In ordinary transverse vibration there exists an alternating strain in the material of the shaft which absorbs energy and fatigues the material. When two vibrations combine with a rotation to make a circular whirl, the strain no longer alternates but is fixed and constant for any particular speed, so that the air resistance is all there is to limit the amplitude of the whirl. This looks very small but it must be remembered that the disturbing force $M\omega^2 r$ is also generally very small.

It is, of course, very rarely safe to run for any length of time at the critical speed unless steps are taken to increase the friction by some means.

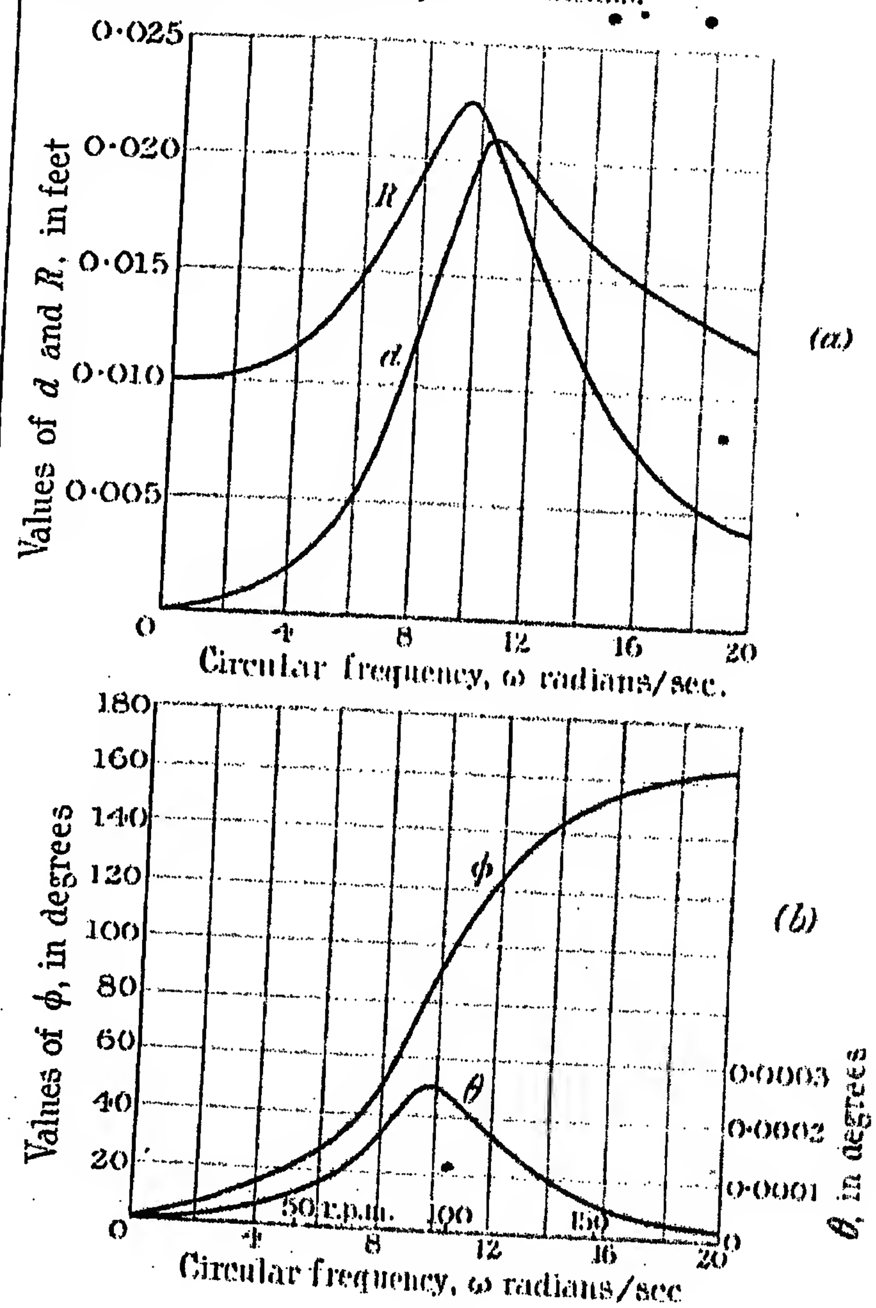

FIG. 7.

All the above remarks refer to a vertical shaft. The case of the horizontal shaft presents some additional interest; this shaft is deflected by the force of gravity by an amount equal to Mg/F.

At speeds under the critical, the shaft will not straighten itself but will continue to sag while revolving.

It is important to realize that although the shaft appears to keep the same form and to be stationary in space, it actually bends during each revolution. The material of the shaft is subjected to an alternation of strain, the only difference between this and the case

of simple vibration being that here the strain travels round the section instead of across a diameter.

In changing from a rectilinear vibration to a circular whirl, two of the fundamental properties of vibration become hidden. In a rectilinear vibration the material of the shaft suffers an alternation of strain from a maximum at the ends of the vibration to zero in the centre. In a similar way, the energy of the mass changes from all potential at the ends of the vibration to all kinetic when passing through the position of rest.

In adding two rectilinear vibrations at right angles to form a circular vibration the material of the shaft still suffers an alternation of strain, but the mass appears to lose its characteristic change in energy from potential to kinetic, and vice versa, it being now endowed with uniform circular motion.

On further adding a rotation, of a speed equal to the frequency of vibration, the shaft no longer suffers alternation of strain, each portion of it having a strain fixed in direction and amount.

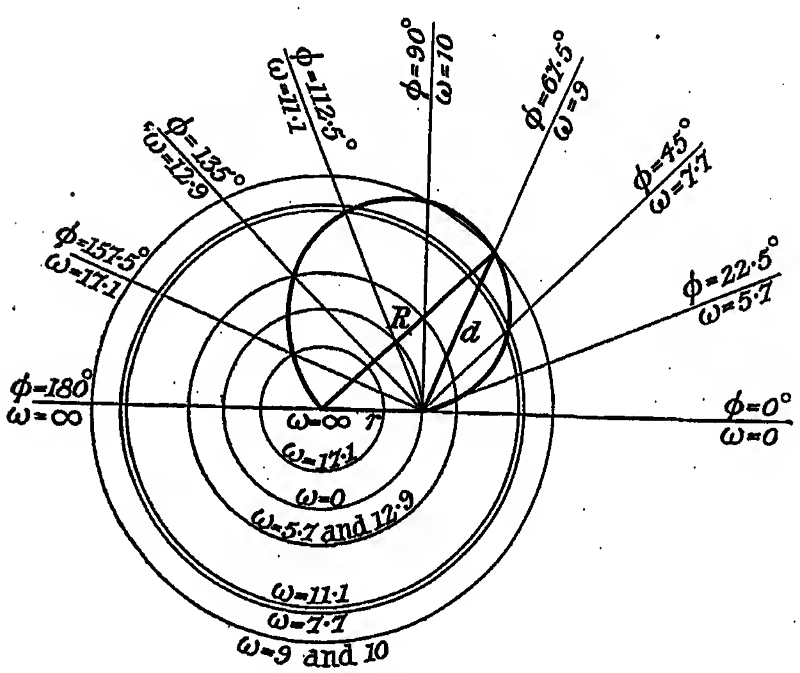

FIG. 8.

These two series of changes may seem to some minds to show that the motion is no longer a vibration; but there are other examples in nature of a body suffering a combination of several different motions at once, in which the combined motion, although undoubtedly the resultant of the various component motions, does not partake of the nature of any one of them, but, like the whirl of a shaft, is capable of being resolved again into each component with its recognizable peculiarity.

A conical pendulum is a good example of this. A mass revolving in a circular path at the end of a string is a pendulum obeying the laws of vibration and travelling round in its circle in the same time as it would travel across the corresponding diameter if it were endowed with only one of the two rectilinear vibrations. The projection of this circular motion on any two vertical planes would be identical with the motion of an ordinary pendulum of the same length. Yet the combined motion has neither of the two characteristic properties of ordinary vibration; there is no alternation of strain in the material and no change of energy of the mass from kinetic to potential.

Experimental Verification.

We have made the following experiments which can easily be repeated and which we think throw light on the subject of whirling.

The first is the classical experiment of a mass on a bent shaft. If run for any time at a speed in revolutions per second equal to its natural frequency in vibrations per second, it runs further and further out of truth until something breaks, but if hurried through this critical speed it runs truer at much higher speeds than at very low speeds.

Next we fixed two parallel guides stationary in space just far enough apart to allow free motion of the shaft. On repeating the above experiment all the motion was in the plane of the guides but otherwise obeyed the same law, i.e. the vibrations increased until the critical and then almost died away.

Next, the same guides were used but revolved with the shaft as in a centrifugal governor. The shaft then whirled further out until the critical speed but would not go back again and run true above this speed.

Next, the guides were removed and the flywheel mass was illuminated by a neon lamp through a contact maker on the shaft which switched on the lamp for about 1° of revolution. (The neon lamp will withstand double voltage under these conditions and will give more light.) A spot was painted on the flywheel and a pointer fixed in space so that the neon lamp was illuminated when these two were together at very low speeds. On increasing the speed the spot was seen to describe a circular path, as shown in Fig. 8. It was arranged that the flywheel should be illuminated at the instant when the initial eccentricity was opposite the pointer. If d and r were always in the same line, the spot would be seen, on increasing the speed, to move in this direction further from the centre, instead of which it moved round the circular path shown in Fig. 8, and at the critical speed the shaft was shown to be displaced at right angles to the original eccentricity. At high speeds the spot settled down in line with the pointer but nearer the axis of rotation.

Other Critical Speeds.

It has been suggested that a possible critical condition occurs when the shaft is rotating at 71 per cent of the true whirling speed. This has been based upon the idea that as the shaft is rotated its effective stiffness is reduced by the centrifugal force. We have seen that the true whirling speed is at an angular velocity $a = \sqrt{(F/M)}$, F being the true stiffness of the shaft. It is assumed that the effective stiffness of the shaft in rotation might be $(F - M\omega^2)$, and by analogy another critical speed might be expected at an angular velocity

$$\omega_1 = \sqrt{[(F - M\omega_1^2)/M]} = \sqrt{(a^2 - \omega_1^2)}$$

from which

$$\omega_1 = \frac{a}{\sqrt{2}} = 0 \cdot 71a$$

We have repeatedly run shafts at 0·71 of their true critical speed, with negative results, and it may definitely

be stated that no such additional critical speed exists. In the light of our previous remarks it is evident that the reason for this is that resonance can only occur if there is a disturbing force acting at right angles to the restoring force, and this is only the case at the speed for true whirling. At all other speeds, including that particularly under discussion, the line of action has a fixed and definite orientation to the disturbing force appropriate to the speed, and it is only at the true speed of whirling that this angle has a value of 90°, and consequently only at this speed that the conditions are critical.

All our work refers to a shaft with an initial eccentricity which provides the disturbing force (all real shafts being necessarily of this kind), and what happens in the case of a perfectly true shaft need not be discussed at length. A periodic disturbing force external to the rotating system and of the same circular frequency might be provided, in which case the shaft would remain perfectly stable at all speeds other than that corresponding to the natural frequency. Only when a speed corresponding to the natural frequency is reached would there be instability.

The case considered, of a mass placed centrally on a weightless shaft, is chosen for its simplicity in demonstrating the particular points raised. The more complicated happenings of whirling, e.g. second and other critical speeds, are, however, explainable with increased simplicity on the vibration theory. A shaft may whirl in as many ways as it can be set into transverse vibration.

If the masses are so placed, e.g. at the end of an overhung shaft, that their plane of rotation is affected by whirling, then gyrostatic forces will be called into play which may slightly modify the fundamental critical speeds and even introduce others entirely due to gyrostatic action. This has been investigated by Stodola (see Bibliography).

TEES-SIDE SUB-CENTRE: CHAIRMAN'S ADDRESS

By C. O. Brettelle, Member.

(Abstract *of Address delivered at* Middlesbrough, *23rd November*, 1923.)

ELECTRICITY SUPPLY—SOME TENDENCIES.

The title given to this address implies a regard for the future and therefore for the past also, since it is necessary to study history if only in order to prevent history repeating itself. In 1882, the year of the first Electric Lighting Act, two theories were uppermost in men's minds, and with those theories new subjects for industrial legislation had to be squared. One was the kind of municipal socialism associated with Joseph Chamberlain's early career, and the other rested on a belief in the virtue of unrestricted competition and unfettered private enterprise. These not altogether compatible views were compromised in the Act referred to by jettisoning private enterprise; for the terms upon which it was permitted to function were such as to make it an adventure too speculative to win the investor, and too sure not to yield a golden harvest to excite the speculator. Thus the role of pioneer mainly devolved upon the municipalities, which was not only a reversal of the orthodox principle that the financial risks attaching to untried schemes should be left to individual effort, but it also deprived the industry of the greater latitude in experiment, so valuable in initial stages, more readily possible under private control. At the present time the total capital sunk in the supply industry is close on £200 000 000 (nearly double what it was in 1914) divided about equally between public and private interests. Of the 90 millions privately subscribed, 40 per cent is in the form of debentures, which appears to indicate that even now the inducements to capital are not any too good.

What our legislators overlooked was, on the one hand, that the needs of local government did not automatically delimit the area most suitable for the supply of electricity, and, on the other hand, that electricity from public mains has, and always will have, powerful competitors, since people want light, power and heat of the most efficient kind, irrespective of its form. Furthermore, the value of competition as a factor in keeping prices at a low level is dependent on the ratio of standing charges to running charges being low. In the business of supplying electricity this ratio has always been very high; as standing charges, rightly considered, include not only interest, depreciation and obsolescence in respect of generating plant and mains, but also all those operating costs that do not vary with output, such as by far the greater proportion of salaries and wages and even some part of the costs of overhaul and maintenance and of the fuel burned in banking boilers between peaks.

Nevertheless, it was deemed advisable to make competition compulsory by Act of Parliament, and so in London we find Orders for the same area granted to two companies which, until 1908, were forbidden to combine or enter into working arrangements, and were compelled to lay their cables in the same streets. Thus standing charges were duplicated and the additional cost necessarily handed on to the consumers. It was not until the year 1900 that a broader view was reflected in the passing of special Acts for the supply of energy for power purposes over wide areas. The incentive came from an awakening to the possibilities of extra-high-tension three-phase transmission. Technical and commercial considerations alike demanded that the supply of electricity should be regarded as something more than a struggle with the local gas undertaking, and an advance from the parochial to the regional outlook was made. Progress towards the present stage was hastened by the impressiveness of the work performed by electricity during the war; but the appointment of a directing and co-ordinating body such as the Commission would have become, sooner or later, as necessary to our welfare in peace as a general staff would be in war. This appointment, together with the Electrical Development Association jointly subsidized by undertakings for their common good, symbolizes the advance, as it were, from the heptarchy, an aggregate of isolated units, to the nation, built up of consciously related parts each enjoying a liberal measure of self-government. The coming of the Commissioners is perhaps 10 years overdue, but not much more, since in the earliest days of any movement a tendency towards semi-anarchy has its value in breeding a race of self-reliant men and in producing a welter of differing ideas and practices, from which a later centralization can select. Particularly in this country is diversity truly creative. It is sometimes termed "muddling through" and is as wasteful and as triumphant in its result as evolution itself, of which indeed it is but a healthy manifestation.

Another sign of the trend towards the larger outlook is seen in the machinery voluntarily set up for the discussion of matters of common interest among the three partners in industry, viz. capital, technical and administrative staffs, and manual workers. In the electricity supply industry the Whitley idea is perhaps more strongly entrenched than anywhere and should undoubtedly arouse esprit de corps among all who work within it, in addition to serving its more obvious purpose of encouraging conciliatory methods. The need to attract capital has been referred to, but brains

are requisite for its application. In order to attract good men remuneration must be adequate, and an improvement is to be noted in this respect from the days when it might truthfully be said that the income of an electrical engineer did not run to the consumption of his own product. Insistence on proper training and qualifications of entrants is a necessary concomitant. Recent apprenticeship schemes appear to have this in view rather than less desirable ends, while it is significant that this question of training is now being dealt with by the Whitley Boards and also that many public bodies require candidates for positions to hold some grade of membership of this Institution.

That the new times require more scientifically-trained men than did the old days will be patent to anyone comparing one of the older stations with a modern more or less standardized turbine station.

Then the most important instruments were on the switchboard, facilitating maintenance or restoration of supply, while only a CO_2 recorder (if that) gave some kind of a clue as to what was the efficiency of the stoking. The chief qualities of a good station engineer were initiative and resource in emergency, whereas to-day his counterpart is almost necessarily a fuel economist first of all, and the most carefully regarded instruments are (or should be) in the boiler house.

Technical education, however, has its limitations, and an engineer who is only an engineer is less than an engineer. It must be supplemented by a general education and a knowledge of the world that will enable him to profit by every enlargement of his experience. It has been well said that the ultimate test for the survival of Western civilization will be the ability of European nations to adapt moral and mental faculties to situations formed by progress in mechanics. Magnanimity and a sense of proportion are therefore particularly to be desired in electrical engineers whose part in material advancement is destined to be of ever increasing importance. Though there are many proofs that our profession is not deficient in these respects, it is obvious that a difficult and possibly a thankless task is in front of the Commissioners in reconciling the conflicting interests of divers undertakings and in compelling backward undertakings to be more progressive. It may be that on the North-East Coast we are apt to underrate the difficulties involved in co-operation between undertakings elsewhere, as we have here what has been aptly described as a "Joint Electricity Authority without its drawbacks," due to the fact that arrangements for mutual assistance are in force wherever practicable between municipalities, power companies and industries having waste heat for disposal. These arrangements are none the less happy for having come about as ordinary business transactions—the only efficient substitute for force or fraternity that our civilization has yet devised for dealing with its wants on a large scale. As regards systems of supply, the image of the future is reflected in the most advanced current practice. That is to say, the best of the existing three-phase alternating-current power stations will be linked together to supplement the output of new stations running at as near 100 per cent load factor as possible, and subject to the control of one load dispatcher for each group. The capacity of these new stations will be as large as permitted by the sites available, having due regard to water supply and railway sidings, but will probably not greatly exceed 200 000 kW under one roof. Auxiliary plant, it goes without saying, will be driven by alternating-current motors. Thermal efficiencies will probably be at least 30 per cent better than the highest (17·8 per cent) hitherto obtained, or in other words 1 kWh will be generated from little more than $1\frac{1}{4}$ lb. of fuel, which is under half of last year's average for all public generating stations; though whether the last 1 per cent or so of such efficiency will justify the cost of obtaining it has to be proved.

Coal, by means of which all but 5 per cent of $5\frac{1}{2}$ thousand million units were generated last year for public supply, will doubtless continue to be the main source of our energy. The tendency will be to raise steam pressures considerably, and the 475 lb. per sq. in. at one power station in this neighbourhood is probably only the precursor of still greater advances on older practice. The gas turbine, however, is an interesting possibility of the future. One of 10 000 kW is said to be running on oil-gas in Germany with an overall thermal efficiency of 28 per cent, which is, nevertheless, probably not sufficiently in advance of reasonably anticipated steam performance to affect the situation to any marked degree, taking into account all relevant factors.

Water power, with its superficial prospect of getting something for nothing, has its fascinations for many people, but the amount of coal to be saved by this means is not likely to be appreciable. Instances of its successful exploitation are few, and those on only a small scale, the aggregate output now being but 32 million units per annum, or about one-half of 1 per cent of the total generated by all methods. It is estimated that in Scotland, where the potentialities are greater than in England, about 140 000 kW is available from this source, but the average capital cost for power station construction alone has been given at a figure at least twice as much as that for a large steam station. To transmit this power to the big industrial centres would necessitate, on an average, the running of 80 miles of transmission line over very rough country; consequently it is not easy to see how the actual cost of current to the consumer can compare favourably with that supplied from a station like the one at Dalmarnock. Probably the solution will be the erection at the cascades of works having a load factor approaching 100 per cent, as, for instance, has already been done in the case of the aluminium works in North Wales and near Ben Nevis, when capital charges, not inflated by expenditure on transmission lines, being spread over a large number of units are relatively of less importance. In similar manner illusory hopes are sometimes aroused by "waste heat," from which last year the quite respectable amount of 184 million units were produced, or about $3\frac{1}{4}$ per cent of the total; but the capital charges per unit are high owing to the comparatively small size of the power stations and the need to provide adequate independent standby. This source, moreover, will

tend to dry up due to more efficient plant reducing the amount of waste heat for disposal and due to its intensive use in the works themselves, either as raw heat or else for the generation of electricity for major operations such as smelting, rolling and winding, so that the other requirements of the works must be supplemented by current from the public mains.

Although it would seem that coal is destined to continue to occupy the premier place as fuel in the production of electricity, it does not follow that combustion will always be carried out in the same wasteful manner as it is to-day. A far-reaching development would be the generation of steam for producing electricity as a by-product of the slow destruction of coal for its valuable constituents. So far very little has been attempted in this direction, but it would appear to offer scope for the dangerous game of prophecy.

Turning to the question of transmission, the three-phase system will, it is safe to assume, hold its own at pressures in excess of those now in common use in this country, and 60 000 to 70 000 volts is likely to be common practice in the early future.

It is not suggested that what are sometimes termed "super-power stations" with extra-high-tension transmission will meet the demand for electricity everywhere. The medium-sized station situated at an appreciable distance from a transmission system and efficient for local requirements will no doubt continue its individual existence as long as its operating costs are low enough to make interconnection commercially unsound.

There still remain the problems of supply to the small town, the village and the isolated farm. The needs of the first can in most cases be met, until a bulk supply becomes available, by oil engines and suction producer-gas engines. Supply to a village or township presents greater difficulties. The tendency seems to be for such undertakings to be established without statutory powers, as the £300 or so necessary to acquire Parliamentary sanction would be a heavy item in the capital expenditure. Thus of the 30 consents given by the Electricity Commissioners during the past year for the erection of new generating stations, no less than 18 were for non-statutory undertakings. Seldom could the financial prospects be made attractive unless the cost of generating plant and attendance were eliminated to some extent by taking energy in bulk from a transmission system. Failing that, current might be obtained from the plant of a local industry or water wheel, or else from a small petrol or paraffin set at a garage or on the premises of a hardware merchant willing to risk financial loss from the sale of current in return for the exiguous profit to be derived from wiring houses and selling fittings. A further alternative would be co-operation with the local gas undertaking (if any) so that administrative and operating expenses could be shared. In any case it is very important that these plants should be designed to be semi-automatic and self-regulating, as constant attendance would be out of the question, in view of the expense. Supply would be available only from dusk to dawn in many instances, and reliability must be deemed to be of quite secondary importance. Over-insurance in this respect, always to be guarded against, would prove an insuperable handicap to a small concern.

The cost of tapping a transmission line, without sacrificing its security, to meet a demand of a few kilowatts is often almost prohibitive, and, *a fortiori*, to supply individual farms is generally entirely so. There is here a very important field for investigation, since it is imperative that agriculture should receive whatever stimulus may be possible. Apart from the necessity of a modicum of home-grown food in case of national emergency, it is essential that we, as an industrial country, should continue to recuperate our urban stock from men reared in more natural surroundings.

While referring to distributing systems it would be as well to touch upon the question of their administration. It is on the whole desirable that this side of the business, which does not so noticeably lend itself to centralized control, should remain in its present hands, whether municipal or company. It is, nevertheless, urgent that steps should be taken to secure a greater measure of uniformity in low-tension pressures. As things are, apparatus in use in one town may be unsuitable elsewhere, and this must add appreciably to its cost.

If electricity is to be generated and transmitted as three-phase alternating current there is a clear gain in distributing it on this or, in the case of residential or shopping centres, on the single-phase system. Any special advantages of direct current are in all but a few cases offset by the cost of, and losses in, transformation, and by the heavier outlay on the maintenance of mains. It is, furthermore, without the flexibility of alternating current to cope with overloading in congested districts and with the growth of suburbs.

General rules are nevertheless no substitute for intelligence in dealing with special instances. Thus we have the case of the industrial quarter of a town where many direct-current motors have been installed, the cost of replacing which would more than balance the capitalized savings accruing from a change-over to alternating current. In this connection it should be borne in mind that constant attendance at converting substations is likely to be greatly reduced in the near future, as automatic systems and rectifiers come into more general use. No one need be sorry for this change; for attendance at a substation, though useful as a method of gaining experience, becomes after a very short time of service an occupation fit only for a Robot.

The case of the battery vehicle, which is assured of a brilliant future, can be met by the provision of small rectifier stations, just as the requirements of the present-day motorist are met by the kerb-side petrol pump.

There are, in addition, many special industrial processes requiring direct current, but its chief enclave will undoubtedly be found in railway traction.

One feels almost sorry to be compelled to agree with the findings of the Kennedy Committee of 1920 in this respect, but the weight of technical evidence submitted was overwhelmingly in favour of committing

us to a far-reaching high-tension direct-current scheme.

Electrification of the main lines will undoubtedly have an important bearing on the transmission schemes of the future, and it is greatly to be hoped that the railway companies will now tackle this problem in earnest. One cannot but suppose that the North-Eastern Railway, if its past record is any criterion, would have already made more headway in this direction but for the necessity of waiting for other districts to come into line. Sir Vincent Raven's datum line of 2 lb. of coal per unit will without doubt be common power-station practice before the railways are ready. The electrification of suburban traffic, where quick acceleration is of greatest importance, has long passed beyond debate, and mineral transport has been tried within a few miles of this hall. Standby losses that have so much weight in the latter case are of greater moment than is generally realized in express train service, while the flattening out of maximum speeds may be expected to reduce maintenance costs.

Main-line traction, though representing a potential demand for electrical energy on a colossal scale—no estimate of the extent appears to be available—is only one of the directions in which immense developments may be expected. Heating in all its forms presents an almost limitless field. The possibilities of the situation may be sensed from what is already a fact in the United States. At Pittsburg we find no less than 335 000 kW of industrial heating load, of which roughly two-thirds are accounted for by the iron and steel works, leaving no less than 110 000 kW for various industrial uses.

So far the scope of domestic heating (which includes cooking) has been restricted to fairly well-to-do people and to somewhat specialized housing schemes. It is in this respect that electricity now meets with the keenest competition, especially in providing economically enough hot water to fulfil civilized needs. General acceptance of its superiority to other heating agents calls for the education of the public along lines familiar to those of us who remember the debates of some 20 years ago as to whether electricity was even as good an illuminant as gas, and when it was generally assumed to be necessarily much more expensive. It is true that electric lamps have been considerably improved since those days, but also it is clear that in the design of cooking and heating apparatus finality is a good way ahead of us. That the public is now in a mood to respond to culture is shown by the fact that last year the consumption of electricity in this country was greater than at any previous period—greater than during the war or the post-war boom. This increase is attributed mainly to domestic uses, which, unaffected to the same degree as industrial supplies by trade depression, have justified the expectation of their stabilizing effect on output.

The goal of the supply industry is to fulfil a public service and not merely to indicate with what efficiency we can generate electricity, however important a bearing the latter may have on the position, and the credit of low works costs is a barren one unless we can at the same time awaken a demand for the product. The old saying that "demand creates supply" is true only up to the point of normal saturation. If that point is to be passed—and judged by modern standards it is reached at so early a stage that a commercial system dependent upon it would be primitive in the extreme—the supply must create the demand.

The utilitarian philosophy, which left its mark on the methods of the last century, failed to take into account, among other things, that lack of introspective faculty is common and that inertia is the ruling passion of mankind. Man does not intuitively know what he wants, save as he is directed by a few primitive impulses, and he is usually disinclined to make much effort to discover his needs beyond the satisfaction of such impulses, ambition included. The fruits of the increasingly large sums spent during the last decade in advertising furnish an indication of how supply creates the demand; and we have a more pointed illustration in the forward policy of some gas undertakings which let out cookers and fires either free or at a nominal rent in order to excite a demand for their gas. The result is an effective demand many hundreds per cent in excess of the unexcited demand. In addition to the demand thus directly created there is a further stimulant in the suggestion of the ability of the familiar agent—electricity, gas or whatever it may be—to fulfil various requirements. It will be evident that the development of electrical heating to an appreciable degree depends upon the cost and reliability of the apparatus, and this implies its hire, supervision and maintenance by the supply authority. A supply authority would do well to confine its attention in this respect to such apparatus as really fulfils a daily need and which consumes an appreciable amount of energy. Other articles will, with the help of a suitable tariff and educative propaganda, find their way into common use as a matter of course.

One method of compassing this excitation would be to set aside a portion of any financial surplus to form the basis of what might be called a profit-sharing scheme with the consumers. Each of the latter would be presented on payment of his account with a voucher proportional in value to the amount paid for current in the preceding 12 months. These vouchers could be exchanged for, or given in part payment of, scheduled current-consuming apparatus at the showrooms of contractors or of the undertaking itself, in which the cashier's office should be located. Presumably the next year there would be an increase in consumption of current and therefore in the profits and also, with snowball effect, in the kilowatts of the apparatus given to the consumers as their share in this co-operative enterprise, and so on.

The framing of a suitable tariff plays a very important part in the process of stimulation. The most successful domestic tariffs include a high fixed charge (whether based on the number of lampholders installed, rateable value, floor space, or so many units at a high figure, etc.) and a low running charge. The ideal to be aimed at is to reduce the latter to negligible proportions, thus at the same time meeting the standing charges of the supply authority and enabling the consumer to anticipate within a small margin what his

liabilities will be. The *arrière-pensée* is of course that the consumer will use current more freely. A choice of tariffs at the present stage, when new habits of thought have to be inculcated and psychology has therefore to be taken into account, can well be offered to prospective consumers who press for it. It is no longer incumbent on an undertaking to charge on a flat rate of so much per unit; but it will probably be expedient to continue to do so rather than lose business, if only for the sake of the consumer who desires simplicity above everything, provided the flat rate be made less favourable than those constructed on a more scientific basis. This proviso is quite legitimate, since the consumer chooses the flat rate either out of idiosyncrasy or else because he finds it enables him to evade his share of the standing charges.

So much for domestic tariffs designed mainly to foster the heating load with its desirable possibility of a Sunday peak. The industrial load naturally requires a different method of approach. There is in the first place the greater amount of current consumed. There is also the greater diversity of conditions, as well as the necessity for a direct reference to economic values, which are not always the chief care of the same individual consumer *qua* domestic man.

A rough approximation towards covering standing charges such as may be allowed in a domestic tariff would be unsuitable for industry, though the same general principle should be adopted (as in the case of water power supplies) of a fixed charge as high as possible and a running charge as low as possible. The importance of standing charges cannot be too much stressed. To take an example from figures recently cited in the technical Press in connection with a modern medium-sized generating station. It was found that to increase the load factor from 20 per cent to 40 per cent decreased the fuel cost per unit by only 5 per cent, and that the total cost of repairs, maintenance, oil, water and stores increased in proportion to the output. For the same variation in load factor, the capital charges and salaries and wages per unit were halved. Thus running charges drop from, say, 0·41d. to 0·398d. per unit, whereas standing charges drop from 0·614d. to 0·307d. per unit. Carry this calculation to 100 per cent load factor and we find running charges 0·386d., as compared with only 0·204d. standing charges. These standing charges refer to the generating station only. If they be doubled it will show nearly enough for our purpose the effect of standing charges on the position of the undertaking as a whole. In designing a tariff, running charges can conveniently be considered to be constant within limits for a given price of coal, but the standing charges have to be adjusted over a wide range if they are to be equitable. The maximum-demand system usually meets the case between consumers of the same class, but not necessarily between those of different classes. For instance, the maximum load of one consumer may coincide with the peak load of the station, whereas that of another may be made at a more convenient hour of the day or night or during the week-end, thus adding very little to the standing charges of the undertaking. Care must be taken to avoid incorrectly allocating standing charges so as to depreciate the competitive value of electricity.

In practice it is not, of course, always possible to carry fully into effect these principles, which are based, as most principles are, upon a static conception of things. In reality conditions are for ever changing, so that a reasonable estimate of net results has to be made for some time ahead, and some compromise is necessary. The consumption and demand at every works fluctuate from month to month; strikes, lock-outs and foreign complications occur; or the undertaking develops, necessitating the installation of new plant and mains, more or less costly than the old.

The flat rate usually quoted for current taken in relatively small quantities is more defensible for motive power than for lighting. If a two-part tariff were imposed upon each consumer operating one or two motors intermittently, the resultant average rate per unit would frequently be prohibitive. It would also be inequitable, as the diversity of the incidence of the demand on the power station makes it probable that the standing charges would be considerably more than covered. It will be obvious, however, that a flat rate is a compromise and must in many cases involve the undertaking in a loss.

It has been said that commercial supremacy in days to come will fall to the nation having the most efficiently exploited resources for the generation of electricity in abundance. Let us for the moment imagine ourselves living in the omnipotent and omniscient State of the Utopians. We will assume that the State has made a special feature of electricity supply. The rulers would desire to foster various industries, some for the wealth they would bring to the country, others for advantages of a social kind. There would be no better instrument to their hand for compassing their ends than electricity; for electricity provides the almost ideal flexible coupling between the prime mover of the most efficient kind and the smallest machine, and presents an extreme illustration of the economic paradox that the displacement of the labour of hundreds of men may provide work for thousands. It furnishes the only practicable means of de-concentrating industry, and is the sole hope of any revival of cottage craftsmanship. It brings the only prospect of dissipating the pillar of cloud by day and by night over our cities and makes possible cleanliness without drudgery in the home. It also gives an enlargement of intellectual and material resources by its instrumentality in promoting rapid and economical transport. In short, electricity presents the best material framework on which to base the old democratic formula of "the greatest happiness of the greatest number." We know, of course, that such a State and such rulers never will exist, and that any less perfect substitute would not fulfil our purpose as well as we can with reasonable luck and courage accomplish it ourselves. But Utopias have their uses. They present to our view some kind of a mirage towards which to blaze out our path, knowing that we must depend on our own efforts, yet willing to co-operate with all who have a similar goal, rubbing off our angles in the give-and-take of things, and, it may be, gaining a few bruises in their stead.

NORTH-WESTERN CENTRE: CHAIRMAN'S ADDRESS

By G. A. JUHLIN, Member.

(ABSTRACT *of Address delivered at* MANCHESTER, *6th November*, 1923.)

The electrical industry, in common with other great industries, is at present passing through difficult times, and no one can predict what the future has in store. It is at such times as these that the moral fibre of those engaged in the industry is tested to its utmost.

I think it is well that we should realize that our Institution has a great responsibility, and that it behoves everyone to pull his full weight in order to make a speedy recovery possible. How this weight is to be applied must of necessity be determined by each member himself, but I suggest that one way is to attend our meetings and to give his knowledge freely. It is also incumbent upon those responsible for the governing of the Institution to give every facility to all members to contribute papers and to enter into the discussions.

I am not sure that at present we are working on the best lines to obtain the results that we wish to obtain, which I take to be the lifting of our industry to the highest possible eminence throughout the world. To attain this position it is necessary to encourage every branch of the industry to give its quota of knowledge; but I am afraid that our present system is not conducive to this condition. There seems to me to be a tendency to set a standard which deters members from presenting papers, because they feel that the subject with which they are able to deal is too mundane to present in the form of a paper, or that it is not sufficiently technical to be accepted.

In order to obtain the best results from an industry it is essential that the user and the maker of the plant should be in close contact. It would therefore appear desirable to encourage papers from operating engineers. In using this expression I am including not only those engaged in the generation of power but also power users. Electricity is constantly being introduced as a motive power into new fields, each having special requirements which must be given consideration in the construction or the general lay-out of the plant.

Consider, for example, colliery installations with their many special requirements. This is, of course, a field where electrical energy has been in use for many years, and yet comparatively few papers on the subject have come before this Institution. There is, undoubtedly, need for co-operation between this Institution and the engineers responsible for electrical installations in our collieries. It seems a great pity that a separate organization should cater for the mining electrical engineers, and it would certainly indicate that some effort should be made to obtain co-operation.

Marine work bristles with special requirements, and is a comparatively new field as far as electricity is concerned. In other directions also there seems to be room for expansion.

Speaking from the point of view of manufacturing, there seems to be need for more papers in connection with actual workshop problems. This side of our industry is not strongly represented in the Institution, and I am convinced that this fact is retarding our progress very considerably.

It is not possible to obtain satisfactory results without considering all factors that make the whole. Manufacturing methods are so closely related to designing that they can hardly be separated if progress is to be made. While designers interchange views through the medium of our meetings, there is a great deal of reticence regarding shop matters. This is very apparent when comparing the conditions in this respect in the United States with those in this country.

I am firmly of the opinion that a great deal could be done by encouraging the members to present papers dealing with manufacturing problems and shop organization. It would certainly bring out the fact that the manufacturing side offers a promising field for the technically trained engineer, which field does not seem to be fully appreciated at present.

The statement that we can solve our industrial problem only by increasing output has been made so often that it is becoming hackneyed. I do not think it is appreciated, however, that this cannot be obtained by the efforts of the workmen alone. It can only be done by careful organization and elimination of useless effort, and this surely is the work of the engineer, whether he be engaged in designing or manufacturing. I believe that it is because this fact has been recognized in the United States that they have progressed so fast.

There are of course many other factors, which cannot be dealt with here, conducive to the rapid strides of electrical engineering in America. There is one factor, however, which is very prominent. The question of utility is the keynote of all work. Super-excellence is not looked for or considered to be worth paying for. I was impressed by the remarks of an American operating engineer looking at a switchboard over here, to the effect that there was an unnecessary amount of nickel-plating on the instruments and the board generally. He said: "In our country we consider it bad, because it is apt to distract the attention of the operator due to the reflection of the lighting. We believe that the dials should be the most prominent thing on the board." It is difficult to decide how far to go in regard to the general question of appearance, for there is undoubtedly a psychological effect produced in giving the man responsible for looking after the plant something in which he will take pride, but I suggest that the mean lies somewhere between the practice of this country and that of America.

In comparing electrical development in this country

with the progress in America, it is necessary to consider the conditions affecting these developments. Natural resources in the form of water power have been potent factors in developing the electrical industry in America, coupled with the fact that very few towns had a gas supply at the time electricity was introduced. In this country, on the other hand, electricity has had to compete with a highly developed gas industry, which naturally retarded its progress.

One must also bear in mind that labour conditions have a great influence on the amount of power used in industry generally, and countries where labour is scarce have been forced to adopt means to reduce hand labour to the greatest possible extent.

While the progress in respect of the quantity of electrical plant in this country is behind that of other countries the quality is, in my opinion, second to none. I think that this is reflected in the excellent results as regards continuity of supply from our generating stations.

Generating Plant.

With regard to the size of units, British manufacturers are in a position to meet the demands in this respect. Sets capable of developing 40 000 kVA at 1 500 r.p.m., and 18 750 kVA at 3 000 r.p.m., are in commercial operation, and 25 000-kVA units at 3 000 r.p.m. are under construction. Ten years ago the largest unit at 3 000 r.p.m. was of 3 750 kVA rating, so that the development in the size has been truly remarkable.

The total electrical breakdowns of turbo generating plant manufactured, reported by two of the large companies, showed that in 1921 the total breakdowns experienced on their plant represented less than 1 per cent. Recent figures show that this figure is decreasing, which is a splendid result if we consider that pioneer work is being undertaken all the time.

Regarding the size of individual units, it should be stated that much larger units have been built both in the United States and in Germany than in Great Britain, except at 3 000 r.p.m. There seems to be a tendency to regard the size of the units built as a measure of the manufacturing capabilities of the country, whereas it is really only an indication that there is a demand for such large units.

A recent report on the operation of the 60 000-kVA sets installed in Germany during the war leads one to doubt whether these large units are justified. Should the demand for such large units arise in this country, however, there is no doubt that it would be met.

I have not been able to obtain any definite figures of the output of turbo generating plant in the United States, but I believe it to be approximately 2 million kVA per annum. In addition a large amount of hydro-electric plant is installed. Comparatively little hydro-electric work has been done in this country owing to lack of demand. Since the Armistice, however, considerable progress has been made in this class of work, orders having been received from the Dominions for generating plant, high-tension transformers, and switchgear.

The following table shows the total capacity of turbo-generator plant ordered in each year since 1912:

Year	Total kW	Year	Total kW
1912	162 000	1918	344 000
1913	271 000	1919	500 000
1914	269 000	1920	736 000
1915	333 000	1921	146 000
1916	344 000	1922	339 000
1917	562 000	1923	405 000

I think that this may be regarded as a very satisfactory rate of increase, and it is of interest to note that there has been a distinct upward tendency during the last two years. The small output for 1921 is, of course, due to the trade depression.

Transformers.

Since the Armistice, rapid strides have been made in transformer design and construction in this country. Considerable progress has been made, both in the size of unit and in the maximum voltage, to meet the requirements of the large power stations now being erected and also the requirements of the Colonial markets, where extra-high-tension transmission is being rapidly extended.

The largest transformers which have so far been built in this country are the 19 500-kVA three-phase 50-cycle transformers for the Barton power station of the Manchester Corporation, and the 7 800-kVA single-phase 25-cycle transformers for the Dalmarnock power station of the Glasgow Corporation. The latter size corresponds to 15 000 kVA at 50 cycles. Both these sets of transformers are of the oil-immersed forced-cooled type with oil circulation through external coolers provided with water cooling.

One of the principal problems in these very large units for super-stations is the question of transport and handling on site, which considerations govern the limiting size of units. The 19 500-kVA Barton transformers were actually built and shipped to the site with the transformers in the tanks and complete with oil, the total weight being 60 tons.

In high-tension transformer work it is satisfactory to note that British manufacturers have already obtained orders and delivered to the Dominions transformers for pressures up to 110 000 volts, and it can be confidently asserted that British transformer makers are now in a position to build satisfactory transformers for the requirements of any part of the world, and can successfully meet foreign competition.

Another interesting development, so far as tranformer practice in this country is concerned, is the growing use of outdoor transformers. These have, of course, been in use for many years in America, where conditions differ from those in this country.

It was not until building costs became so high during the war period that the question of outdoor substations was seriously considered in this country. Such transformer substations are now in operation in England, in many instances for 22 000 and 33 000 volts, and in one case for 66 000 volts.

The majority of these transformers are connected to extra-high-tension underground cables, which are led into the transformer through ironclad cable-sealing bells or trifurcating boxes of weatherproof construction.

In agricultural districts where a power supply is being

opened up there is also a tendency to place small distribution transformers out of doors, either mounted on poles or on concrete platforms.

In extra-high-tension transformers for cable testing, three-phase sets up to 300 000 volts have recently been built in this country, and single-phase units for insulator testing up to 500 000 volts.

Switchgear.

The increase in output from generating stations has necessitated development as regards breaking capacity of oil switches, in order to ensure satisfactory clearing of faults on the system. Armour-clad designs have been adopted for systems up to 35 000 volts, individual breakers having a rupturing capacity of $1\frac{1}{2}$ million kVA. All connectors are insulated and embedded in compound, which results in a very compact design.

American practice has developed in a different direction, the phases being completely segregated from each other.

Outdoor switchgear has been developed to correspond to the transformer development.

The first station of this type to go into service was that at High-street, Manchester. Similar gear is being installed at other places. The use of pole-mounted switchgear is also increasing, several schemes being in progress.

Considerable advance has been made in the detail design of the switches, and all this has increased the reliability in operation. Extensive tests have been undertaken in this country and in the United States. The fact that information of this kind is interchanged between the two countries is of immense value and has the effect of facilitating progress.

Industrial Plant.

The greatest progress has undoubtedly been made in our steel-works. Rolling mills have been electrified extensively and it is satisfactory to find that in 1921 there were more than 600 electrically driven rolling mills in this country, the largest of these having a maximum rating of 21 000 horse-power. About 300 of these mill motors have a normal rating of 300 h.p. or above. An interesting application of electrical driving is that of a tyre mill, a number of which have been installed. Owing to the changing ratio of inside to outside diameter of the billet in roughing, the speed of the rolls must have a variable ratio. This is obtained in a simple way by providing a separate motor for each roll and connecting them in series. Excellent results both as regards quality and output have been obtained from these mills. That the electrical drive is recognized as being superior to the steam drive is shown by the fact that practically all large reversing mills installed in recent years have been electrically driven and have proved an unqualified success.

It may be of interest to state that in 1921 the number of electrically driven rolling mills of 300 h.p. and above in the United States was more than 700, totalling over a million horse-power. A recent statement gives the total horse-power of electric motors employed in the steel industry of that country as 5 millions, and the total electrical energy absorbed as 8 million units per annum. It is difficult to visualize such stupendous figures, which are an excellent testimony to the successful use of electricity.

Mining Work.

Owing to the depressed state of the coal industry, comparatively small progress has been made as regards the installation in collieries of electrical plant, excepting winders. The need for increased output from the pits has brought the electrical winder into its own, and a considerable number of these have been installed in recent years, both for alternating and for direct current.

An interesting development in connection with winders is that known as the "S.P." scheme. Briefly this consists of a turbine driving direct-current generators through gearing, with a flywheel mounted on the shaft of the generators. By a special governor the speed of the turbine is reduced when a peak occurs, thus allowing the flywheel to give out its stored energy. In connection with the flywheel used in conjunction with the Ilgner sets, considerable progress has been made in design. By adopting special high-grade materials which permit of high peripheral speeds, it is possible to obtain 3·25 h.p.-seconds of stored energy per lb. weight of the wheel. This figure shows a high degree of efficiency in the utilization of material.

Marine Work.

The use of electricity on board ship is increasing very rapidly. So far it has not been employed to any extent for propelling machinery for British ships. An interesting example of the use of electricity for auxiliary machinery for marine work is that of an oil tanker. Thirty ships have been equipped with electrically operated auxiliaries.

Traction.

Considerable progress has been made in connection with the electrification of railways within the Empire. Although no main-line electrification has been undertaken in Great Britain, some of the Dominions have taken the lead in this respect. In South Africa direct current at 3 000 volts has been adopted, and for some of the Indian Railways at 1 500 volts.

Recent Developments in the U.S.A. and Canada.

This year has been remarkable as regards the demand for electrical plant in the United States. Turbo-generators of 62 500 kVA capacity in one machine are under construction. The speed of these units is 1 200 r.p.m., the frequency being 60 cycles. The weight of the rotor of one of these machines is over 100 tons.

Water-wheel generators having an output of 45 000 kVA have been in successful operation for about two years in the Queenston power house of the Ontario Power Commission. Five such units are at present in work, and five additional sets each having a capacity of 55 000 kVA are under construction.

Still larger units are under construction for the Niagara Falls Power Company, which is situated on the American side of the Falls. Two sets each having an output of 65 000 kW will be installed. The rotor of one of these generators is built up of 10 rings, side by side, each

weighing 40 000 lb., the diameter being 23 feet. The total weight of each machine is over 700 tons. Some generators built in 1903 for this Company had a capacity of 3 750 kW, so that in 20 years the size of individual units has increased 17 times—a truly remarkable development.

The question of "linking-up" is receiving a great deal of consideration, and as an example of what is being done in this connection may be mentioned that a frequency-changer of 35 000 kVA capacity is being installed for the purpose of interconnecting the 25- and 60-cycle systems of the New York Edison Company.

Other units of 15 000 kVA to 20 000 kVA capacity are under construction for various power companies. Synchronous condensers for transmission-line regulation having a capacity of 35 000 kVA have been installed, as well as many smaller units.

A notable advance in high-tension transmission work was the putting into commercial service of the 220 000-volt system of the Southern California Edison, and the South Pacific Gas and Electric Company. This is the highest voltage yet adopted for commercial work. Some indication of the size of oil switches may be gathered from the following figures:—

Weight of switch with oil	45 tons
Oil required	2 000 gallons per pole
Height to top of terminal	17 ft. 6 in.
Size of tanks	8 ft. × 5 ft. × 8 in.

Railway electrification is being undertaken on a large scale. The Virginia Railroad recently placed an order for the electrification of a part of their system, as it was found impossible to handle the mineral traffic with steam locomotives.

One of the most remarkable developments in America is what is known as the "Supervisory Control" system. Two methods of achieving control have been developed. The first is a system of relays and signalling devices, which link up all the stations to be controlled. This is termed "Audible Supervision," and is mainly adopted for hydro-electric generating plants and small sub-stations. The general scheme is that the supervisor can at any time put himself into telephonic communication with any station under his control by means of a specially developed keyboard and automatic dial.

If he desires to ascertain the conditions of operation in, say, No. 4 station he simply presses No. 4 key and the telephone dial connects him to No. 4 station. By means of audible signals he can ascertain the head of water, gate opening, etc. These signals are repeated automatically until another dialling operation is made by the supervisor.

"Trouble" alarm-circuits may be used to warn the supervisor that something has happened. This may be the operation of an overload trip on a circuit breaker, or any other operation that can close a relay. The warning is obtained by sending a high-frequency current over the line received by a loud-speaker in the supervisor's office.

The second system is that of "Visual Control." This has been developed for large systems with a number of large substations. Briefly the operation of this system is as follows:

For each operation in the substation there is a definite numerical code. The signal is transmitted by telephone keys which operate relays, and these in turn operate an automatic selector switch. Through this the code is transmitted to the station and decoded by a similar selector switch which operates the required relays performing any desired operation, such as closing a circuit breaker. Having performed the operation, the relays signal back to the supervisor the fact that the required operation has been performed. Small lamps are used for this purpose, hence the "Visual Control." The lamps are covered by coloured buttons, a red one indicating a closed circuit and a white one an open circuit. The relays and selector switches are those used for standard automatic telephone work, which have been in use for years, so that the system does not depend on new and therefore experimental plant.

One of the most interesting and, from an operative point of view, most important points is that incorrect operation is almost impossible, because the whole operation is reported back from the substation to the supervisor. The receiving circuit used in connection with the sender in the supervisor's office, and the automatic sender in the substation, will not under any condition respond to any incomplete or distorted code.

The tramway company in Cleveland (Ohio) operates four automatic substations, which are also controlled by a supervisor located in the offices of the company. The supervisor has full control of all the plant through two pairs of telephone wires, which are part of the telephone company's network. Exhaustive tests were made before the system was adopted, in order to determine whether the arrangement would cause any disturbance in the normal operation of the telephone system, but it was found to be entirely satisfactory. Operation has been highly successful and four more substations are being equipped with this control system.

Through the kindness of the chief engineer of the tramway company, I was able to see a rotary converter transferred from one section of the system to another, and it was certainly an object lesson on the efficiency of the system. I was told that since the supervisory control had been installed they had had less difficulty in operating the plant when disturbances occurred on the system than before the control was adopted. This was attributed to the fact that the operator is detached and therefore not influenced by the disturbance, and also that mistakes cannot be made in the operation.

About 40 equipments to control from 1 to 16 substations are installed or under construction. A number of these are for the audible system for water-wheel stations.

In conclusion I would say that while we in this country are in many respects behind other countries in electrical developments, the leeway is gradually being reduced.

I have already referred to the question of quality and I feel convinced that, given a fair field, the electrical industry, whether in actual manufacturing or in the generation of power, will meet any demands for power that may be put upon it. I am also sure of this, that if we in this Institution do our part, as I have no doubt will be the case, there is every reason to look forward to an increased prestige of our industry.

PROCEEDINGS OF THE INSTITUTION.

702ND ORDINARY MEETING, 18 OCTOBER, 1923.

(Held in the Institution Lecture Theatre.)

Mr. F. Gill, O.B.E., Past-President, took the chair at 6 p.m.

The minutes of the Annual General Meeting of the 31st May, 1923, were taken as read and were confirmed and signed.

The Chairman announced the result of the ballot to fill the vacancies on the Council [see *Institution Notes*, No. 39, page (17) July, 1923], and a vote of thanks was passed to the scrutineers of the ballot.

A list of candidates for election and transfer approved by the Council for ballot was taken as read and was ordered to be suspended in the Hall.

The following list of donors was taken as read and the thanks of the meeting were accorded to them.

Benevolent Fund: F. W. D. Adcock; Anonymous; F. J. Baldwin; C. A. Beaton; A. L. Bedford; H. E. Blackiston; E. W. Broadbent; J. E. Calverley; F. W. Capper; H. Cheesman; G. D. Clegg; C. H. Colborn; A. C. de Oliveira; E. T. G. Donovan; W. Duncan; F. J. Edgar; A. R. Everest; W. Eynon; L. E. Felix-Smith; C. F. Fowler; A. Graham; J. R. W. Grainge; F. W. Green; E. Greenhalgh; J. G. Griffin; W. E. Haley; E. Halton; J. S. Hasdell; E. A. Hick; G. A. D. Hill; R. S. Hobson; H. Howard; E. I. Hunter; V. R. Hurle; The Informal Meetings Committee (per J. F. Avila); H. B. Jackson; W. G. C. Jackson; L. G. Jeary; A. B. Johnstone; W. H. M. Kelman; H. Kitchen; W. E. Lane; F. A. Lawson; J. Lingard; P. G. Lloyd; G. A. Maquay; F. C. Meaby; A. W. Metcalf; J. Mirrey; A. T. K. Moir; F. Morton; S. R. Mullard; C. A. Newell; G. Nicolson; A. M. Niven; W. H. Parker; A. S. Peek; L. W. Phillips; W. Redman; A. J. Roberts; J. Russell; C. V. Sampson; C. D. Scrafton; J. F. Shipley; J. W. Slorach; J. L. Smith; W. E. Swale; A. M. Taylor; J. A. Troughton; E. O. Turner; R. N. Vyvyan; S. J. Watson; Western Centre (per T. Hood); J. W. Wheeler; H. K. Whitehorn; E. Williams; F. H. Williams; L. E. Wood; T. Wood.

The Premiums and Scholarships [see *Institution Notes*, No. 39, page (18), July, and No. 40, page (21), October, 1923] awarded during the session 1922–23 were presented by the Chairman to such of the recipients as were present.

The chair was then vacated by Mr. F. Gill and taken by **Dr. Alexander Russell** amid applause.

Dr. S. Z. de Ferranti: When one remembers the size to which this Institution has grown; when one recalls the leading position that it occupies in the country and the vast electrical interests that it represents, one realizes, in some small degree, the responsibility of its President. By rights I should have run over the work of the past year and reminded you of all that has been done in the interests of the electrical industry in which Mr. Gill, our retiring President, has of course taken a leading part. On behalf of all of the members I thank Mr. Gill most warmly for all he has done during his year of office. There is one thing in connection with what he has done of which I should like specially to remind you. Everyone to-day is seeking peace among the nations, and all sorts of schemes are being devised for ensuring it. One of the chief means of bringing about this result is, I think, the freest possible intercommunication. Not only do we want easy and fast travelling between all parts of the earth, so that people may see each other and get to know each other better in these busy times, but we want something more than that; we want instant and direct communication with many people. Mr. Gill has done a great deal in the way of recommending the lines that should be followed to obtain a much more efficient international telephonic communication. That, I am sure, has been most valuable work. Mr. Gill is, as you know, an expert on all telephonic matters, and I should say on every means of electrical communication. Knowledge is a great and important thing that carries much power with it; but I think you will all agree with me that there is something greater than knowledge, and that is character. This our retiring President possesses and has shown to a great degree. It is for his good services in this direction that I think we are even more indebted to him than for the technical work that he has done, and I am sure that we shall all remember him for his excellent qualities as a man. I beg to propose: "That the best thanks of the Institution be accorded to Mr. Frank Gill for the very able manner in which he has filled the office of President during the past year."

Mr. Ll. B. Atkinson: It is a very great pleasure to me to second the resolution proposed by Dr. Ferranti. Perhaps I can speak with regard to our retiring President from even closer quarters than Dr. Ferranti has done, because as I have passed through the chair more recently than Dr. Ferranti there are many matters on which Mr. Gill has given me the opportunity of discussion with him and of obtaining mutual help. I can only tell you that at every stage he has given an amount of thought and conscientious care and consideration to our interests as an Institution that it would be very difficult to equal, and I am quite sure could not be surpassed. We have had as President, as has already been stated, a man of very great ability and very ripe judgment, but he has not made decisions hastily—not until he has studied them very closely from every possible angle. A thought came into my mind a few days ago when I was thinking of this the first Institution meeting of the session. I

do not know who it was that said "The hour always brings the man," but I was very much struck, in turning over in my mind the names of the Presidents that I have known, to realize how true that statement is—that the hour always brings the man. If you study the list of recent Presidents I am sure you will agree that every one of them has, because of his particular knowledge, because of his particular activities, or because of his particular powers or abilities, been able to do one of two things—either to perform something which at that moment was badly needed in connection with the Institution, or to give some message and help to the public with the mutual backing of himself and the Institution. The retiring President is no exception to that rule. Dr. Ferranti has already referred to the particular point of interest which strikes me at the moment. In Mr. Gill we have the consulting engineer of a great corporation, who possesses a world-wide acceptance as a great expert, and who was able at the proper moment to make proposals as to European telephonic communication which could not have been made with greater force or ability by anybody else, and which were made, if I may say so, with greater power because he was our President. That strikes me as the last example of the point which I have been emphasizing.

The resolution was then put by the President and carried with acclamation.

Mr. F. Gill: It is difficult adequately to thank you for what has been said. If there has been any success it has been due to assistance received from those who are concerned in the running of the Institution. I should like to particularize to some extent; I owe a great deal during the past year to the Past-Presidents, to the Vice-Presidents, to the Members of Council, to the members of the Local Centre Committees all over the country, to the exceedingly efficient staff which the Institution possesses, and to Mr. Rowell, the Secretary. But that is not all. I wish to say, in the name of the Institution, that we owe a great deal to the electrical Press for their attitude towards the Institution. Due to that help, work for the Institution during the past year has been one continuous pleasure, although it has been hard work. It is very stimulating to the man who happens to occupy the chair to find the amount of help and sympathy that he receives from all the membership. Not only that, but he very quickly learns what perhaps he had not expected at first, namely, that he can count on and that he can call for help, and get it every time. Last year when I spoke to the Institution I said something about ideals of service. If I have been of any service to the Institution I am more than content.

The President then delivered his Inaugural Address (see page 1).

Sir Richard Glazebrook: I have now to propose "That the best thanks of the Institution be accorded to Dr. Alexander Russell for his interesting and instructive Presidential Address, and that, with his permission, the Address be printed in the *Journal* of the Institution." The duty is a pleasant one because I have known Dr. Alexander Russell for many years, and have been closely and intimately connected with him in many interesting and important problems. I have realized during all that time his devotion to the science of electricity; his interest in it, and the efforts he has made to promote it from various points of view and in many directions. It is a pleasure to me to be able to congratulate him at this meeting on sitting in the important chair he now occupies and to thank him for the Address he has given us this evening. There are, however, some elements of sadness connected with proposing this resolution, because I believe that privilege is usually conferred on the senior Past-President who happens to be at the meeting, and it is not altogether pleasant to be reminded how old one is getting. I was very much struck by what Mr. Atkinson said as to the man fitting the occasion; and I suggest to you that on this occasion we have a man who is very well fitted for the position he occupies. Electricity has progressed in the past 25 years, shall I say, at an enormous rate. The difficulties accompanying this progress have become more and more obvious to us all; and I think at the same time it has been more and more realized that, in order to solve those difficulties, in order to help forward the advance, in order to accelerate the rate of progress, it is necessary that those who are responsible for the task should have great powers of mathematical and scientific investigation and ample knowledge of theory, and those are the qualifications of our present President. You have heard him refer in his Address to some of the important problems connected with electricity. You have heard, for example, what he said about cables and the immense voltages that they can now transmit. No one has done more than he has to tell us what is theoretically possible in that direction—to calculate the forces, the stresses, and so on, that arise in the use of these great pressures—and the same remark can be made with regard to many of the other problems that he has mentioned. He has indicated the necessity for their solution; he has himself helped in many respects in the solution as far as it has gone at present; and I am sure that he has thoroughly deserved the distinction that has now been conferred upon him, and that you will desire to thank him for the Address which he has delivered. I beg to move the resolution I have just read.

Mr. C. P. Sparks: It is a great privilege to second this vote of thanks and I ask you to pass it with acclamation.

The resolution was then put to the meeting by Mr. F. Gill, Past-President, and was carried with acclamation. After the President had briefly replied, the meeting terminated at 7.32 p.m.

A DYNAMIC MODEL OF A VALVE AND OSCILLATING CIRCUIT.

By R. C. CLINKER, Member.

(Paper received 20th October, and read before the WIRELESS SECTION *21st November, 1923.)*

SUMMARY.

A mechanical model is described which represents the action of a 3-electrode valve when coupled to an oscillatory circuit. A string moving around pulleys, one of which is driven by a small motor, represents by its motion the current through the valve. The oscillatory circuit is represented by a spring and a weighted pulley. By a mechanical coupling between the spring and a brake on the driving motor the effect of the intermittent current through the valve is obtained, and the system exhibits self-maintained oscillations. A note is added on a "negative resistance" effect obtained with a centrifugal friction governor.

The model described in this paper was the result of an attempt to produce a mechanical system which should demonstrate as closely as possible the action

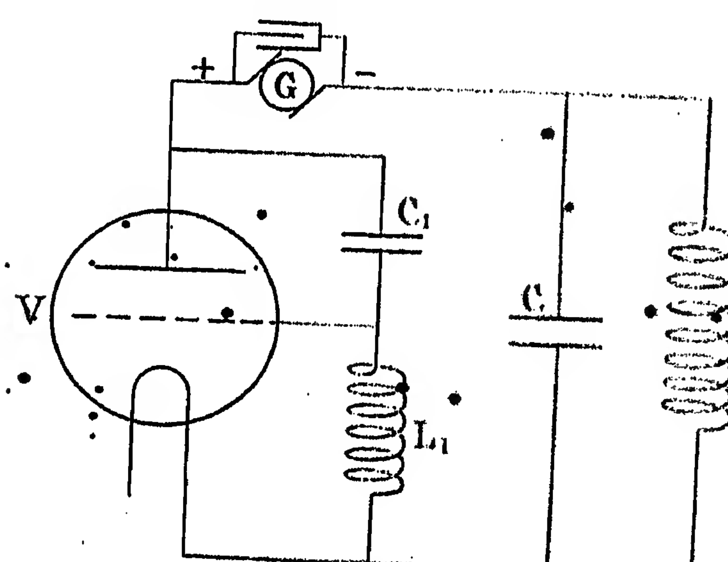

FIG. 1.

of a 3-electrode valve in keeping an electric circuit in continuous oscillation. In devising the model, the author had in mind the dictum of Prof. Jenkin * as to the desirability of a model having some similarity of appearance to the electrical circuit to be illustrated. The model is intended to represent, as closely as possible, the well-known circuit shown in Fig. 1.

Here C and L represent the capacity and inductance, respectively, of the oscillating circuit. G is the source of power. The grid of the valve is capacity-coupled to the anode by condenser C_1.

It will be noted that in this circuit the current carried by coil L includes a d.c. component which passes between the anode and filament of the valve. The two components may be separated by the "shunt" method of exciting the anode shown in Fig. 2, where the main inductance carries only the alternating component.

It would have been preferable in some respects to have made the model represent Fig. 2, but the complications necessary to represent inductance L_2 made it advisable to adhere to the simpler circuit of Fig. 1.

The baseboard, A, of the model (see Fig. 3) is dead-blacked, and upon it is painted a diagram of the circuit, the various parts of the latter being marked underneath the corresponding mechanical parts. A flexible string, S_1, is led round pulleys 1, 2, 3, 4, 5, 6 and 7, of which 3 and 5 are "floating" and the remainder pivoted on the baseboard. Pulley 4 is of large diameter and its mass (together with weights, W, fixed to it) represents the inductance L (Fig. 1). By removing or adding weights, the frequency is varied. String S_1 represents the path of the anode current, and its motion, the motion of the electrons through the valve and oscillating circuit. It passes up in front of the valve V, whose anode, grid

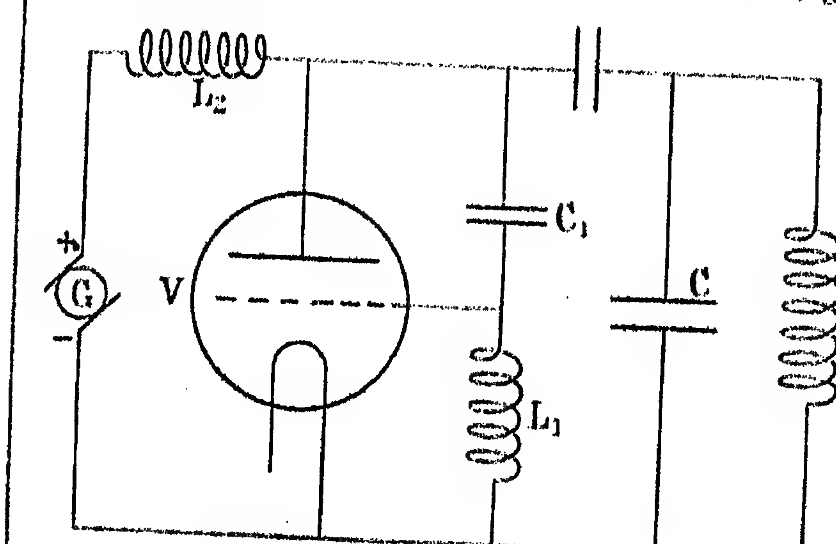

FIG. 2.

and filament are represented in relief by pieces of wood. Another string, S_2, which passes around fixed pulleys 8 and 9, joins the centres of pulleys 3 and 5. The "condenser," C, consists of a flat spring fixed rigidly at D and attached to string S_2 at E. It will be seen, therefore, that the oscillating circuit consists of the mass M, the spring C, and the four pulleys 3, 5, 8 and 9. These four pulleys, and also M, are on ball bearings to reduce friction, i.e. to keep down the resistance of the oscillating circuit. It will be noted that, if string S_1 be held at rest at the valve, spring C and mass M are still free to oscillate. The d.c. source of power is represented by pulley 1, which is driven in a clockwise direction by a small motor behind the baseboard.

A toothed wheel on the shaft of pulley 1 drives a centrifugal governor of the gramophone type. The friction brake controlling the speed of this governor is operated by a thread F, which is attached to a point P on spring ("condenser") C, and passes over a pulley and through the baseboard at the back of which

* See *Journal I.E.E.*, 1922, vol. 60, p. 939.

it is attached to the governor. This thread forms the "coupling" between the grid and the oscillating circuit, and this coupling is varied by sliding P along C. Matters are arranged so that a downward motion of C, i.e. a counter-clockwise rotation of M, draws the brake off the governor and increases the speed of string S_1. The actual grid is represented by a sliding metal strip, G, which is perforated and attached by thread H to spring C. A downward motion of C draws G to the right and uncovers a series of white spots and plus signs, thus representing the grid as "open," or positively charged.

Further, an upward motion of C uncovers a series of minus signs, showing negative electrification.

The action of the model, in mechanical terms, is as follows :—

Upon the motor being started suddenly, string S_1 commences to move. Mass M cannot, however, start instantly. Its lag causes spring C to be drawn downwards, displacing pulleys 3 and 5 to left and right respectively. This action applies an accelerating torque

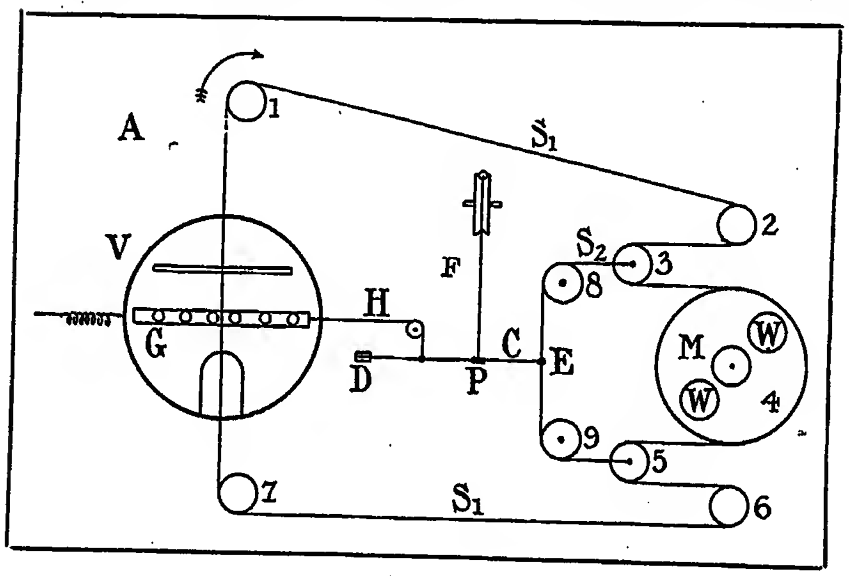

FIG. 3.

to M, and also increases the speed of string S_1 to a maximum, by releasing the governor brake. During this time M gains speed, and E returns towards the centre. When E reaches the centre, however, mass M has a greater peripheral speed than pulley 1, whose speed has been further lessened by the upward motion of E. Consequently E overshoots the central point and, in so doing, applies the brake to a maximum extent and stops pulley 1 altogether. C then returns to the centre, again starting pulley 1, and the operation is repeated, i.e. continuous oscillation is kept up. The string moves forward in a series of jumps, and pulley 4 exhibits an oscillatory motion superposed on a unidirectional one. It is unnecessary to repeat the description of the process as applied to the actual electrical circuit.

By releasing a set screw holding pulley 1 to its shaft, the string may be freely moved by hand, and the experiments described by Prof. Jenkin may be repeated as follow :—

(1) Applying a low-frequency motion oscillates pulley 4, but spring C is not appreciably stressed. This represents the passage of a low-frequency current through the inductance only.

(2) A high-frequency motion passes through almost entirely by means of spring C, that is, a high-frequency current passes through the condenser only.

(3) Slowly reducing the frequency until the motions of spring and mass are equal, demonstrates "resonance." A small motion of the hand produces a large motion of the spring and mass.

It is very interesting, in this last case, to note how much tension has to be put upon the string. This is an excellent illustration of the fact that the impedance of a parallel combination of inductance and capacity is very high at the resonant frequency, if the resistance be low. If L, C and R be the three constants, then the impedance at the resonant frequency is closely equal to $L/(CR)$ ohms, and the combination acts as a resistance having this value.

It is seen also that the phases of the currents carried by condenser and coil are nearly in quadrature with their resultant (the external current). This is illustrated by the model, in which careful observation shows that the maximum velocity of the string through the valve (maximum anode current) occurs at the zero of oscillation velocity (or main oscillating current).

Many illustrations in the mechanical field can be given as analogues of the "negative resistance" property of a coupled 3-electrode valve. The author ventures to add one further illustration, noticed when

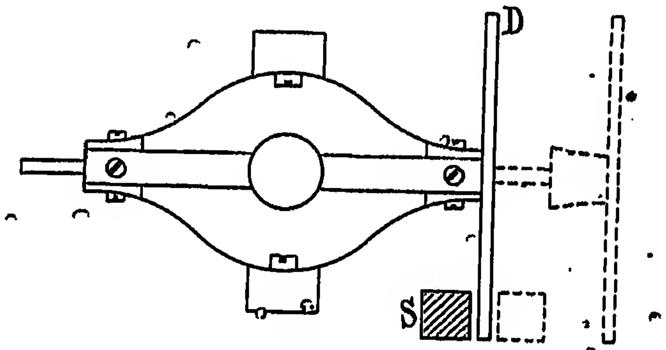

FIG. 4.

constructing the model described. This is provided by the well-known friction-governor mechanism. In Fig. 4 is a diagrammatic view of such a governor. When in rotation, the disc D is drawn along the shaft towards the left hand. If it touches a stop S, a constant speed of rotation is reached because a small increase of speed greatly increases the friction and a small decrease greatly decreases the friction. This results in dynamic *stability*.

But place stop S on the right-hand side and move it slowly towards the disc until it lightly touches. The effect is now opposite to the above. The slight friction retards the motion, reduces the centrifugal force and increases the pressure, thus causing cumulative action which stops the governor. In fact the action is almost instantaneous if S be rigidly held. The result then is dynamic *instability*, and illustrates negative resistance.

It is easy with such an arrangement to produce continuous oscillation, if the stop S is attached to an oscillating system.

In conclusion, the author desires to thank the British Thomson-Houston Co. for laboratory facilities used in preparing the model, also Mr. W. Forbes Boyd and Mr. L. A. Barry for valuable suggestions and help.

DISCUSSION BEFORE THE WIRELESS SECTION, 21 NOVEMBER, 1923.

Mr. G. G. Blake: As the inventor of a valve model exhibited before the Wireless Society of London on 22nd November, 1922, and now used for instructional purposes in the Royal Air Force, I have been particularly interested in the author's most ingenious model. I think that the two models may stand in most friendly relation one with the other. While the author's shows the production of oscillations by a valve, and is a dynamical model, mine shows the effect of incoming oscillations upon the grid of a receiving valve and its plate current, and is a mechanical model, giving actual

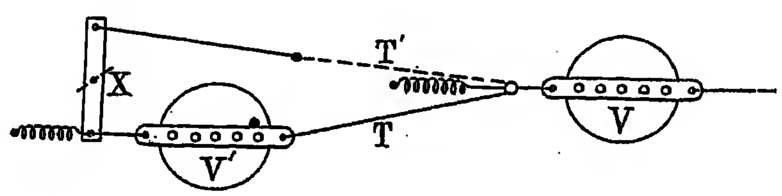

FIG. A.

measurements on calibrated scales. One model appears to me to be the complement of the other. The author's dynamical representation of inductance is very ingenious, while another point which I particularly noted was the reduction of resistance in the oscillating circuit by means of ball bearings. It has occurred to me that, with very slight addition, the "neutrodyne" principle might also be illustrated by his model. As most members will remember, this principle was first employed by Round in his 1913 patent,* in which he showed a condenser connected to the grid to negative the effect of capacity between grid and plate. In 1915 G. W. Wright,† in his dimmed valve limiter, showed an electromagnetic method of balancing out the capacity between grid and plate, and, in 1923, Hazeltine in a paper before the Radio Club of America showed a circuit in which he negatived the internal capacity of the valve by reversed phase capacity coupling, and termed it the "neutrodyne" circuit. A second valve, V_1, might be coupled to valve V of the author's model, as shown in Fig. A, to represent the capacity coupling between two circuits due to the internal capacity of the valve. This coupling could then be neutralized by the addition of a second elastic

* No. 28413/1913.

† No. 8920/1915.

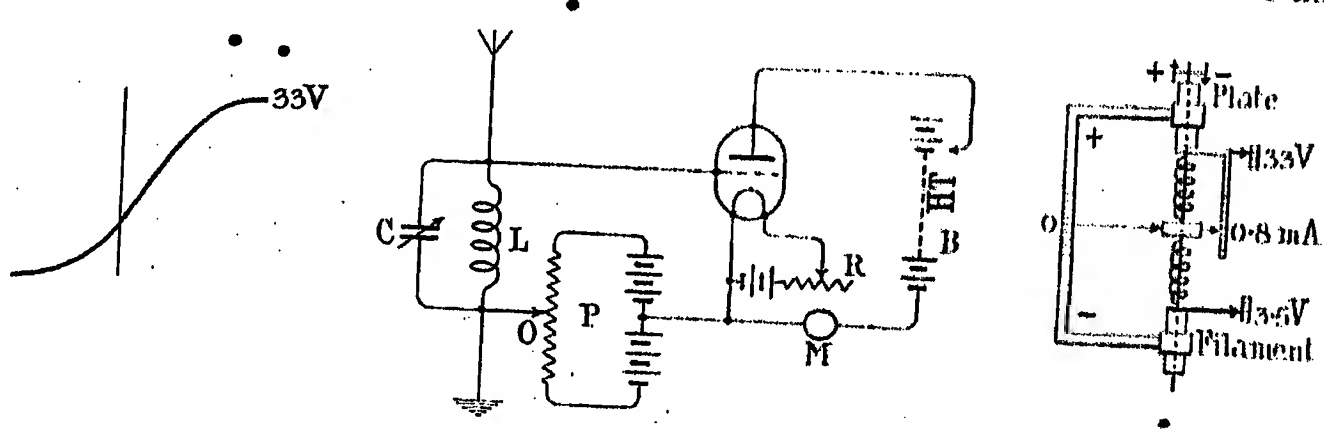

FIG. B.

thread, T_1, acting in opposite phase by means of a pivoted arm X. Another method of illustrating the neutrodyne principle would be to negative the effect of the "coupling thread" F on the model itself and so neutralize the coupling between plate and grid circuits. In a circuit such as that shown in Fig. B there are four variable factors: (1) The grid potential, which can be varied by the potentiometer, O; (2) the filament potential, which can be regulated by the resistance, R; (3) the plate voltage, which can be varied by the H.T. battery, B; and (4) the oscillations produced by the incoming waves in the aerial circuit, CL, which vary the grid potential. There is also a milliammeter, M, in the plate circuit. Fig. C illustrates my mechanical model. A spring, V, is employed to represent the plate current. In the centre of the spring, and attached thereto, is a metal disc, G, representing the grid potential of the valve. On the left is a scale, on which the grid voltages are indicated. It is provided with a pointer P, which indicates the correct position in which the grid-potential disc should be placed to represent various negative or positive values with respect to the filament of the valve. The filament voltage is varied by more or less compression on the lower end of the spring, and the voltages are indicated on a scale. The plate voltage is varied by adjusting the compression of the upper half of the spring, and the voltages are indicated upon a plate-voltage scale. A fourth scale, S, is also provided on which the values of plate current can be read in milliamperes. The values of the scales and the curves represented by the model shown this evening are from a French R valve. The Royal Air Force have worked out similar scales and curves to suit the various types of valve which they employ, and these scales are easily interchangeable for use with the same model. The received oscillations are represented by the movements up and down of a metal rod R, which passes through the centre of the spring V and is coupled to the grid voltage disc, G, by an adjustable slipping contact at the centre of the disc through which it passes.

The oscillations are obtained by means of an eccentric below the rod turned by means of handle H. Adjustment of the eccentric is provided in order to demon-

strate the effect of alterations in amplitude. Two painted arrows (red and white) at the top of the rod indicate the phase. All movements of the grid disc above zero on the grid potential scale represent positive grid potential, and those below zero, negative potential. Referring again to Fig. B (which is reproduced from my paper before the London Wireless Society) the effect of alteration of any of the factors (1), (2) and (3) in the valve circuit can be shown on the plate current, both with the aerial quiescent or when influenced by incoming oscillations, and the action of the valve can be observed when used for amplifying or when recti-

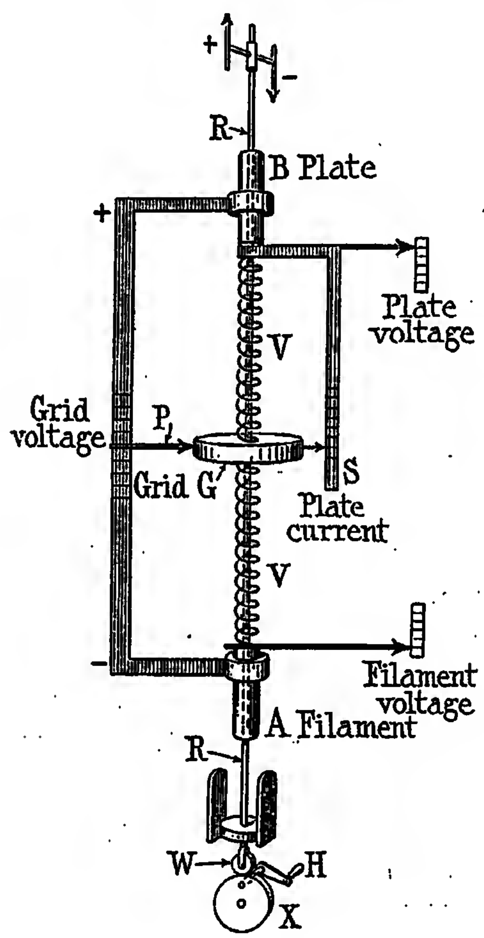

FIG. C.

fying, at different points on the characteristic curve of the valve. The amplification factor also can be demonstrated. Three volts positive on the grid of the valve when the plate voltage is 33 and the filament voltage 3·5, brings us to the top of the characteristic curve, and gives a reading of 1·5 mA. With the grid of the valve at zero, an increase of 21 volts on the plate voltage, making it 54 volts, gives us (when employing the same filament voltage) the same reading (1·5 mA). By dividing the former into the latter we get 7 as the amplification factor. When considering the action of the model it is useful to note that an increase of filament voltage increases the density of the spring coils and makes it impossible for the negative phase of the oscillations to affect the grid-potential disc. This can be likened to an increase of electrons from the filament of a valve, when its temperature is increased, creating a space charge.

Mr. L. B. Turner: The author's model is very ingenious and complete, but I question whether any such model can really assist in explaining the oscillating triode. When (as here) a model must be more complicated than can be grasped by the eye, mathematical analysis must be resorted to; and since one set of mathematical symbols is as good as another, I prefer to deal with the actual quantities instead of others representing them, however close may be the analogy.

Professor C. F. Jenkin (*communicated*): The device of a massive wheel instead of loads on the string is ingenious and allows the direct current to flow. The use of a motor to keep things going is a step ahead. My only criticism is that the condenser and coil C_1, L_1, do not appear to be represented in the model, but I am not sufficiently familiar with the circuit shown in Fig. 1 to know if this omission is of any significance.

Mr. R. C. Clinker (*in reply*): I am much obliged to Mr. Blake for his suggestion as to the "neutrodyne" addition. His suggested arrangement, it is true, would enable the action of the neutrodyne in preventing oscillation to be clearly shown. I feel, however, that a model should be as simple as possible.

With regard to Mr. Turner's remarks, I think that whether or not one desires to have a model of an electrical action depends upon whether one wishes to get a physical grasp of the action, or is content to employ the mathematical machine only. Those students (and there are many) to whom a mathematical demonstration does not appeal as being an explanation, invariably endeavour to form a mental picture of what is going on. To such, a model is an invaluable help, so long as the analogy is not overstrained. In the case under discussion, where we substitute a mechanical mass for an inductance coil, and a spring for a condenser, the analogy is so close as to make it seem that we are dealing with the same fundamentals in the two cases—electrical and mechanical. It is frequently difficult for a student to grasp the principle of the so-called "stopper" or "rejector" circuit consisting of an inductance and capacity in parallel. The statement that its impedance at resonant frequency reaches a maximum of $L/(CR)$ ohms does not give him an explanation. A few minutes' handling of such a model, however, when he can actually feel the resistance offered to the hand by the string at one particular frequency, and observe the relative phases of the motions, impresses the principle on his mind with a clearness that no mathematical demonstration can give.

DISCUSSION ON

"DIRECTIONAL WIRELESS TELEGRAPHY IN AIRCRAFT." *

Dr. R. L. Smith-Rose (*communicated*): All those who have had any experience with the operation of wireless direction-finding on stations will not envy the author his work of making this art sufficiently reliable and accurate for aerial navigation. The difficulties inherent in direction-finding stations are by no means few when the latter are on a good site on land, and are all greatly magnified in an aeroplane in flight. Apart from the actual operational difficulties of taking steady readings, the local errors due to the machine itself must be investigated and corrected. As is shown in the paper, it is not always sufficient to calibrate the machine on the ground or sea when the direction-finding set is required for use in the air. The effect of the metal work and wires contained in the machine offers a problem similar to that provided by the effect of a ship and several error curves given in the paper, I must express my dissatisfaction at the evidence supposed to show the change in quadrantal error from day to day, e.g. in Fig. 3. The maximum difference in the two curves there given is about 6 degrees, yet a change of about 5 degrees at midday, and a total change of 9 degrees shown in Fig. 14, are attributed to another cause. The effect of bonding all metal joints in the machine to maintain constancy of resistance of all current paths, apparently from Fig. 6, reduces the error curve to about half its original amplitude, and is thus an important result of the investigation. With the error amplitude of the order of 6°, and a fairly constant calibration curve, compensation for these effects becomes a practical proposition. Concerning the effect of harmonics in the radiated wave, the errors indicated by Fig. 13

TABLE A.

Variations in Apparent Bearing of Poldhu ($\lambda = 2 \cdot 8$ *km* "*spark*") *at the* 0930 *and* 2130 *Transmissions over the Year March* 1921–*March* 1922.

Teddington	247·9	295	3·7	190	38·3

* Some 400 readings taken on other transmissions from Poldhu during night periods show a total variation of 57·5°.

described recently by Mr. Horton in his paper on "Wireless Direction-Finding in Steel Ships." † In this treatment it was shown that in addition to a deviation in the apparent bearing which varies with the wave-length, due to the structure of the ship, there is usually an accompanying "blurring" or flattening of the minimum with consequent decreased accuracy in observing the bearing. With the Robinson system as described by the author, in which the operation of switching or commutating the connections of the "auxiliary" coil is precisely equivalent to the swinging of a single frame or search coil through a fairly large angle (usually about 30°) through the minimum, this flattening of the minimum would probably be unnoticed, unless the rotating coils are deliberately moved into their minimum position. In connection with the are indeed surprising, for although the fields of the waves of higher frequencies than the fundamental will certainly be modified to different extents by the presence of the metal work of the machine, these fields have little effect on the receiving coil, which is presumably tuned to resonance with the fundamental wave. The concluding portion of the paper deals with the "Daily Variation in Directional Wireless Bearings" which variations are stated to be "of the order of 2° or 3° in this part of the world," although Fig. 14 actually shows a total variation of 9°. It is to be presumed that the results illustrated in Figs. 14 to 18 were obtained at a fixed ground station quite free from any machines, metal work or other surroundings which might cause local errors whether fixed or variable. Unless the fulfilment of these conditions is very carefully attended to, the value of the results as illustrating variations due to some external cause, such, for example, as may be

* Paper by Flight-Lieutenant C. K. Chandler (see vol. 61, page 803).
† *Journal I.E.E.*, 1923, vol. 61, p. 1049.

connected with the atmosphere, is very limited. The most striking thing about this part of the paper is that the author does not appear to have encountered the class of error generally termed "night effect," and his curves show a complete absence of this error, which all other experience has shown to be very much greater in magnitude than the errors in the daytime. For instance, the curves in Figs. 14 to 16 all show their largest error at from one to two hours after midday, and thus in daylight, although the times of observation extend in each case from several hours before sunrise until several hours after sunset. In connection with these curves I should like to ask the author at what intervals the observations, as represented by these curves, were taken. To study the variations in detail, it is important that observations of bearings should be taken regularly at 5- or 10-minute intervals. In Fig. 14, for example, the observations appear to extend from 0100 until 2100, but a great deal of recent experience in connection with 24-hour watches has shown that it is seldom that any transmitting station (except by special arrangement) works continuously for such a period without intervals of from one to several hours, during which much valuable information as to the variations may be lost. During the past three years I have, under the direction of the Radio Research Board, collected many thousands of observations on the variations of the bearings of some 40 fixed transmitting stations. To illustrate the relative magnitude of the variations commonly experienced in this country both by day and by night, a summary of the readings taken on the spark transmission of Poldhu, a station evidently much used by the author, at 0930 and 2130 respectively for the year 1921, is given in Table A. The readings were all taken on Robinson direction-finding sets on comparatively good sites on land.

Many similar examples can be given from the large mass of results, the collation of which is now being carried out. It should also be emphasized that the figures given in the table represent the *extreme variations* in the bearings experienced over a period of one year in the course of daily observation, and such variations are not necessarily of frequent occurrence. In Table B the results of one year's observations of the bearings of various spark transmitting stations at three receiving stations are shown in the form of percentages.

From this table it will be seen that although there is a small number of day readings with an error greater than 2°, the proportion of these of the total is so small as to be practically negligible for many applications of direction-finding. The proportion of readings with a day error greater than 5° is entirely negligible. The errors are seen to be much more common at night, although in this case errors greater than 20° are extremely rare. I can support to some extent the conclusion reached by the author that the variations are small when the transmission is in a N–S direction, but the evidence is somewhat conflicting and needs more confirmation. For example, the bearings of Paris [(FL), spark, 2·6 km], observed at Teddington at night over a period of one year, show a total variation of 6·3°; whereas those observed on Paris [(UFP), continuous wave, 2·4 km], a station in close proximity to FL, show a variation of 22·3° during the same periods. The permanent error of the mean observed bearing in each case is negligible, while the variations in the daytime are of the same order (7°) in each case. The difference may be in some way connected with the change from damped to undamped waves, but the cause is by no means obvious. The theory advanced by the author is, of course, applicable only to daylight variations since it requires an ionization gradient in the lower atmosphere. With the exact data that are now being compiled on this subject, it will shortly be possible to examine quantitatively both this and other theories that have been advanced to explain the various phenomena which are encountered when the radio direction-finder is employed to study the propagation of electromagnetic waves over the earth's surface.

Flight-Lieutenant C. K. Chandler (*in reply*): Dr. Smith-Rose objects to the evidence showing the change in quadrantal error from day to day and considers that it is probably due to the daily variation in bearing. It is

pointed out, however, that a change in the apparent position of the transmitting station would produce a permanent error in the quadrantal-error curve equivalent to raising or lowering the base line. In the curves shown, the whole character of the curve changes, showing that a local effect is producing the error. Further, after bonding, these large differences between the curves taken on successive days disappear and accurate bearings become the general rule. Previously, of several hundred bearings taken, only a very small proportion were accurate. Thus, with a properly bonded aircraft the error curve remained constant from day to day, but with no bonding the error curve was constantly changing. The fact that the bonding reduces the maximum error shows that this error cannot depend on the daily variation except in so far as this affects the error curve as a whole.

With regard to the question of the effects of harmonics in the incoming wave, these will only have a large effect when two conditions are fulfilled, viz.: (1) When the metal-work circuits are in resonance with the harmonic in question, i.e. Zx in Equation (11) is small. (2) When the voltage generated by the harmonic in the metal work is large compared with that generated in the directional wireless aerial, i.e. K in Equation (11) is large. Requirement (2) is fulfilled when the whole of the metal-work of the aircraft acts as an open aerial as distinct from a loop aerial. An examination of Fig. 13 will show that the main component of the Milton curve is a sine θ component, indicating that it is produced by the metal-work of the aircraft acting as an open aerial. This open-aerial circuit does not resonate to the fundamental wave used in the case of Fig. 13, as is shown by the curve for Poldhu taken on the same aircraft, with the same wave-length, on the same day, where the main component is a sine 2θ function, indicating that the metal-work is acting as a loop so far as the fundamental is concerned. It is thus considered that the Milton curve is due to the metal-work of the aircraft acting as an open aerial and resonating to one of the harmonics in the heavily distorted wave radiated from the Milton station. This oscillating current in the metal-work will induce a large voltage at harmonic frequency in the D.W. aerial, and therefore cause an error in the bearing. It must be borne in mind that the station at Milton was a spark station having a power of 2 kW and was only 30 miles away from the receiving aircraft.

In connection with the daily variation in bearing of wireless transmitting stations, these are stated in the paper to be of the order of from 2° to 3° as a general rule, since this is the conclusion drawn as the result of some hundreds of readings taken over a period of eight months. The curves shown in the paper give an idea of the maximum variations likely to be experienced and were qualified by the above statement. The requirements for accuracy were carefully attended to and more than one site was carefully selected, the requirements mentioned by Dr. Smith-Rose being duly considered. Further, the observers were continually changed in order to check observations from day to day. The bearings were taken every hour, by special arrangements available at the time, which is much more frequent than can generally be obtained. More frequent readings would of course have been much better, but were unavailable. It is considered, however, that the curves give valuable information as to the kind of errors to be met with and their variations—matters of the utmost importance to the navigator. Some of the variations in bearing given by Dr. Smith-Rose are extraordinarily large. In the author's experience extending over several years no variations of this magnitude have ever been recorded when working on spark stations, and had they arisen it would have been impossible not to notice them. From Table B it is noted that not more than 2 per cent of the readings taken show variations greater than the range included in the errors given in the paper. Might it not be possible that these are in the nature of freaks and errors in observation? When using continuous-wave stations for bearings the variations have been found to be of the same order as those with spark stations. On occasions exceptionally large variations were found, but these were invariably traced to accidental couplings between the directional wireless aerial system and the local heterodyne circuits.

With regard to the statement by Dr. Smith-Rose that the theory put forward in the paper requires an ionization gradient in the lower atmosphere, the author does not agree with this, but considers that the gradient is produced in the upper atmosphere and that the whole wave is affected by the refraction of the upper portion. This is borne out by the fact that any ionization in the lower atmosphere would be affected by meteorological conditions. Every effort was made to connect the variations in bearing with meteorological conditions existing between the transmitting and receiving stations, but without any success. It was this consideration that led the author to consider the question of an ionization gradient in the upper atmosphere. The quantitative examination of this problem mentioned by Dr. Smith-Rose should be of the greatest assistance to those engaged in the application of directional wireless to navigation, since it should enable the navigator to make corrections for these variations which are at present neglected to a large extent.

INSTITUTION NOTES.

Annual Dinner.

The Annual Dinner of the Institution will be held on Thursday, 21st February, 1924, at the Hotel Cecil, at 7 p.m. for 7.30. Full particulars will shortly be circulated.

Associate Membership Examination Results: October 1923.

International Conference on Large Electricity Supply Systems.

The Secretary has received the following account of the proceedings at the above Conference from Mr. W. B. Woodhouse, who attended it as the senior delegate of the Institution:—

The second International Conference on this subject was held at Paris on the 26th November, 1923, and following days under the auspices of the Union des Syndicats de l'Electricité. Representatives of the following nations were present:—

Austria, Belgium, Canada, Czecho-Slovakia, Denmark, France, Great Britain, Holland, Hungary, Italy, Japan, Norway, Poland, Russia, South Africa, Spain, Sweden, Switzerland, Turkey and United States of America.

The official representatives of the Institution were Messrs. W. B. Woodhouse (senior delegate), P. V. Hunter, C.B.E., and E. B. Wedmore. Other British engineers were present, including Mr. A. Page who represented the Electricity Commission.

A large number of Reports were presented and discussed dealing with problems in connection with the generation of electricity, the construction and operation of transmission systems, and with statutory regulations for securing the safety of the public and continuity of supply.

The British delegates presented three Reports:—

(1) Summary of Recent Researches in Great Britain relating to overhead Line Material and Construction, by Messrs. E. B. Wedmore and W. B. Woodhouse.

(2) Summary of Researches on the Heating of Buried Cables, by Messrs. P. V. Hunter and E. B. Wedmore.

(3) Report on the Earthing of the Neutral Point of High-Voltage Systems, by Mr. J. R. Beard.

The reports and discussion covered a very wide field, and there is little doubt that the discussion of these subjects by so representative an international body will be most beneficial in promoting general agreement as to methods to be adopted and in standardization of practice.

The Conference, as in the case of the first Conference held in 1921, was followed by a meeting of the International Electrotechnical Commission, and the harmonious working of these two bodies will, no doubt, be very beneficial.

During the Conference a number of the foreign engineers were presented to M. Millerand, President of the French Republic, among them being Messrs. Hunter, Borlase Matthews, Page, Wedmore and Woodhouse.

W. B. W.

AN INVESTIGATION OF THE FRICTION BETWEEN SLIDING SURFACES, WITH SPECIAL REFERENCE TO THE EFFECTS PRODUCED BY ELECTRIC CURRENTS PASSING ACROSS SUCH SURFACES.*

[Abstract of Thesis accepted for the Degree of Ph.D. (Science) in the University of London.]

By H. Monteagle Barlow, B.Sc.(Eng.), Ph.D., Student.

(*Paper first received 27th August, 1923, and in final form 22nd January, 1924.*)

Summary.

It has often been demonstrated that when an electric current is passed across certain sliding contacts the friction undergoes a change. In most cases the flow of electricity across the junction is accompanied by an increase in the friction, but in a few instances a slipping action is produced. Both these effects have been applied to the operation of telephone devices, etc., but only a tentative explanation has so far been given of many of the complicated phenomena with which they are associated. In this paper are described a number of experiments designed to elucidate these intricate processes, and in the light of these investigations an attempt has been made to build up a comprehensive theory of their action.

Introduction.

It is proposed to divide the experimental work into three principal sections.

In the first the mechanical effects of relative motion between the parts of various contacts will be considered.

In the second the effects accompanying the passage of an electric current between sliding surfaces will be investigated, (*a*) with reference to good conductors and (*b*) with reference to semi-conductors.

In the third some suggestive observations on stationary imperfect contacts will be described.

Survey of Other Work on the Passage of Electricity across an Imperfect Contact.

Edison seems to have been the first to observe an effect due to an electric current passing across a sliding contact. In 1877 † he found that when a platina-faced wire was drawn over a piece of compressed chalk moistened with certain chemicals, e.g. a solution of hydrate of potash, and a current was passed through the contact, the friction of the wire upon the chalk depended largely on the magnitude and direction of the current.

Edison did not attempt to explain his discovery, but it was generally supposed that the effect was due to electrolytic action at the contact. Sir William Barrett ‡ showed this view to be untenable, and pointed out that if the chalk were dry the friction was increased by the passage of a current, and that a similar effect occurred when the chalk was replaced by a piece of brass.

Barrett's work does not appear to have stimulated any further research on this subject, but in 1905 Appleyard * described a somewhat similar phenomenon. When investigating the apparent decrease in the resistance of a piece of press-spahn with increase of voltage between two rigid electrodes he was led to suspect a variation in the pressure at the contacts and thus to the discovery of what he called a "retentive force" between the dielectric and the metal.

In 1917 Messrs. Johnsen and Rahbek † practically re-discovered Appleyard's "retentive force" and showed that strong adhesive forces were developed when a current passed between certain "semi-conductors" and a metallic plate in close contact with such materials.

Heyl ‡ has attempted to measure the variation in the friction forces between iron and mercury when a current is passed across the junction. The damping effect of an oscillating rod dipping into mercury was observed with and without a current passing through the system. No change in the friction as great as 1 per cent was recorded. A similar experiment with a carbon rod gave a decrease in the friction of about 14 per cent, but the effect was attributed to heating.

This summary would certainly be incomplete if no reference were made to the coherer. It is well known that the action of this instrument has been attributed to electrostatic attraction between its parts. Whether this is correct or not still remains an open question, but it must be admitted that its operation bears at least a striking resemblance to Appleyard's experiments on metal-dielectric contacts. A very large amount of work has been done on the characteristic resistance-changes at imperfect contacts, and it would lead us too far afield to discuss this in detail.

In connection with the mechanical forces between the parts of a coherer, accompanying the resistance changes, the work of Shaw and Garrett § is particularly interesting. By a most ingenious device they measured the force exerted between two copper wires when cohering.

Another field of investigation which has yielded some important observations in this connection is included under "short spark discharges." It has been suggested that the minute gaps which unquestionably exist at an imperfect contact assist in the conduction of electricity

from the one surface to the other. A single-point coherer has no practical existence; it is really a coherer of many contacts, and consequently there must be air spaces at the junction, some partly and some wholly enclosed. The passage of electricity between two electrodes separated by a gaseous dielectric differs from ordinary metallic conduction, inasmuch as both positive and negative ions normally participate. But the nature of the discharge seems to be influenced to some extent by the dimensions of the gap.

After a careful study of the numerous researches on exceedingly short sparks we are of opinion that the balance of evidence is unquestionably in favour of very thin films of gas having an abnormally high conductivity.

As far as we are aware, no experiments have yet been made with high-frequency alternating fields. Some interesting results might be obtained in this direction. The fact that thin films of gas are not good insulators must be recognized if we are to construct anything like a complete theory of imperfect contact phenomena.

Description of Apparatus.

The apparatus was primarily designed to measure the variation in the normal pressure at a sliding contact when carrying a current.

A few preliminary experiments on the force required to separate a copper disc and a piece of lithographic stone having a potential difference between them, had made it abundantly clear that consistent results could be obtained only when the surfaces were sliding over one another. However carefully the contact was made, no two positions of the disc on the stone were sufficiently alike to render definite the force exerted across the interface. But by measuring the variation in the friction forces between the two parts this difficulty is completely overcome, since with suitable damping arrangements the relative disposition of the surfaces in all positions is obviously averaged. With a knowledge of the co-efficient of friction the change in the pressure between the surfaces may be deduced, provided, of course, that the current produces no other effect.

Experience having shown that the most intimate contact was obtained by grinding, it was clearly desirable that the relative position of the surfaces during this operation should be the same as that during the test. Two different arrangements were employed, which we shall distinguish as the "Torsion" and "Steelyard" apparatus.

Torsion apparatus.—This arrangement is shown in Figs. 1 and 2. The sliding parts consisted of two concentric flat rings, (2) and (8), the upper one being attached to a torsion wire (13) and the lower one supported on a horizontal table rotated by a motor. The twisting force due to the friction at their contact was measured by revolving the torsion head (24) until the top ring was brought back to its position when freely suspended.

In view of the fact established by those who have investigated coherer action, that the coherence is enormously influenced by the degree of oxidation of the particles of metal employed, arrangements were made to surround our sliding surfaces with a non-oxidizing atmosphere. This was done by enclosing the active parts in a gas chamber (10) having an oil seal (3) to allow relative motion. All the parts attached to the lower end of the torsion wire were made of aluminium to make the initial pressure between the surfaces as small as possible and to eliminate stray magnetic action. The current was led to the upper contact ring through a mercury trough (15), which offered no restraint to twisting but merely provided additional damping.

The lower end of the torsion wire which was of silver steel had a cross-piece (20) fixed to it, and this could move in a vertical slot cut in the aluminium rod (12).

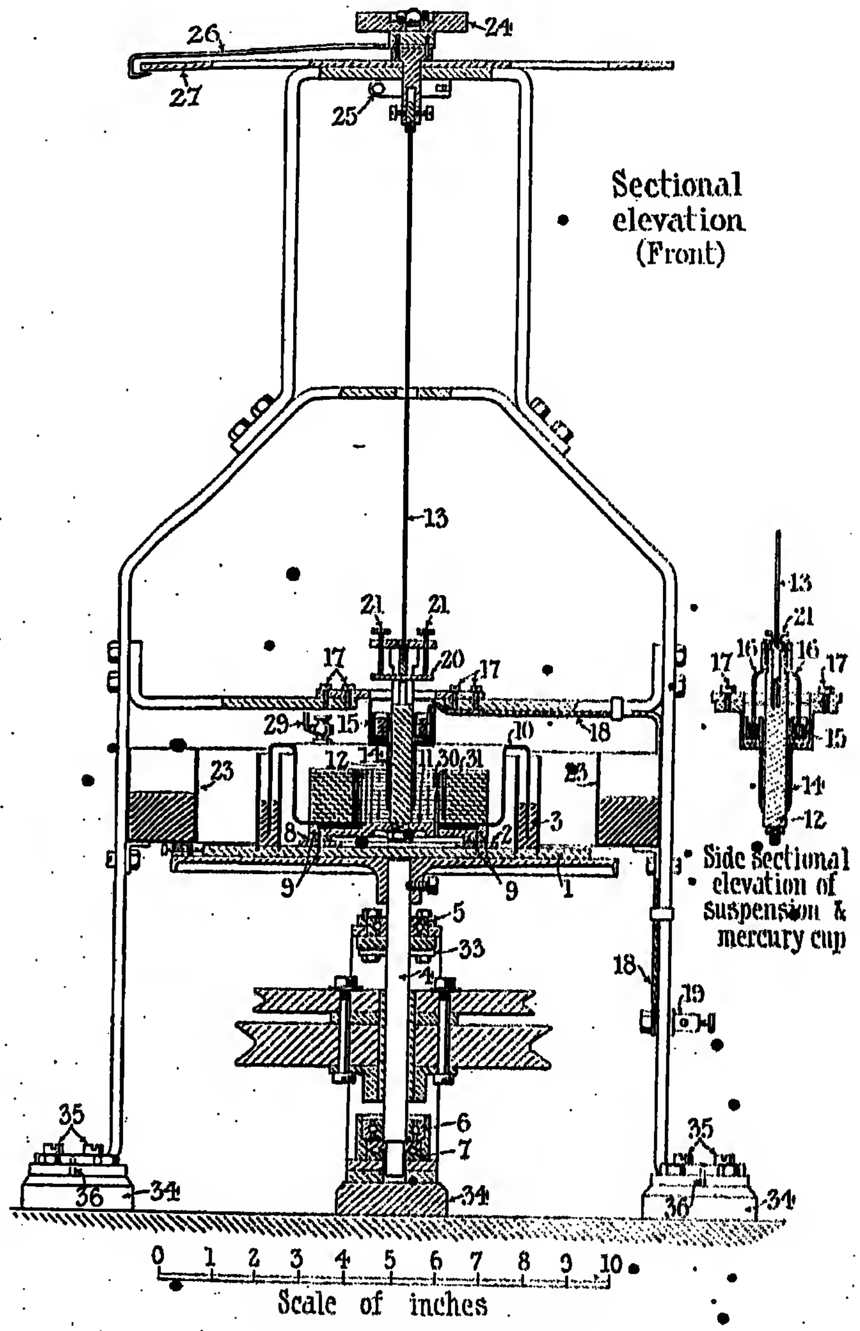

Fig. 1.—Torsion apparatus.

Any change in length of the torsion wire due to twisting or temperature variations was thus automatically compensated for.

Heavy damping was provided by two aluminium arms carrying vanes (22) projecting from the cover of the gas chamber (10) and dipping into another circular trough (23) containing thick oil. Lead weights in the form of rings (31) with a parallel-sided slot, cut from the inner to the outer diameter, were placed in the hollow of the gas-chamber cover so that they exerted pressure directly on the contact surface.

The two parts of the apparatus as a whole were entirely separate and electrically insulated except at the sliding contact. To change the rubbing surfaces the upper parts of the apparatus could be lifted off by removing the four screws (35).

The gas chamber was filled by passing the gas through one of the taps (29) while the air escaped through the rubber tube (30) in the inner diameter of the contact rings.

Two different sizes of torsion wires had to be employed

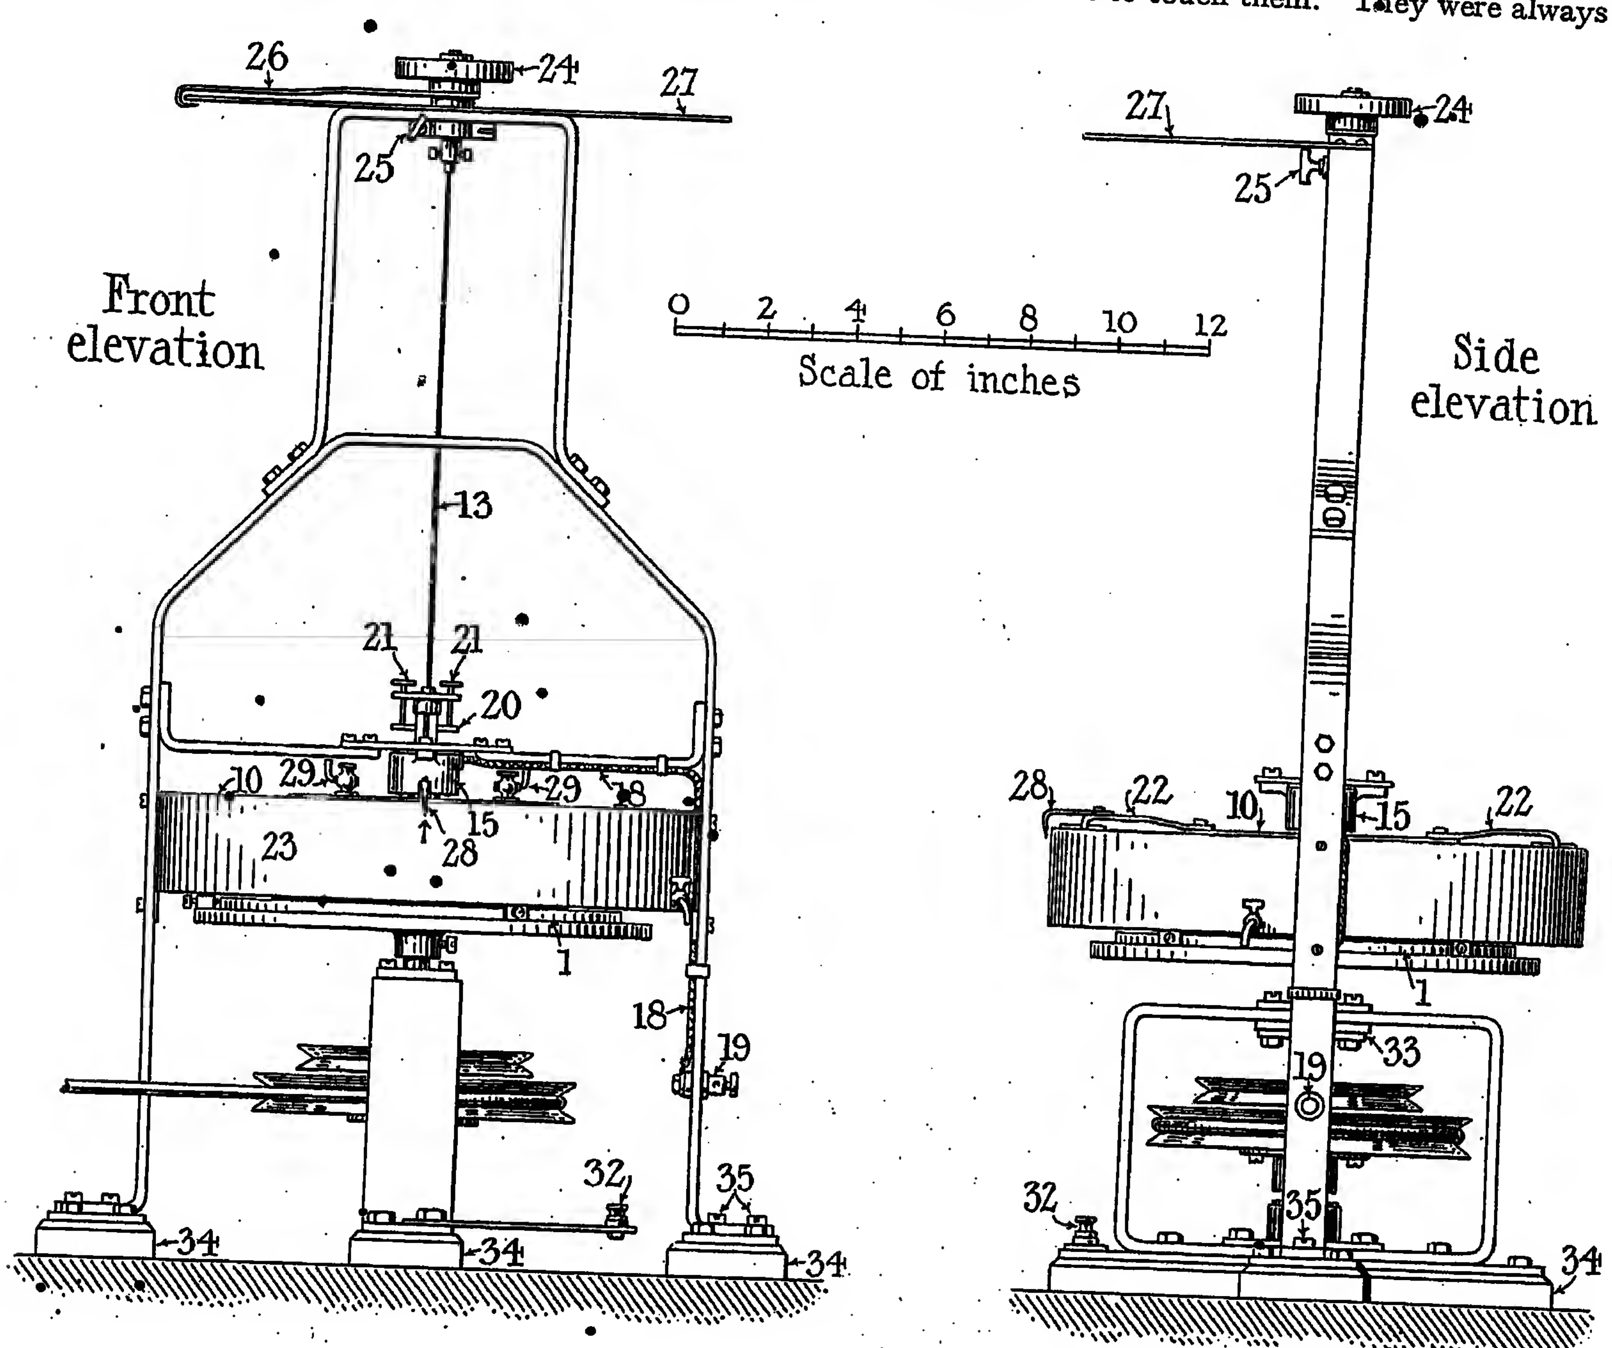

Fig. 2.—Torsion apparatus.

to cover the required range of torque. Both were of silver steel and the same length, but one was $\frac{1}{16}$ inch diameter and the other $\frac{1}{8}$ inch diameter, and they had twisting constants of 1 400 gramme-cm per radian and 22 300 gramme-cm per radian, respectively.

The rubbing surfaces were prepared as follows:—

(1) Ground together in position with flour emery and oil.

(2) Removed from the apparatus and washed with soap and water.

(3) Grinding repeated with very fine carborundum paste until the surfaces assumed a uniform matte appearance.

(4) Removed from the apparatus and washed again with soap and water.

(5) Rinsed in distilled water.

(6) Dried first with linen cloth and then by hot air blast for about 10 minutes to remove dust particles.

(7) Allowed to cool and then replaced in the apparatus.

After the surfaces had been finally washed, great care was taken not to touch them. They were always tested immediately they were cool and, when left overnight, the operations from (4) were repeated in the morning before proceeding with the experiment.

Certain materials required special treatment, which is described when discussing the experimental results.

In all our experiments, except where otherwise stated, we aimed at making the surfaces perfectly dry and clean, having only a discontinuous film of gas between them.

Steelyard apparatus.—The difficulty in obtaining certain non-metals in the form of a ring suitable for testing in the torsion apparatus made it necessary to

construct some other arrangement better adapted to such materials.

The mechanism constructed by Mr. Beauchamp Tower for determining the coefficient of friction of a lubricated journal bearing * suggested the lines on which this design was built up (Figs. 3 and 4).

The semi-conducting cylinder (1) was mounted on a metal shaft (2) and was rotated in a horizontal plane by a motor operating through a reduction gear. On the semi-conducting cylinder rested two brake blocks (17) attached to an aluminium rocker having arms, (18) and (19), projecting in opposite directions. The brake blocks were entirely insulated from one another and from earth, but were connected to two mercury cups (24) through which the current was passed, the circuit being

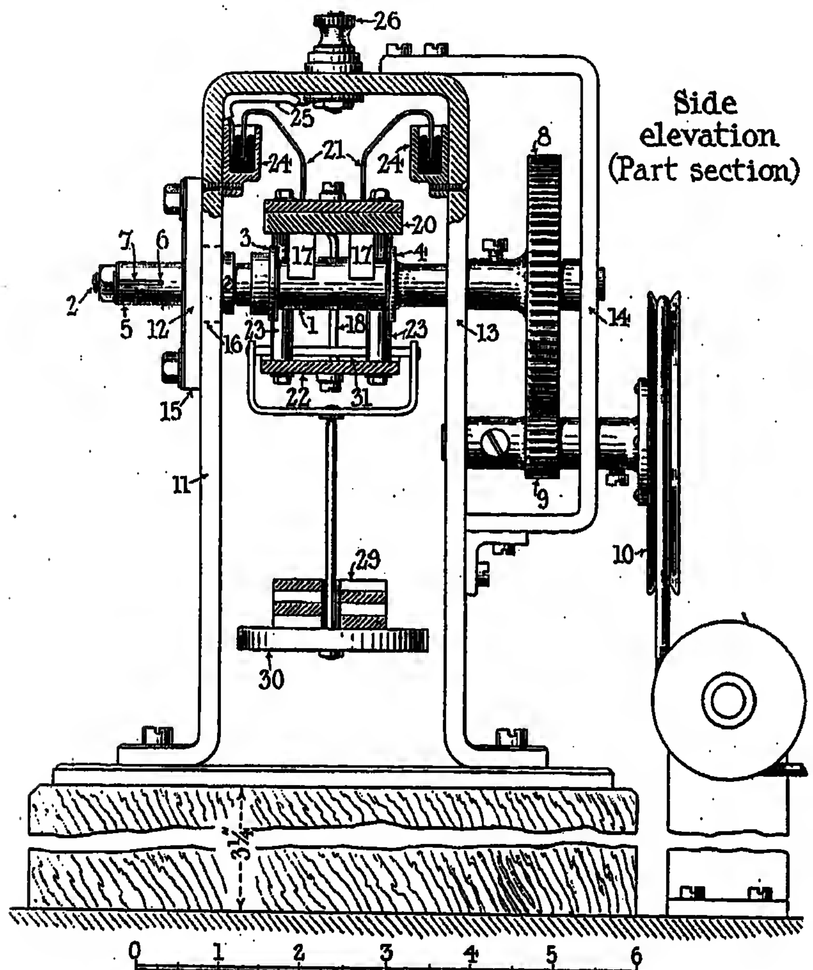

FIG. 3.—Steelyard apparatus.

completed by the semi-conductor. By this means the freedom of the rocker was not interfered with.

The friction forces between the semi-conducting cylinder and the brake blocks were balanced by the jockey-weight (25) on the steelyard arm (19). The other rocker arm (18) carried the damping arrangement, and the pressure applied to the rubbing surfaces could be varied by adding or removing some of the lead weights (29) suspended from a knife-edge (31) on the rocker.

The preparation of the surfaces was much the same as in the torsion apparatus, but under no circumstances were the brake blocks removed from the rocker, or the semi-conducting cylinder from its spindle, until the test was complete.

The position of the jockey-weight when the rocker was exactly balanced was found by temporarily removing the cylinder and replacing it by a horizontal knife-edge on which the brake blocks rested symmetrically.

* *Proceedings of the Institution of Mechanical Engineers*, 1883, p. 632.

Preliminary Measurements and Difficulties.

The first experiments were made on a wrought iron-cast iron contact, and the condition of the surfaces was soon shown to be of the utmost importance in determining the magnitude of the friction-changes accompanying the passage of a current across the junction. The intimacy of the contact, the amount of moisture and foreign matter present, all had a marked influence, and, above all, in the very process of using the surfaces it appeared that they were constantly being changed.

It so happens, however, that when two pieces of dry metal, which have been ground together and carefully cleaned, slide on one another without altering their relative position or the pressure at the contact, the texture of the surfaces does not change uniformly. A state is soon reached when the friction remains very nearly constant, and this continues until suddenly, with practically no warning, seizing takes place.

The duration of the steady state seemed to depend to some extent on the velocity of sliding, and at high speeds it was generally very short. Fig. 5 represents the case of an aluminium-aluminium contact, but the conditions are typical of all metal surfaces. In order to take full advantage of the steady state, the speed of rotation was reduced until the variations in the normal friction forces showed signs of becoming too slow to be properly compensated for by the damping. All the experiments on the metals were made during the constant friction state described above. When seizing occurred the surfaces were re-ground, cleaned and dried again before the tests were continued, and in most cases this operation had to be repeated a dozen times or so. After sliding, the dull matte appearance of the surfaces produced by grinding was partially destroyed. If the contact was good the metallic lustre was restored more or less uniformly over the whole surface.

At first it was thought that something might be gained by polishing the rubbing surfaces, but some experiments on a copper-copper contact showed this view to be erroneous. After grinding the two surfaces together so that they fitted accurately, they were each polished separately with rouge. When replaced in the torsion apparatus and tested in the usual way it was found that they only touched at comparatively few points. The polishing operation had completely distorted them, and the result was a ploughing action which caused seizing.

In many respects non-metals were much easier to handle, chiefly because the steady friction state continued almost indefinitely. In the case of the torsion apparatus the results were found to be exactly the same with and without the gas chamber in use. In view of this fact, the subsequent tests were all carried out in air.

Standards of Comparison.

Since the pressure-change at a semi-conductor contact was found to be principally electrostatic in origin, we

decided that the best basis on which to compare different materials was the drop of potential across the system. In the case of good conductors we had to look to other sources for the cause of the slipping action which is so characteristic of metal-metal contacts. Here the interface P.D. could only be a very small and indefinite fraction of the applied P.D., so that the only reasonable standard of comparison was the current.

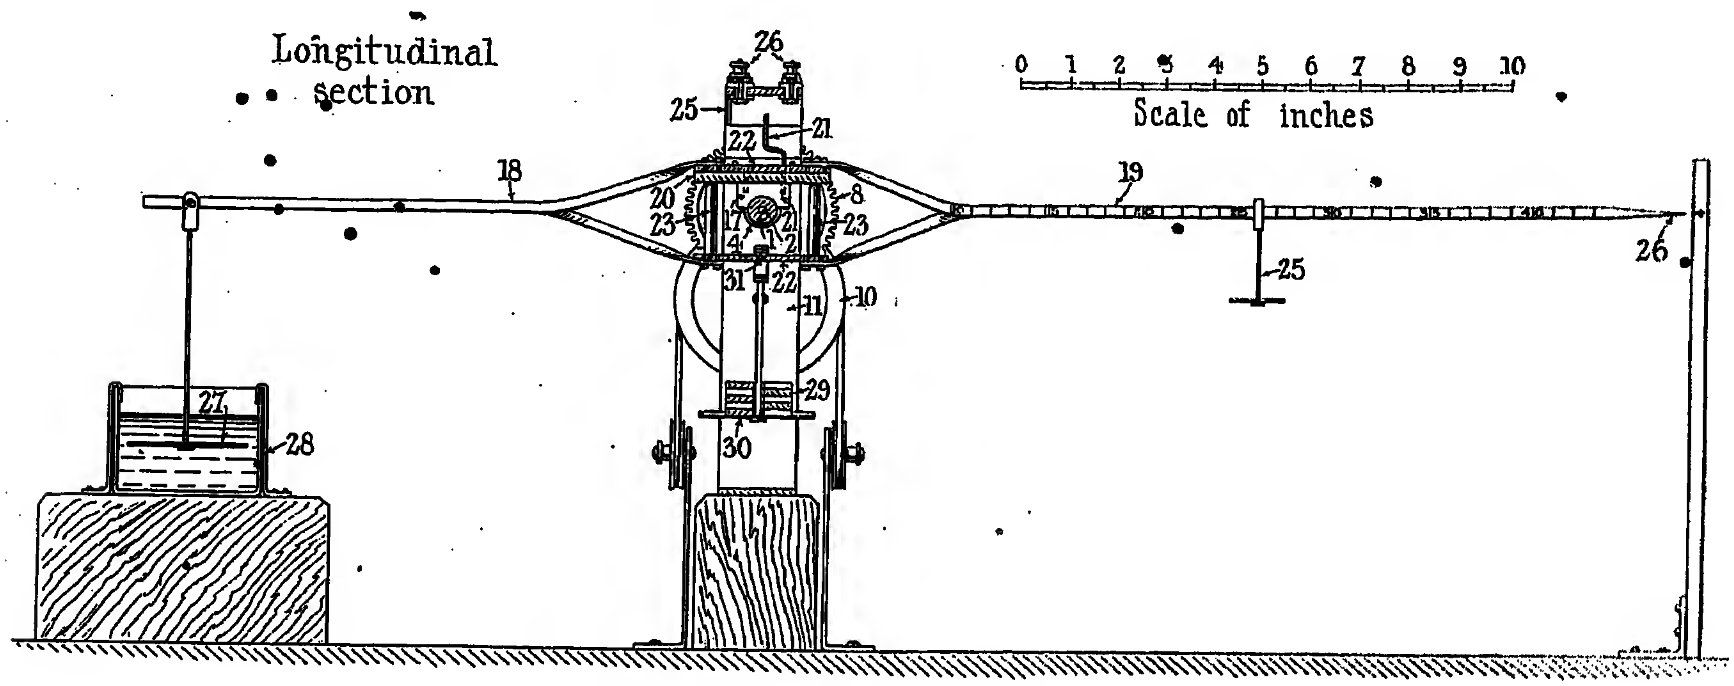

Fig. 4.—Steelyard apparatus.

surfaces, through the tube in the centre. The pressure was kept constant by throttling the output of the blower, and a flexible connection to the gas chamber allowed the air to be passed through while the apparatus was in operation. The temperature of the sliding surfaces was roughly measured by a mercury thermometer at the outlet.

The maximum value recorded was only 30° C., but

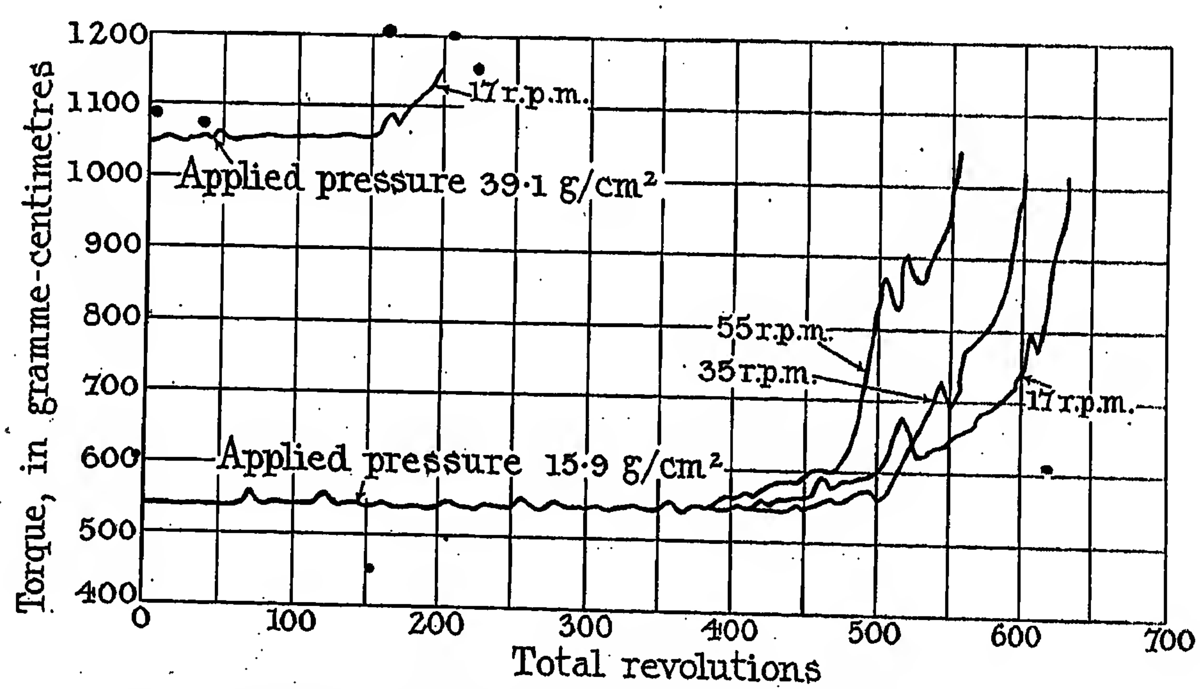

Fig. 5.—Aluminium-aluminium friction, as measured by torsion apparatus.

MECHANICAL EFFECTS AT SLIDING CONTACTS.

Experimental Work.

(1) *Influence of heat.*—A stream of clean hot air was passed through the gas chamber of the torsion apparatus, being admitted by one of the taps on the outer rim and discharged, after passing between the rubbing surfaces over this range the variation in friction was negligible for all the metal-metal contacts. But in the case of copper-graphite there was a decided reduction in the friction forces as the temperature increased, amounting to about − 2·5 gramme-cm per degree C. at a pressure of 18·7 grammes per cm². There were indications that the effect was greater at higher pressures.

The graphite-graphite contact also showed a fall in

friction with increase of temperature, but on a much smaller scale, about $-0\cdot25$ gramme-cm per degree C.

(2) *Relation between friction force and velocity.*—Tests on metal-metal contacts showed a small increase in friction with increase of speed over the range considered, 5 to 100 r.p.m., whilst those including a semi-conductor gave practically no variation.

As an indication of the relation between the static and kinetic friction the following experiment was made on metal surfaces with the torsion apparatus. Having adjusted the torsion head to the equilibrium position for a given steady speed, the motor was shut off and the damping vanes were removed. When the motor was again started, the initial torque in no case exceeded the mean running torque, and was generally a little smaller.

(3) *Influence of surface distortion.*—When a loaded slider is dragged along an elastic plane it will be preceded by compression waves on the surface of the plane. To eliminate any effect due to distortion it is necessary that the slider should be continuous in the direction of its motion. A ring, such as was employed in our experiments, appears to be the only form of slider which satisfies this requirement. But the conditions are very easily altered by cutting radial slots in one of the surfaces.

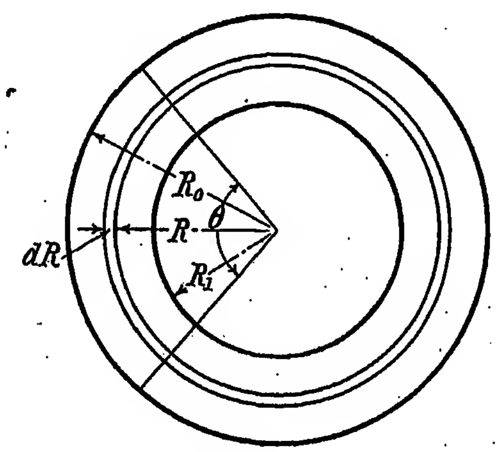

FIG. 6.

Consider a ring, of outside radius R_0 and inside radius R_1, revolving about a vertical axis and rubbing on a flat surface (Fig. 6). If only the area included within the angle θ is operative and the total pressure is P, we have :—

$$\text{Intensity of pressure} = \frac{2P}{\theta(R_0^2 - R_1^2)}$$

Taking an element of area at radius R and of width dR, the elemental friction force dF

$$= \frac{\theta}{2\pi} 2\pi R dR \frac{2P\mu}{\theta(R_0^2 - R_1^2)} = \frac{2P\mu R dR}{(R_0^2 - R_1^2)}$$

where μ = coefficient of friction.

Or total friction torque

$$= \frac{2\mu P}{R_0^2 - R_1^2}\int_{R_1}^{R_0} R^2 dR = \frac{2\mu P}{3(R_0^2 - R_1^2)}(R_0^3 - R_1^3)$$

That is, if T = friction torque,

$$\mu = \frac{3T(R_0^2 - R_1^2)}{2P(R_0^3 - R_1^3)}$$

from which we see that the coefficient of friction for a given size of ring depends only on the slope of the curve connecting torque and total pressure.

According to Amonton's law, therefore, it should be possible to cut any number and any size of radial slots without changing the relation between torque and load.

A large number of experiments were carried out in this way on copper-copper ring contacts of two sizes. The area was gradually reduced from the maximum of 38 cm^2 in the one case, and 27·8 cm^2 in the other, to about 0·25 cm^2. The slope of the torque-pressure curves remained practically constant until the final stages were reached, when there was a small but definite increase. Loads up to 3 000 grammes were used, but unfortunately it was not possible to reduce the contact area further and still maintain its proper sector shape.

Prof. Hardy and Miss I. Doubleday say that the coefficient of friction is a maximum when the surfaces are clean, and give the figure 0·74 for a steel slider on a steel plate in this condition.* The coefficients of friction deduced from our experiments on various metal-metal contacts (Table 1) are, on the average, not more than about 0·15. It is true that the same degree of cleanliness may not have been obtained, but even Hardy's lubricated surfaces yield a figure twice as value of the right order. The fact that rings of different sizes gave the same figures is strongly in favour of this argument.

As the result of some careful experiments on discontinuous sliders of various shapes, Chaumat* came to the conclusion that the friction force depends not only on the pressure, as Amonton's law states, but also on the degree of asymmetry of the loading. Hardy has confirmed this result and attributes the effect to irregular lubrication. Is it not more likely to be due to changes in the retarding forces produced by the deformation of the surfaces?

(4) *The significance of the "initial pressure" between the surfaces.*—If the torque due to the friction between the surfaces is plotted against the pressure, we invariably obtain a straight line which, when produced, does not pass through the origin (Fig. 7). That is to say, the friction does not vanish when the applied load is indefinitely reduced, but there always remains a certain

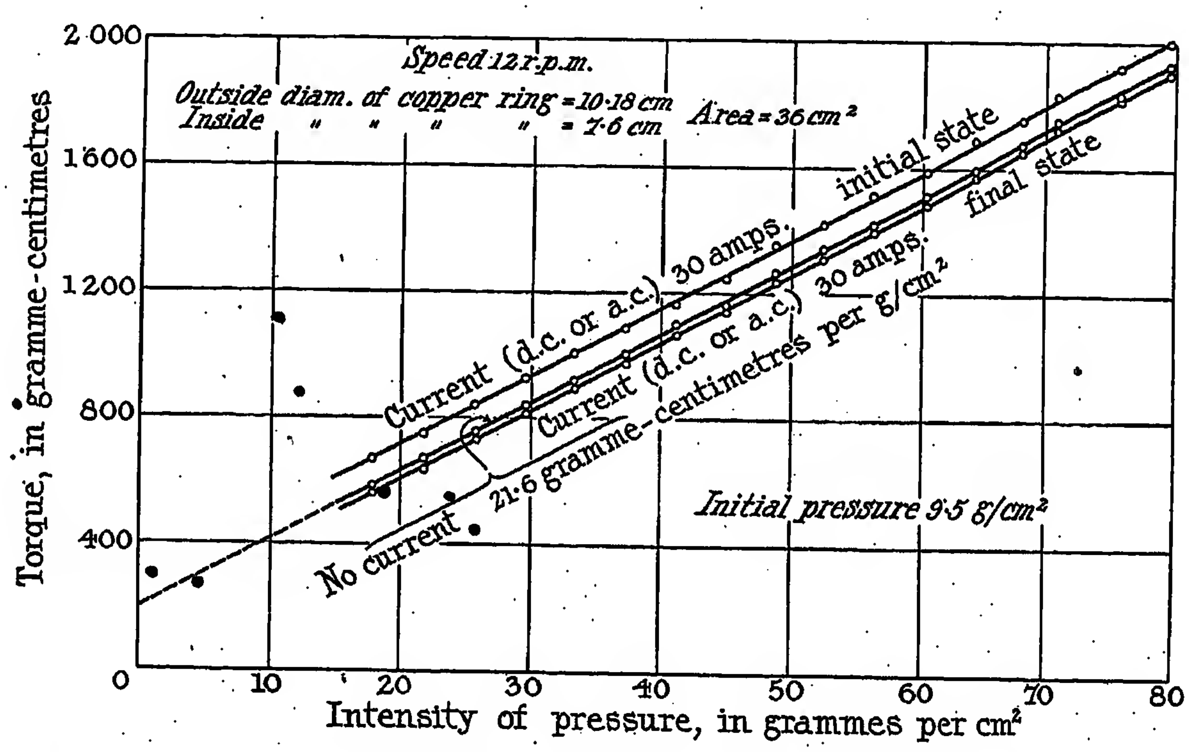

FIG. 7.—Variation of torque with pressure for copper and copper, as measured by torsion apparatus.

great as that which we obtained quite regularly with dry surfaces.

The question arises: Is this discrepancy accounted for by deformation of the contact in the case of the spherical slider employed by Hardy and Miss Doubleday? From a calculation for the maximum intensity of pressure, by the equations due to Hertz † it would appear that the elastic limit of the material must have been closely approached if not exceeded.

It might be objected that our expression for the coefficient of friction of an annular contact assumes the load to be uniformly distributed over the whole extent of the rubbing surface. If the intensity of pressure is greatest near the inner radius of the ring, the calculation will yield an excessive value for μ, or vice versa. We should expect, therefore, an average torque corresponding to what may be conveniently called the "initial pressure" between the surfaces. If the interface was free from moisture, this could only have arisen either (i) from the exclusion of the atmosphere between the surfaces or (ii) from cohesion forces operating at the points of molecular contact. We are inclined to think that the initial pressure is principally attributable to the exclusion of some of the air between the surfaces.

SUMMARY OF RESULTS.

There is plenty of evidence to show that the engaging of asperities is not primarily responsible for the phenomenon of solid friction, although this action undoubtedly amplifies the retarding forces in many cases. Our experiments on surface distortion due to a discontinuous slider demonstrate the effect on a large scale. Its influence is only likely to be of importance with rough

surfaces and high pressures. What we call "seizing" is probably an exaggerated form of surface distortion, and occurs when the elastic limit of the material at the points of contact has been exceeded.

ELECTRICAL EFFECTS AT SLIDING CONTACTS.

Contacts between Good Conductors.

Experimental Work.

(1) *Current-torque changes.*—The change which occurs in the friction torque at a metal-metal contact due to the passage of a steady current is very simple. Fig. 7 represents the case of copper-copper, which is typical of all good conductors. It will be observed that the current does not alter the coefficient of friction but merely adds to, or subtracts from, the pressure between the surfaces an amount depending upon the magnitude of the current passing. Magnetic and non-magnetic metals behave alike in this respect.

The variation of torque with current is much more complicated, although the general characteristics of different contacts are more or less the same. Fig. 8

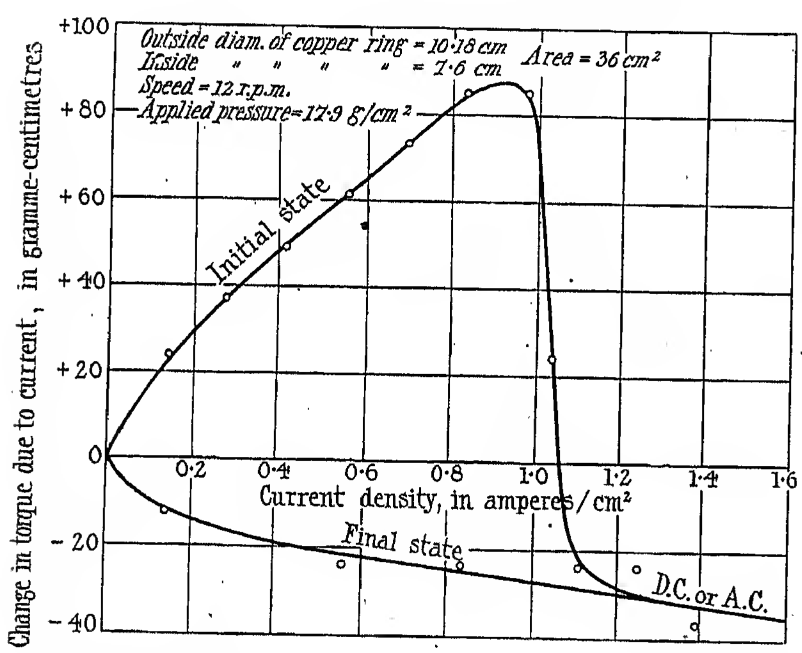

Fig. 8.—Variation of torque with current for copper-copper, as measured by torsion apparatus.

for copper-copper is fairly representative of the average conditions.

After the surfaces have been ground, cleaned and dried, they appear to be in a peculiarly sensitive condition, which we shall characterize as the "initial state." As the current is increased from zero, the friction torque invariably increases, but at a certain critical point the torque suddenly drops and in most cases falls below the no-current value, the drop increasing with further increase of current. If now the current is reduced, the torque returns towards its initial value without any irregular variations. When the current is again increased, the torque-change follows the last part of the first cycle, that is, it generally falls with increase of current. This is the "final state," and its characteristic friction-changes may be repeated any number of times, provided the interval between the tests does not exceed about a quarter of an hour. The "initial state" is always reproduced when the surfaces have been washed and dried, or when they have been left in the "final state" and are not touched for about half an hour. The recovery is gradual and the "initial state" is often partially re-established after a few minutes. If, when the critical current has been exceeded and the "final state" produced, the surfaces are only re-dried in a stream of hot air, the conditions are unaltered, unless sufficient time has elapsed to exercise an influence. Moreover, the "initial state" corresponding to the first part of the cycle can always be repeated any number of times if the current is kept below the critical value.

The actual magnitude of the torque-changes appears

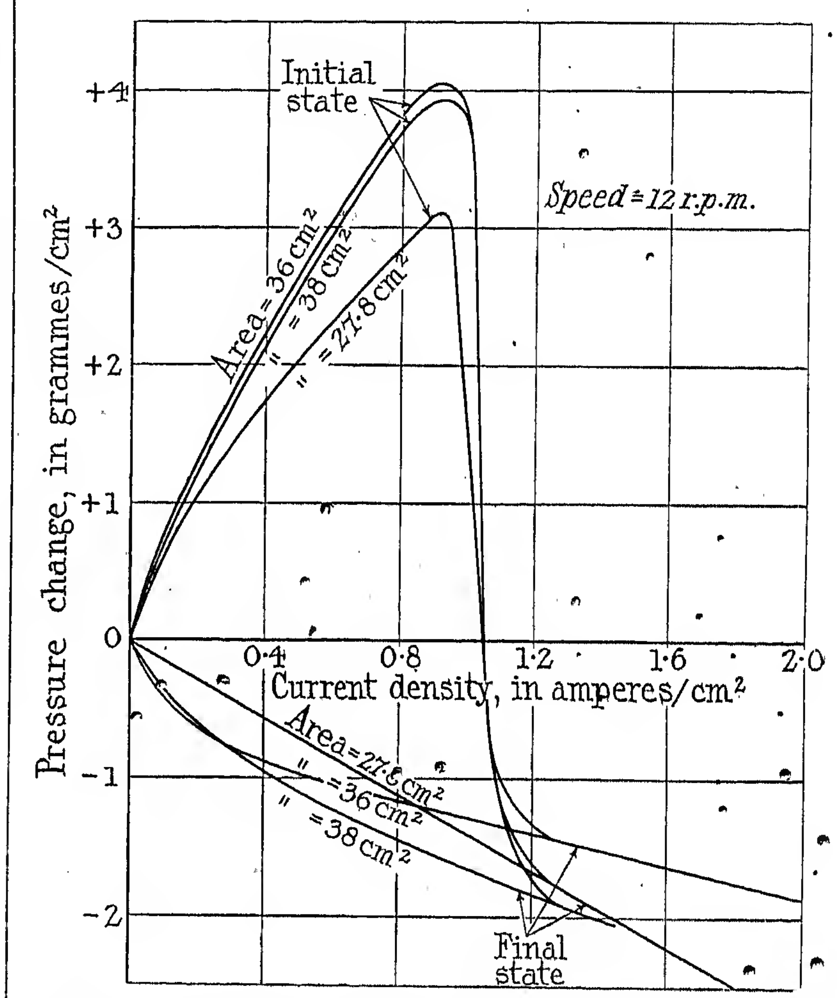

Fig. 9.—Variation of intensity of pressure with current for copper and copper, as measured by torsion apparatus.

to vary with the nature of the contact and the fit of the surfaces. It was noticed that the "stiction" was much more marked when the contact was good.

The full effect of the current does not operate quite instantaneously, particularly in the "initial state." The heavy damping made it difficult to follow the time-changes, especially as these lasted only a few seconds at the most. Even in the "initial state" there always appeared to be a tendency for the current to reduce the friction. On switching on, there was generally a slight transient decrease in the torque, and, on switching off, a similar slight increase. On the whole the observations suggested that there was some building-up action which took a second or two to complete. In all cases the figures represent steady value.

There were also indications that there was a small drop in the no-current pressure between the surfaces at the

transition from the initial to the final state, but the change was scarcely measurable with the apparatus employed.

By combining the torque-current curves with the

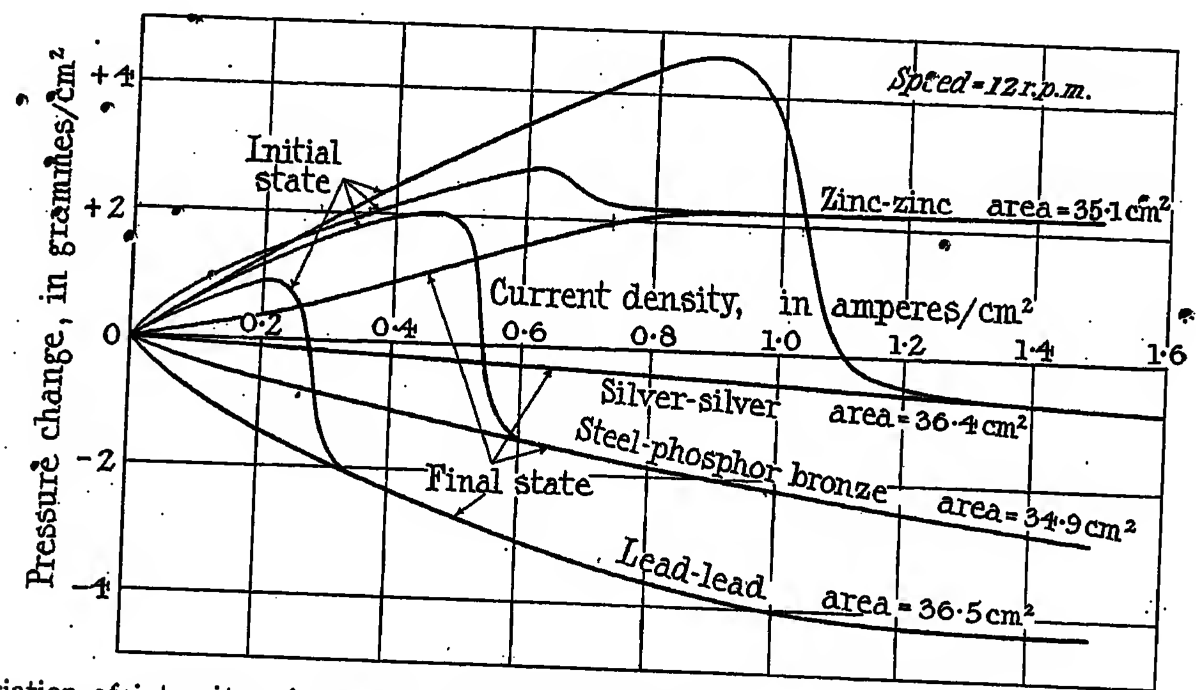

FIG. 10.—Variation of intensity of pressure with current for various metals, as measured by torsion apparatus.

corresponding torque-pressure curves the variation in the intensity of the force across the contact when carrying various currents has been deduced. This was not

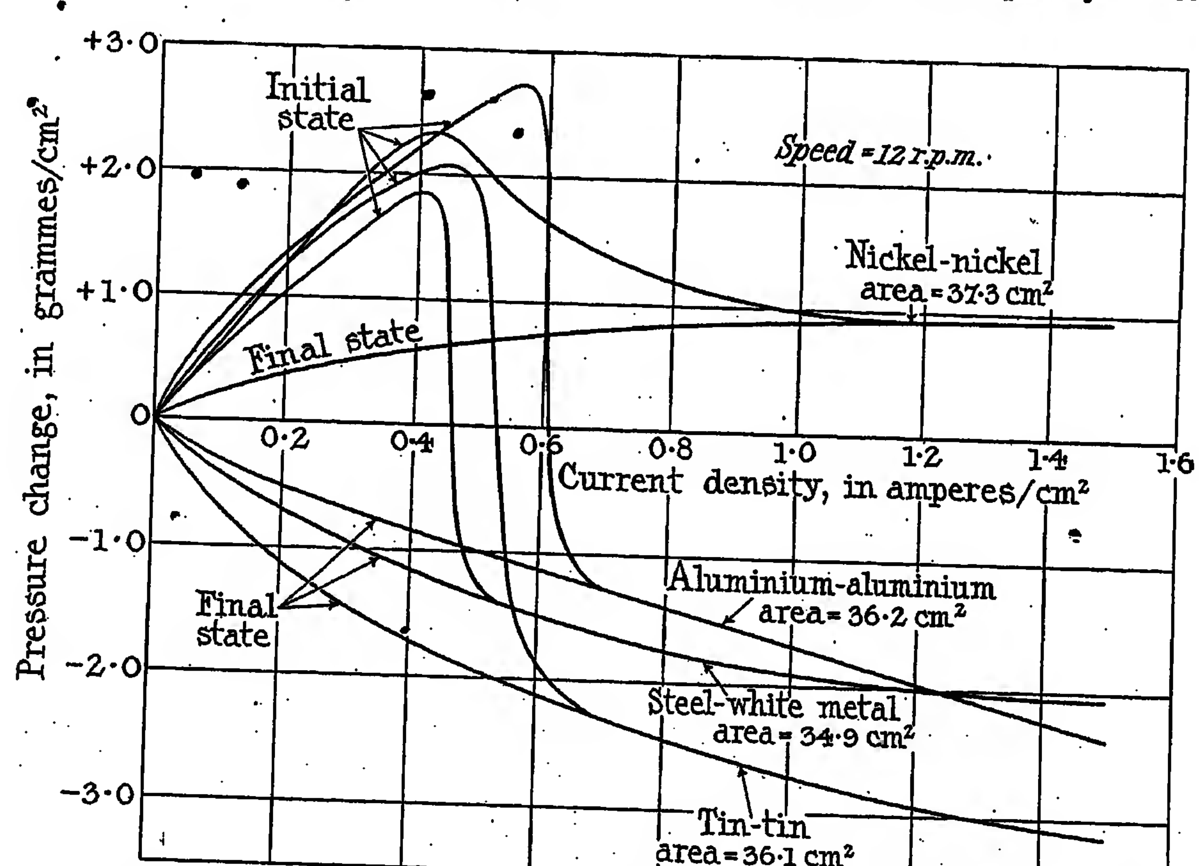

FIG. 11.—Variation of intensity of pressure with current for various metals, as measured by torsion apparatus.

permissible, however, in the case of graphite, on account of the complicating influence of heat. The results are shown in Figs. 9 to 15.

(2) *Influence of electrodynamic action of circuit.*—This effect was proved to be relatively negligible by altering the shape of the circuit so that the loop was very much larger. When the connections to the upper and lower ring extended vertically for considerably greater distances, the changes in the friction forces corresponding to a given current remained unaltered.

(3) *Influence of a liquid film between the sliding surfaces.*—Any trace of moisture between the surfaces enormously reduced the "stiction," and when the interface was really wet a current less than the normal critical value would often cause "slipping." The normal

coefficient of friction was of course also influenced by the water film, which acted as a lubricant, so that a smaller torque corresponded to a given pressure variation, but this does not account for the current effect changing from a positive to a negative one.

Some quantitative measurements were made with a mercury amalgam between two copper surfaces (Table 2). Having secured a good contact by grinding in the usual way, the rings were carefully amalgamated over the whole extent of the sliding faces, so that when placed together in position they formed a continuous metallic conductor without any air pockets between them. Various currents up to 100 amperes were then passed through the system when the two solid parts were in relative motion, and the variation in the friction forces

TABLE 2.

Weight of copper ring = 93 grammes. Speed = 12 r.p.m.

VARIATION OF TORQUE WITH CURRENT AT CONSTANT PRESSURE.

Applied pressure = 17·9 grammes per cm².

Current (amps.)	Current density in amps. per cm²	Torque change in gramme-cm
60	1·67	0
70	1·95	− 6·0
80	2·22	− 12·0
90	2·5	− 18·0
100	2·78	− 31·0

observed. The results show that up to about 60 amperes the "stiction" associated with the gas film between the surfaces was entirely banished, and at larger currents a decided reduction in the friction torque was indicated.

(4) *Comparison between different areas of contact.*—Three different sizes of copper-copper contacts were tested, and all gave the same general characteristics (Fig. 9). The relative magnitude of the effects will be discussed later.

(5) *Influence of velocity of sliding.*—There was no measurable variation in the friction effects of a given current over the range of speed considered, 5 r.p.m. to 100 r.p.m.

The total resistance of the circuit also remained practically constant until the sliding surfaces were brought to rest, when it suddenly dropped. Fig. 16 shows the resistance-changes due to motion for various currents passing across contacts of wrought iron-wrought iron, nickel-nickel, steel-phosphor bronze and copper-copper. In all cases the change decreases with increase of current.

To make these measurements an annular mercury trough was fitted to the outer edge of the brass disc on which the lower contact ring rested. An insulated copper

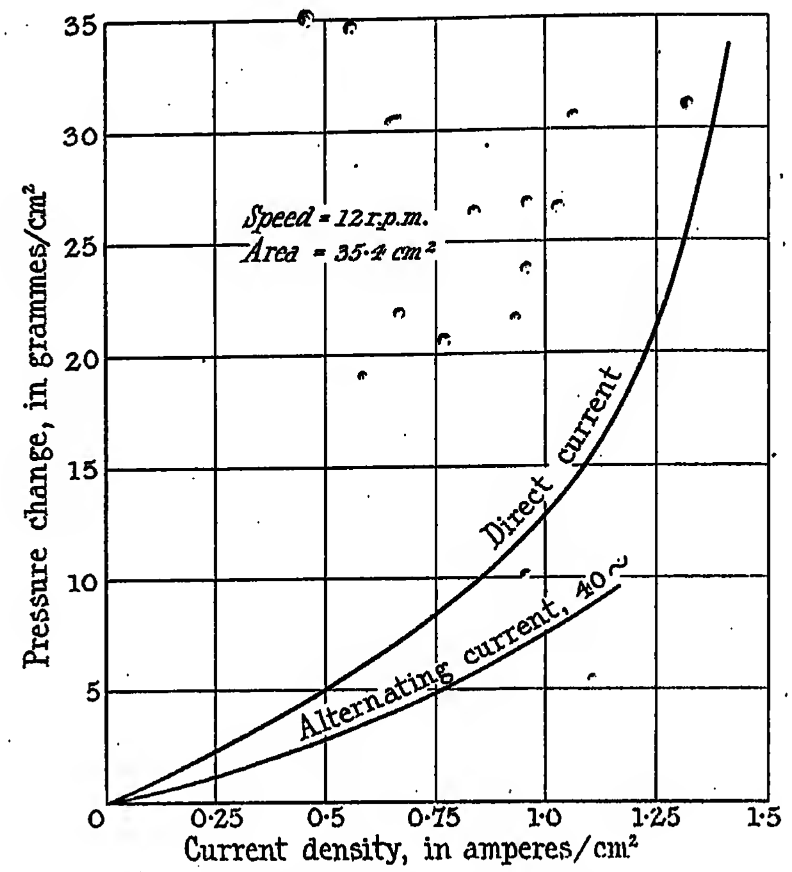

FIG. 12.—Variation of intensity of pressure with current for wrought iron and wrought iron, as measured by torsion apparatus.

wire fixed to the framework and dipping into the mercury trough thus provided a continuous metallic connection

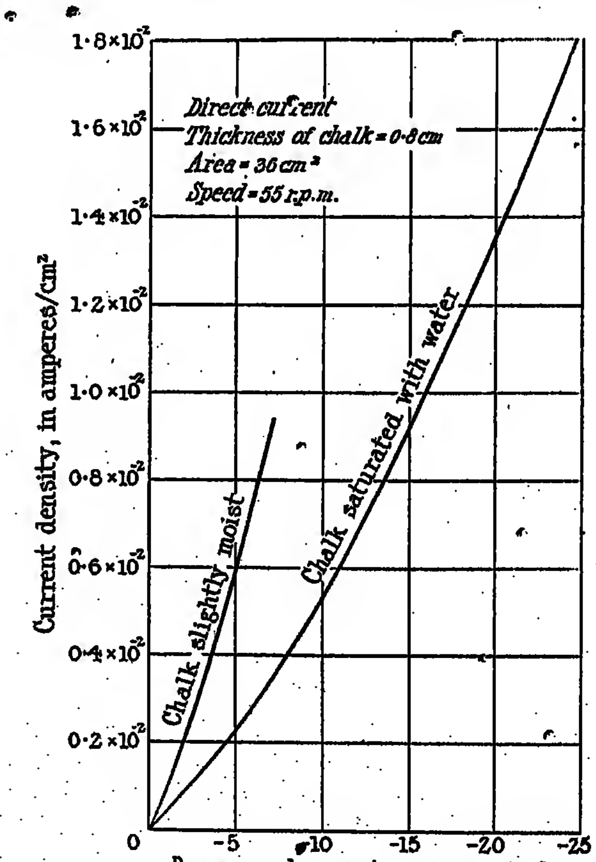

FIG. 13.—Variation of intensity of pressure with current for copper and chalk, as measured by torsion apparatus.

to this ring. By short-circuiting the sliding surfaces it was ascertained that there was no resistance-change

at any of the mercury contacts when the apparatus was set in motion.

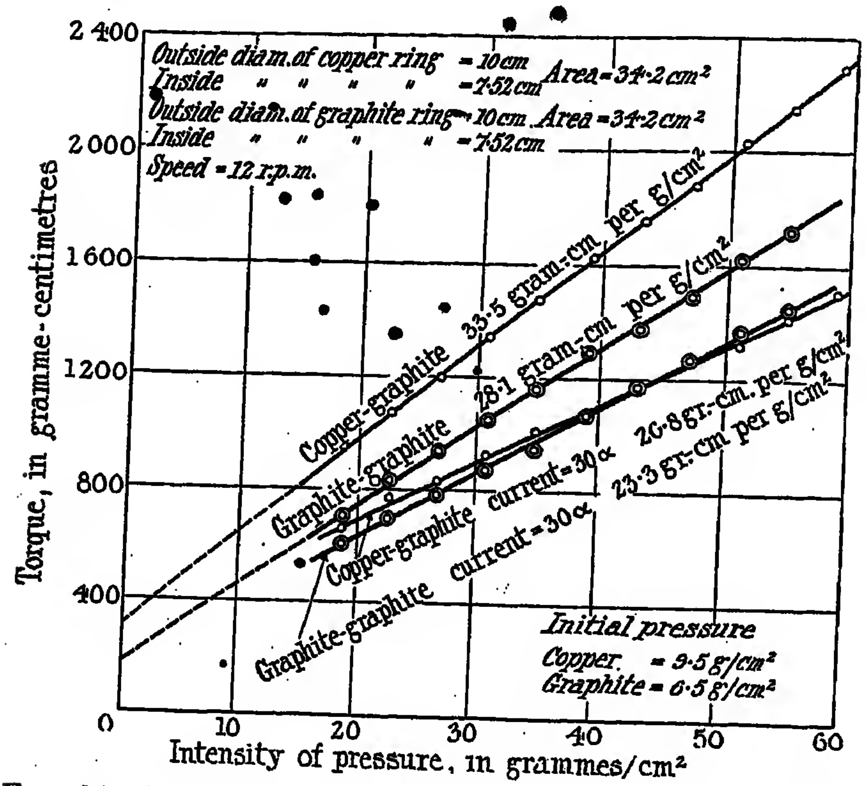

FIG. 14.—Variation of torque with pressure for copper and graphite, and graphite and graphite, as measured by torsion apparatus.

(6) *Instability of resistance.*—This was a very noticeable feature of practically all the contacts tested, and

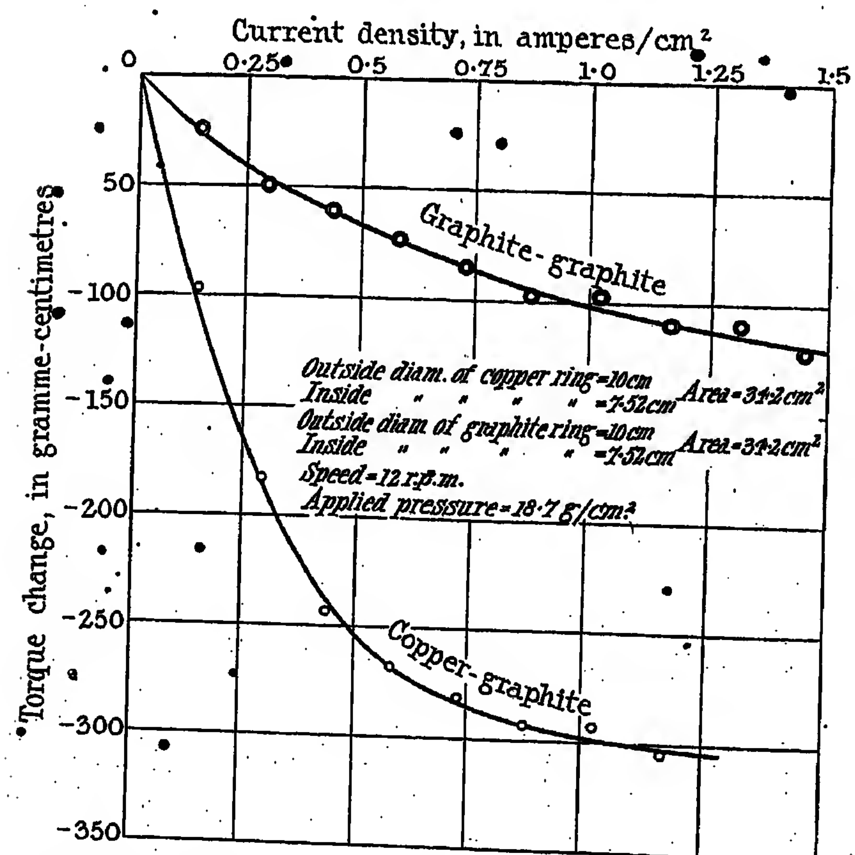

FIG. 15.—Variation of torque with current for copper and graphite, and graphite and graphite, as measured by torsion apparatus.

was in no way associated with mechanical vibration. With a steady applied P.D. the current was continually fluctuating. The effect was perhaps most noticeable when the surfaces were at rest.

(7) *Comparison between the effects of alternating and direct currents.*—Only low-frequency alternating currents (50 cycles per sec.) were employed, but, within the limits of accuracy obtainable, practically no difference was observed between the torque-changes produced by a given R.M.S. value of a varying current, and the corresponding direct current. The initial and final states were precisely the same. There were indications, however, that the "stiction" was not quite as large with alternating current, but the apparatus was not really sufficiently sensitive to decide this point.

These remarks do not apply to the wrought iron-wrought iron contact, which will now be considered separately.

(8) *Effects peculiar to special cases.*

(*a*) *Wrought iron-wrought iron contact.*—The current-pressure changes associated with this contact (Fig. 12)

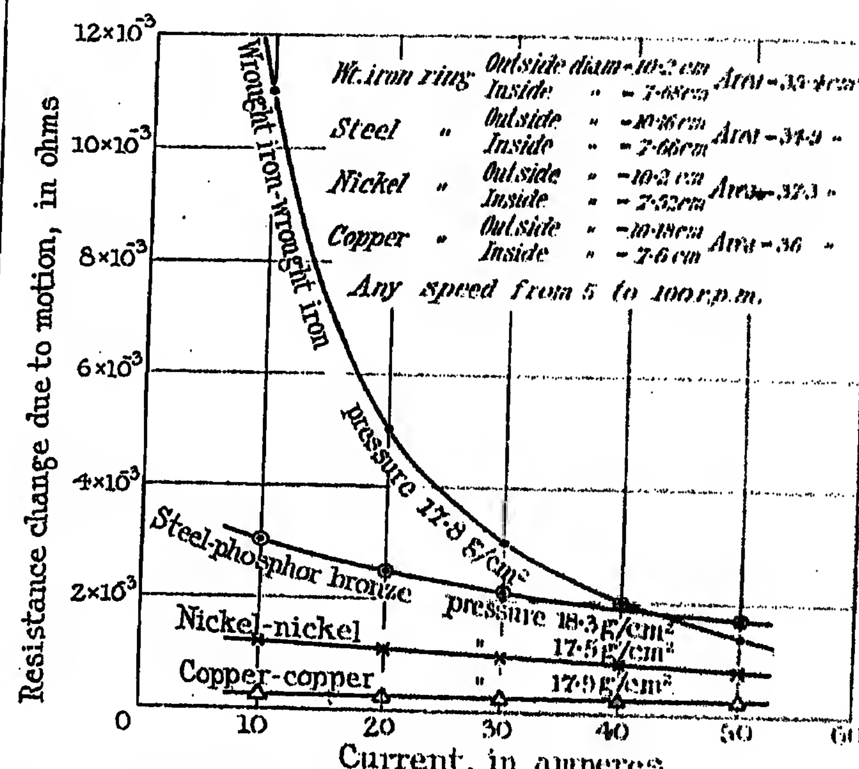

FIG. 16.—Resistance-changes with current between various metals, as measured by torsion apparatus.

differ entirely from those which are so characteristic of all the other metals tested.

There are no initial and final states. The pressure simply increased and decreased regularly with the current, the change being considerably greater than for the non-magnetic materials. The building-up effect was particularly marked, and as much as a quarter of a minute sometimes elapsed before the final steady conditions were reached. Moreover, it was the only case in which an alternating current definitely produced a smaller pressure-change than a direct current of the same value.

The alternating current caused the surfaces to vibrate synchronously, presumably by a periodic variation in the pressure between them.

(*b*) *Nickel-nickel and zinc-zinc contacts.*—These differed from the majority of the metal-metal contacts, inasmuch as the pressure-changes were always positive

(Figs. 10 and 11). The stiction was less in the final state than in the "initial state," and was practically the same for alternating and direct currents.

(*c*) *Copper-graphite contact.*—The fit of the surfaces in this case was perhaps inferior to that obtained with two metals. They were prepared by first grinding with flour emery and water, and then simply allowing them to rub together for some time when slightly moistened. Finally, they were thoroughly dried and tested in the usual way.

No stiction was observed to accompany the passage of a small current across the junction, as Fig. 15 indicates. Possibly the critical current was too small to produce any measurable effect. The "final state" was established immediately and continued indefinitely.

Another peculiarity was that the reduction in the friction due to a given current increased with the pressure applied between the surfaces (Fig. 14).

A considerable amount of heat was generated at the contact when the current was maintained for more than a minute or two, and this seemed to accentuate the slipping effect, the main part of which was simultaneous with the application of the current.

There was no difference between the action of alternating and direct currents.

(*d*) *Graphite-graphite contact.*—The outstanding characteristics of this contact were exactly the same as those of copper and graphite (Figs. 14 and 15). The influence of heat was perhaps less noticeable, and occasionally a small transient stiction effect was observed when the current was first applied.

(*e*) *Copper-chalk contact.*—The friction forces were so irregular in this case that it was difficult to make any observations of value. Small flints in the chalk, which was in its natural state, ploughed the surface of the copper, and to add to the difficulties the current could not be kept constant.

The contact was prepared by scraping the chalk until the marks produced by sliding showed that the fit was tolerably good.

No stiction was observed, and a few preliminary tests made it clear that the effect of a current in reducing the friction was a function of the number of amperes passing and had no relation to the applied potential. There was always an initial rush of current on switching on, and a corresponding drop in the friction torque.

If the current was maintained the effective resistance of the circuit slowly increased, and if the terminal P.D. was kept constant the friction torque gradually returned to its normal value.

When the chalk was moistened, the friction forces became more regular and the results a little more consistent (Fig. 13).

The same current was obtained with widely different applied voltages by varying its time of application, and the curves show that the friction torque is definitely related to the number of amperes passing.

(*f*) *Contact between metallic lead and wood saturated with hydrate of potash.*—This is practically the combination employed by Edison in his original loud-speaking telephone, except that wood was used instead of paper, the surface of which was found to rub up.

It was observed that there was a reduction in the friction when a current was passed across the contact, and that the effect was greater if the lead was connected to the negative side of the supply.

THEORY.

We have seen that the change in the friction at a sliding contact, due to a given current, is independent of both the applied load and the relative velocity. It follows, therefore, that the effect is due to variations in the resultant pressure across the interface.

It is clear that there are two distinct actions involved, one tending to increase the friction and the other tending to decrease it. Certain observations suggest that the effects operate simultaneously in opposition to one another. At a certain critical current, which varies with the nature of the contact, it generally appears that the slipping action suddenly predominates.

(1) *Nature of "stiction effect."*—The increase in the pressure between the surfaces is a necessary consequence of any difference of potential across the interface, and its existence has been practically proved where semi-conductors are involved.

In the "initial state" the "stiction" is by far the more important and, possibly, the only effect.

The irregular behaviour of the wrought iron-wrought iron contact is difficult to understand. We can only suppose that the electrostatic action is supplemented in this case by a magnetic one. The current stream-lines cannot be normal to the plane of separation of the surfaces, so that the encircling magnetic flux crosses the interface at an angle. The relatively high permeability of wrought iron would naturally greatly accentuate this action. The stiction increases much more rapidly than the current, probably because we are working right at the bottom of the magnetization curve for the material.

(2) *Nature of slipping effect.*—It has been shown that the electrodynamic action of the local circuit through the sliding contact had no measurable influence on the pressure between the surfaces, and the effect of the earth's magnetic field must have been equally unimportant on account of the distribution of the conductor to the upper ring. We look, therefore, to the interface for the origin of the observed reduction in pressure between the two parts.

One might suppose a change in the nature of the surfaces by local heating or a small separation of the contact by particles torn away from the solid boundaries. But such considerations are not required by the evidence distinguishing the so-called "initial" and "final" states.

If it is admitted that the numerous gaps between the solid contacts assist in the conduction of electricity across the junction, our selection of the possible causes of the slipping effect is immediately extended.

Many of our results indicate that the reduction in the pressure between the surfaces is primarily a function of the current.

Sir J. J. Thomson * has pointed out that the electric force theoretically required to drag an electron away

* "Conduction of Electricity through Gases."

from a metal surface might easily be realized with even a fraction of a volt across a very small gap. It would seem possible, therefore, that the slipping effect at our sliding contacts was partly due to a bombardment of the surfaces by charged particles projected across the air spaces. A rough calculation is sufficient to show that with currents of the order employed in this investigation such a conception of the mechanism involved is unjustified. The mechanical reaction accompanying the "electric wind" can hardly be supposed to function in the minute gaps with which we are dealing.

Between our rubbing surfaces we probably had both liquid and gaseous conductors through which the current had to pass in crossing the interface. Under favourable conditions the so-called "pinch effect" * may produce considerable mechanical forces between the different parts of a circuit including a mobile conductor, and we suggest that this action is directly responsible for the observed reduction in the pressure at a sliding contact of good conductors when carrying a current.

Whether the film between the surfaces be liquid or gas, the action is much the same. Whether the current is alternating or direct, the forces produced will be practically equally intense. When the interface is wet or bridged by a mercury amalgam we have shown that the initial "stiction" is entirely banished and is generally replaced by a tendency to slip, precisely what one would expect on the assumption that the positive action is due to an electrostatic attraction and the negative one to the so-called "pinch" phenomenon. The liquid film short-circuits the gaps and greatly reduces the potential difference between the surfaces.

Consider the normal case of two metal plates in mutual contact. The interface conductor will in general consist partly of an oxide or sulphide, partly of moisture and partly of gas. For the most part this is mobile and will submit to distortion by striction forces. Although our surfaces were ordinarily dried, it is not to be supposed that they were really free from moisture, and we must regard the gaps as partially occupied by water molecules. The metal will be by far the best conductor and, consequently, the current stream-lines will tend to concentrate at projections on the surfaces. The "pinch" effect will then tend to cause the plates to separate.

Unfortunately, it is impossible to calculate, even approximately, the pressure developed by the "pinch" effect at an imperfect contact carrying a current. We have to remember that the action takes place in a confined space, and that the conducting veins are probably being continually ruptured by a sudden rush of current at one point. When the surfaces are sliding together the conditions are still more complicated. The numerous parallel paths across the contact are continually changing, so that inertia of the interface mobile conductor will have an important influence. The pressure generated by the current in one particular vein will remain some time after it has ceased to conduct, and in this way the total force tending to separate the surfaces may be considerably magnified.

* P. Barry, *L'Industrie Electrique*, 1901, vol. 10, p. 179, and *L'Eclairage Electrique*, 1907, vol. 51, p. 37; also Northrup, *Physical Review*, 1907, vol. 24, p. 474.

The theoretical expression for the pressure produced in a cylindrical conductor, namely

$$p = \frac{I^2}{\pi R^4}(R^2 - r^2)$$

where I = current, and R = external radius, shows that the effect may be very intense over small areas. The conducting veins will contract, and in many cases there will be a complete rupture. If the velocity of displacement is large, the projection of the particles to the right and left of the break may also add to the pressure on the surfaces, and this action will also tend to persist after the current has been stopped and transferred to another part of the contact.

It is interesting to note that A. Sellerio * observed an increased repulsion between the poles of an electric arc when the electrodes were very close together. Further research on this subject might reveal some very interesting facts with regard to the forces accompanying the discharge of electricity across very small gaps.

(3) *The significance of the "critical" current.*—Our experiments have shown that the slipping effect assumes a controlling influence at a certain "critical current." In view of our hypothesis as to the nature of the contact and the action of the interface film, the following explanation at once suggests itself: That the partially conducting layer is suddenly broken down and made a relatively good conductor by ionization. The effect is equivalent to interposing water between the surfaces. The electrostatic attraction forces are enormously reduced by this means, and electromagnetic striction becomes dominant.

In the "initial state" the conduction across the contact is probably mainly through the solid and, perhaps, partly electrolytic. The transition point corresponds to the potential at which metal electrons begin to be dragged across the majority of the gaps, which henceforth assist in the transportation of electricity.

We know that a metal is always more or less spongy, due to the occlusion of air bubbles, and that when the surface is ground some of these are laid open, forming minute pits. When the critical current has been exceeded, these pits will contain ionized gas, which will remain in the conducting state for some little time after the P.D. has been removed. It should perhaps be made clear that the ionization is supposed to be produced through the agency of the electron streams forming the initial discharge across the gaps, and not by the direct action of the electric field.

If, when the contact is in the final or ionized state, the current is switched off, re-combination of the gaseous ions will gradually restore the original conditions. Immersion of the surfaces in water, of course, immediately reproduces the initial state.

We have seen that the full slipping effect does not always operate simultaneously with the application of the current, a fact which is at once explained by the ionization lag. The tendency towards a transient reduction in the friction on making and breaking the circuit, when the interface was in the initial state,

* *Philosophical Magazine*, 1922, vol. 44, p. 765.

may have been an inertia effect accompanying electromagnetic striction in the moisture film before the electrostatic attraction had had time to build up.

On the supposition that friction is due to a lack of correspondence between the direction of sliding and the interface equipotential surface, it is possible that the accumulation of free electricity in the gaps, due to ionization, may slightly modify the distribution of this imaginary frictionless surface. If such is the case the change must be small. We did actually from the fact that the pressure-changes are all approximately of the same order, no deductions of value can be made. This line of investigation was therefore not pursued.

(5) *The relative effects of alternating and direct currents.*—Our hypothesis regarding the nature of the "stiction" and "slipping" effects does not require any great difference between the action of alternating and direct currents where non-magnetic materials are concerned. The observations are, of course, time

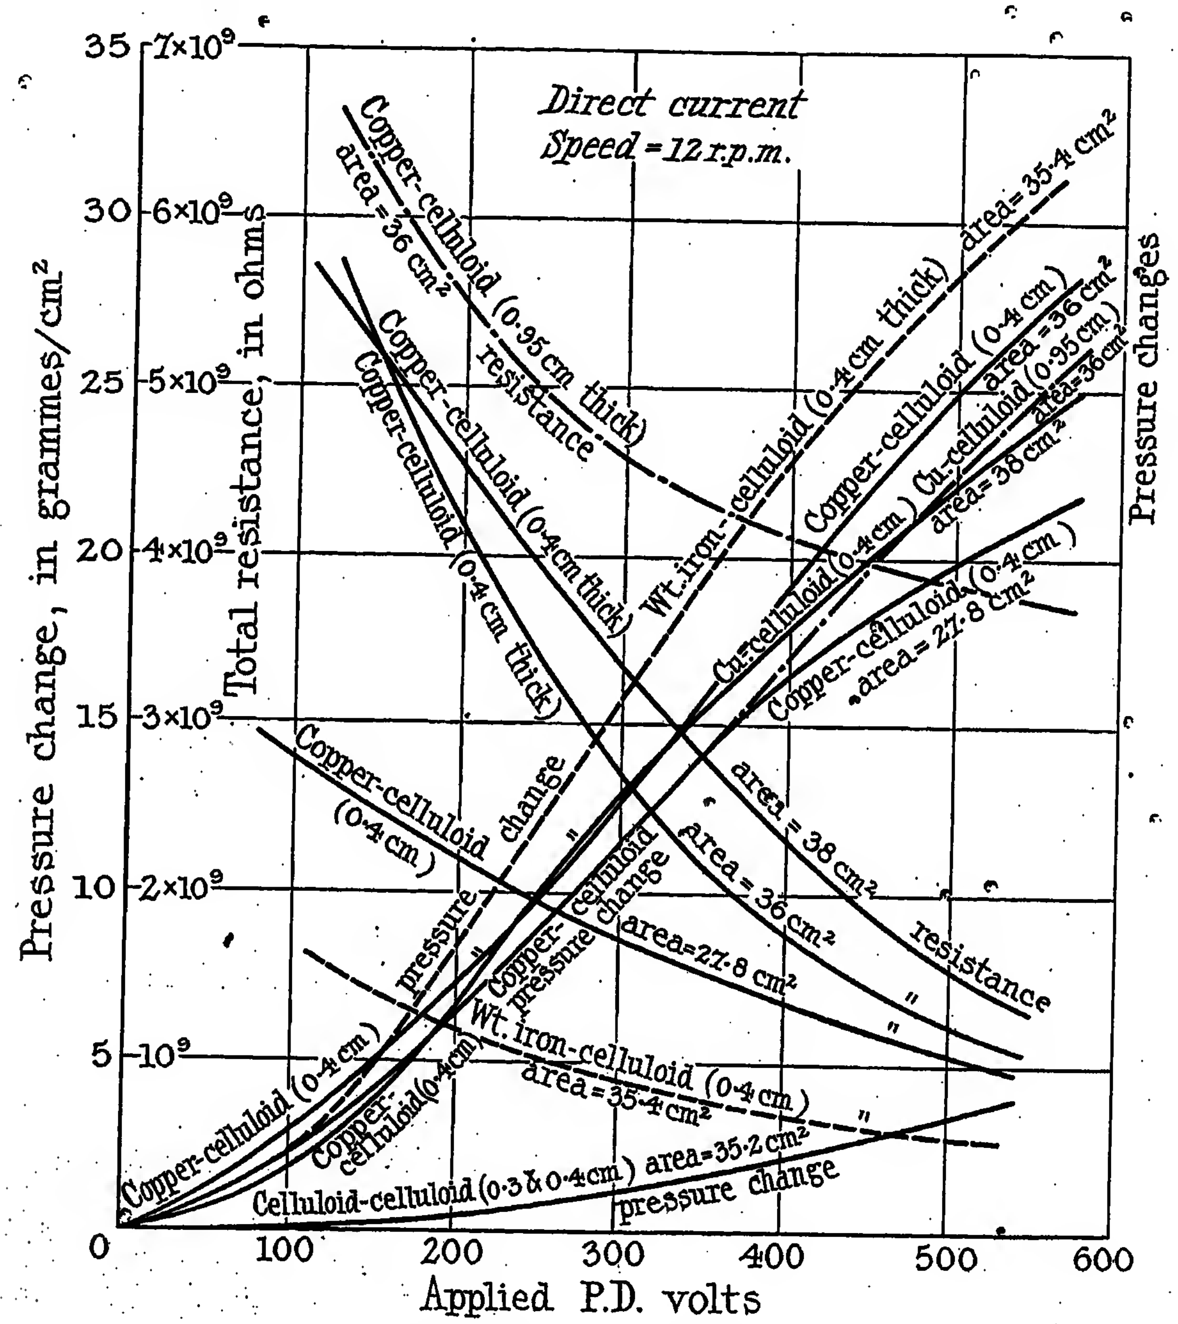

FIG. 17.—Variation in pressure with applied P.D. between various contact areas of copper-celluloid, wrought iron-celluloid and celluloid-celluloid, as measured by torsion apparatus.

observe a slight drop in the no-current torque at the transition from the initial to the final state, but it was scarcely measurable. The coefficient of friction also remained unchanged.

(4) *Influence of the area of contact.*—If in the initial state the electrostatic attraction operated alone the pressure-change corresponding to a given interface P.D. should be independent of the area of contact. We have to remember, however, that the effective transition resistance, and therefore the potential between the surfaces, are actually functions of this area. Apart averages, so that in the case of a varying current the stiction at any rate should be slightly smaller. The magnitude of the effects was unfortunately not large enough for us to get very definite information on this point.

A contact between one magnetic and one non-magnetic metal gave precisely the same results as a contact between two non-magnetic metals, but if both surfaces were iron, the pressure-change corresponding to a given current was very much less with an alternating supply. This is exactly what we should

expect, on the assumption that the effect is partly a magnetic one.

(6) *Contact resistance.*—It is clear from the foregoing discussion that the effective resistance of the interface is fundamentally associated with the friction-changes. In all our sliding contacts the transition resistance fell slightly with increase of current, and the conductivity of the interface film was considerably reduced when the two surfaces were in relative motion. We conclude that the increase in pressure across the contact for a given current is larger during sliding. An examination of Figs. 9 to 11 shows that the critical current varies with the nature of the surfaces. A noticeable feature of the curves is the relation between

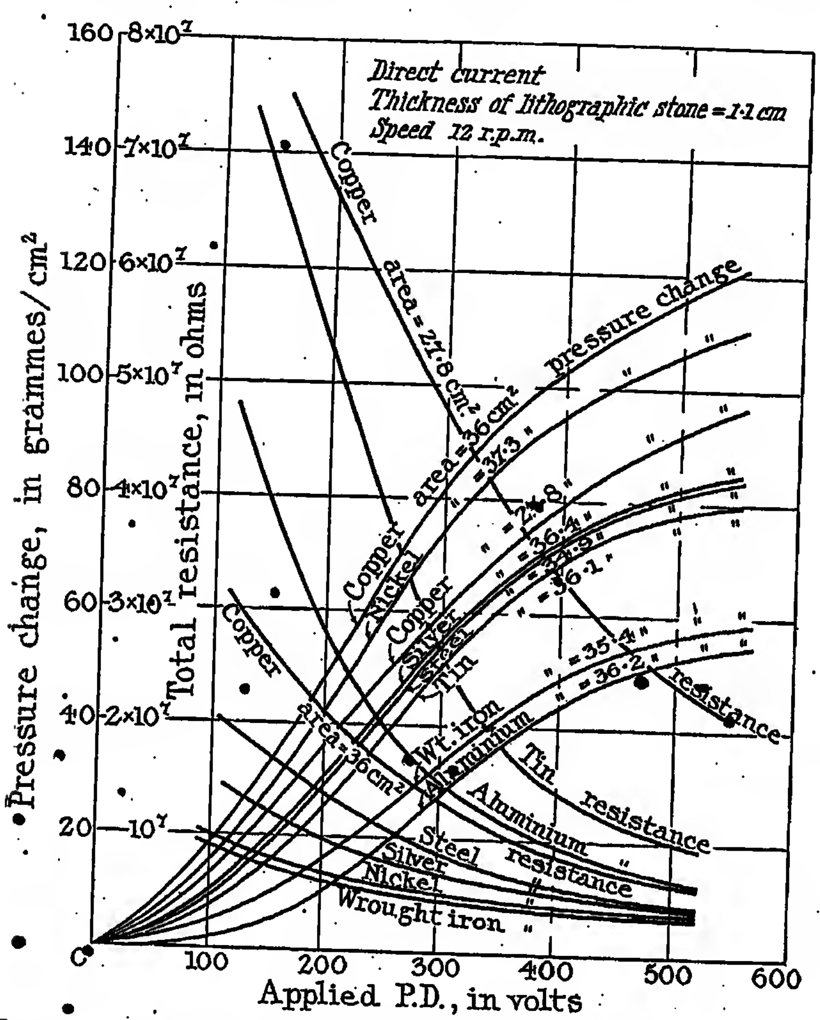

FIG. 18.—Variation of intensity of pressure with applied P.D. between various metals and lithographic stone, as measured by torsion apparatus.

the critical current and the magnitude of the slipping effect. Generally, the greater the one the smaller is the other.

(7) *The influence of the fit of the surfaces on the pressure-changes.*—The larger the gaps, the greater is the tendency towards slipping, principally on account of the rapid reduction in the electrostatic attraction forces.

In the case of copper-graphite, graphite-graphite and copper-chalk, the stiction was completely overcome. On the other hand, in the case of wrought iron-wrought iron, nickel-nickel and zinc-zinc, the slipping effect did not appear. The fit of the surfaces was no doubt partly responsible for these results, but the interface film must also have been an important factor.

Contacts Including a Semi-conductor. Experimental Work.

(1) *Voltage-pressure changes.*—The friction-changes accompanying the passage of a current across a contact including a semi-conductor are very much greater than the corresponding changes occurring at a contact of two good conductors. Moreover, apart from small variations of pressure with the time of application of the current, there are no complicated effects like the "initial" and "final" states observed in the case of metal-metal contacts.

There is always a rapid increase of pressure as the applied potential is increased, up to about 250 volts,

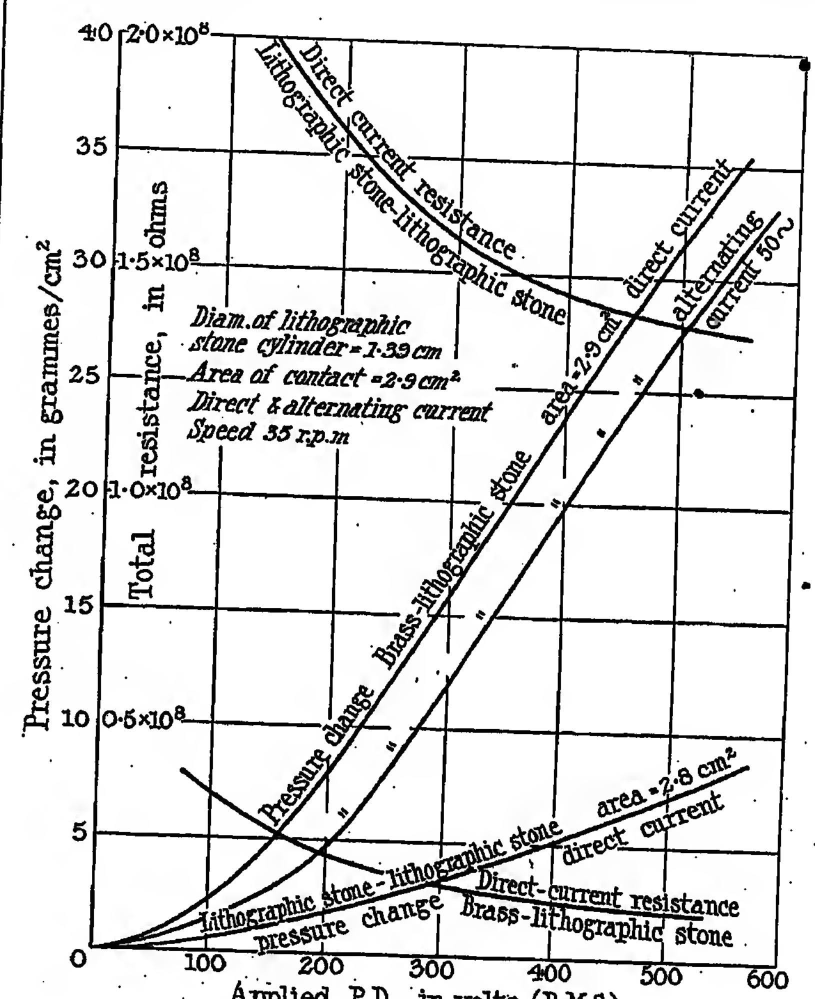

FIG. 19.—Relative pressure-changes corresponding to various R.M.S. applied voltages, as measured by steelyard apparatus.

when the rate of change gradually falls off, forming a point of inflection in the curve (Figs. 17 to 21). The magnitude of the current effect depends both on the nature of the contact and on the thickness of the semi-conductor. Different metals rubbing on the same semi-conductor gave different pressure-changes.

The "stiction" is independent of the force applied between the surfaces, so that a given P.D. merely displaced the torque-pressure curves bodily without altering the coefficient of friction, as in the case of the good conductors.

(2) *Voltage-resistance changes.*—The total resistance of the circuit also varied with the applied P.D. At low voltages it falls rapidly, but tends to a steady value as the potential is indefinitely increased (Figs. 17 to 21).

In many cases it was difficult to get reliable figures for the resistance, on account of its characteristic instability. When the terminal P.D. was perfectly steady, the galvanometer deflection kept jumping up and down, whether the surfaces were in relative motion or not. The effect was exactly the same as that observed with metal-metal contacts. It had nothing to do with vibration, and was generally more marked at the higher voltages.

The pressure-changes appeared to depend very little upon the magnitude of the current passing, and were not perceptibly affected by the resistance instability.

(3) *Variation of torque and resistance with time of application of P.D.*—The total increase in the torque or

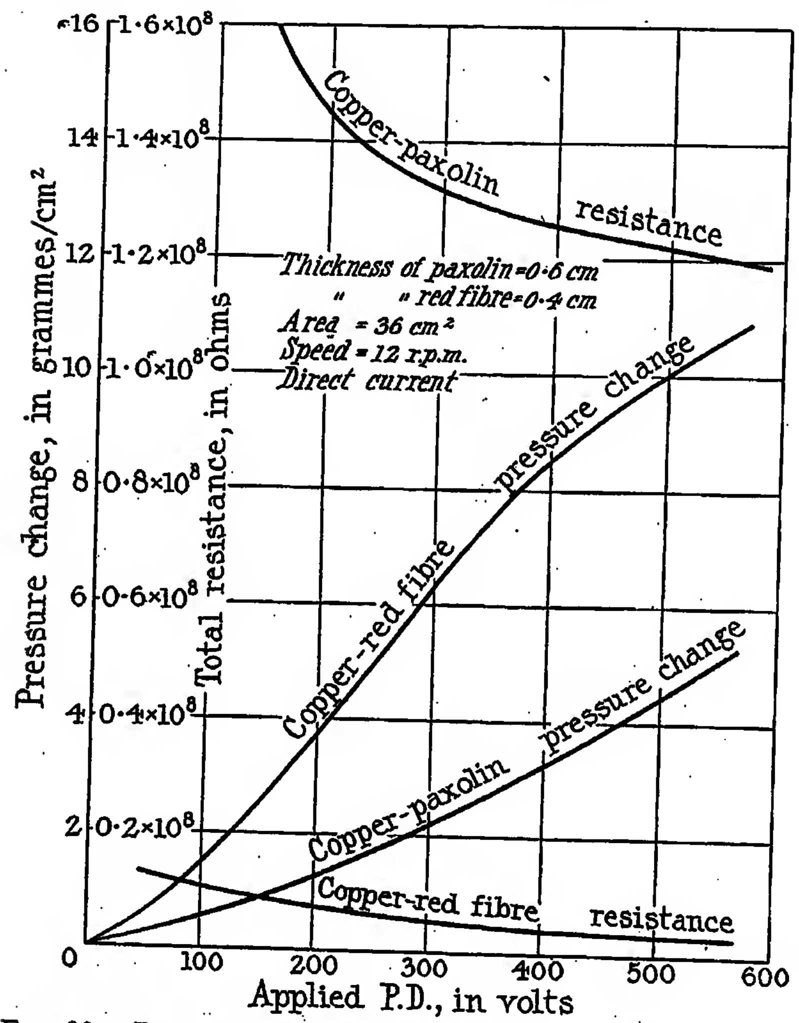

FIG. 20.—Relative pressure-changes corresponding to various R.M.S. applied voltages, as measured by torsion apparatus.

pressure corresponding to a given potential is not usually simultaneous with its application. In most cases there is a lag of a few seconds, the pressure gradually rising to its full value on switching on, and gradually falling to its normal value on switching off. The curves represent final steady values.

In the same way the total resistance of the circuit undergoes a change with time, and usually assumes its greatest average value when the torque or pressure is a maximum.

There are, however, a few exceptions to these generalizations. The contacts of copper and celluloid (xylonite) showed practically no variations in either the torque or the resistance with the time of application of the P.D.

Brass and agate gave a curious directional effect (Fig. 22). In this case, as the torque increased the resistance decreased, and vice versa, the nature of the change depending upon the direction of the current. By repeated reversals when the conditions had become approximately steady, a series of curves was obtained which show the relation between these quantities. The steady value of the torque was independent of the direction of the current, but the effective resistance of the circuit had two final values, according to which brake block was positive and which negative. This asymmetry must have been due to some small difference between the two contacts on the cylinder.

(4) *Influence of moisture between the surfaces.*—When the interface was saturated with water the application

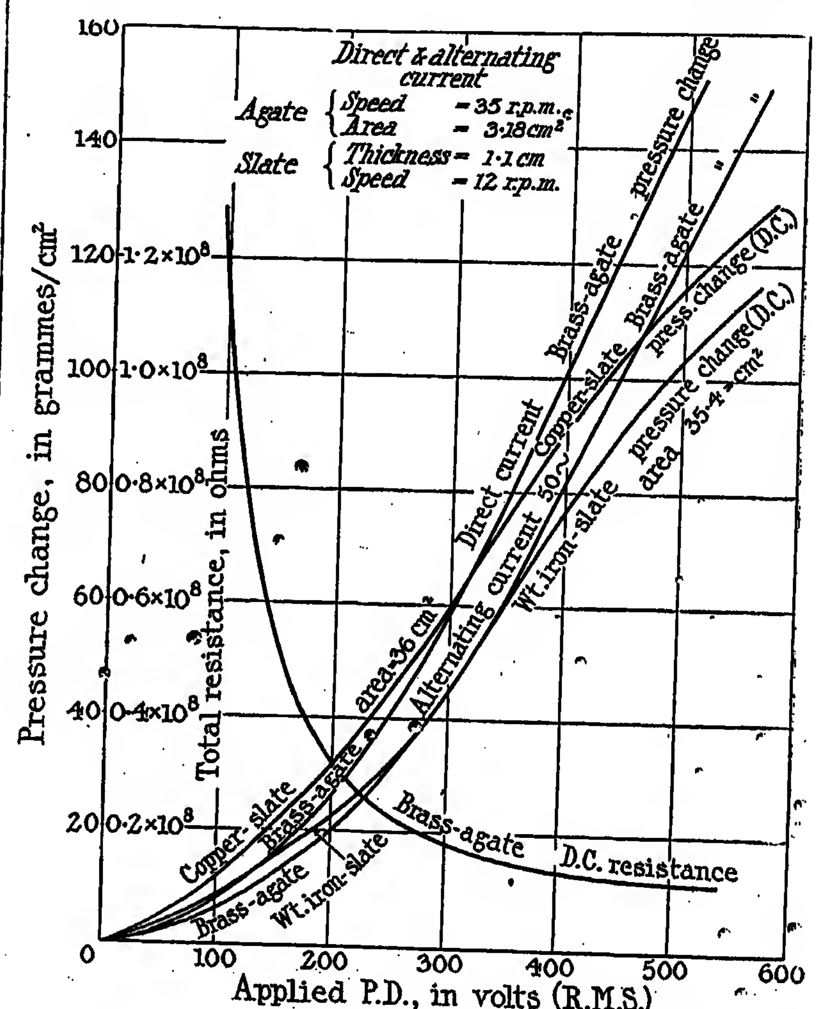

FIG. 21.—Relative pressure-changes corresponding to various R.M.S. applied voltages, as measured by torsion and steelyard apparatus.

of potential differences up to 550 volts produced no observable change in the normal friction forces. This was equally true for all the semi-conductor contacts.

In the case of silver-lithographic stone, the total resistance of the circuit at 550 volts was reduced from about $3 \cdot 9 \times 10^6$ ohms when dry, to about 10^6 ohms when wet. Similarly the resistance of wrought iron and lithographic stone fell from $3 \cdot 1 \times 10^6$ ohms to $1 \cdot 3 \times 10^6$ ohms when water was interposed between the surfaces.

(5) *Comparison between different areas of contact.*—Three different sizes of copper rings were tested in contact with the same sample of celluloid. The results are represented in Fig. 17, and will be discussed later. Celluloid was chosen for this comparison because there

is practically no lag in the pressure-change when a given P.D. is applied.

(6) *Influence of the velocity of sliding.*—As in the case of metal-metal contacts, the velocity of sliding makes very little difference to the pressure-change accompanying the application of a steady P.D.

Brass-agate was, however, exceptional in this respect (Fig. 23). At low voltages there was a decided tendency for the pressure-change to decrease as the speed increased, but at 200 volts this was negligible.

As regards the resistance, the velocity of sliding had no influence until the surfaces were brought to rest, when it gradually fell to a lower average value, taking about half a minute to reach its minimum.

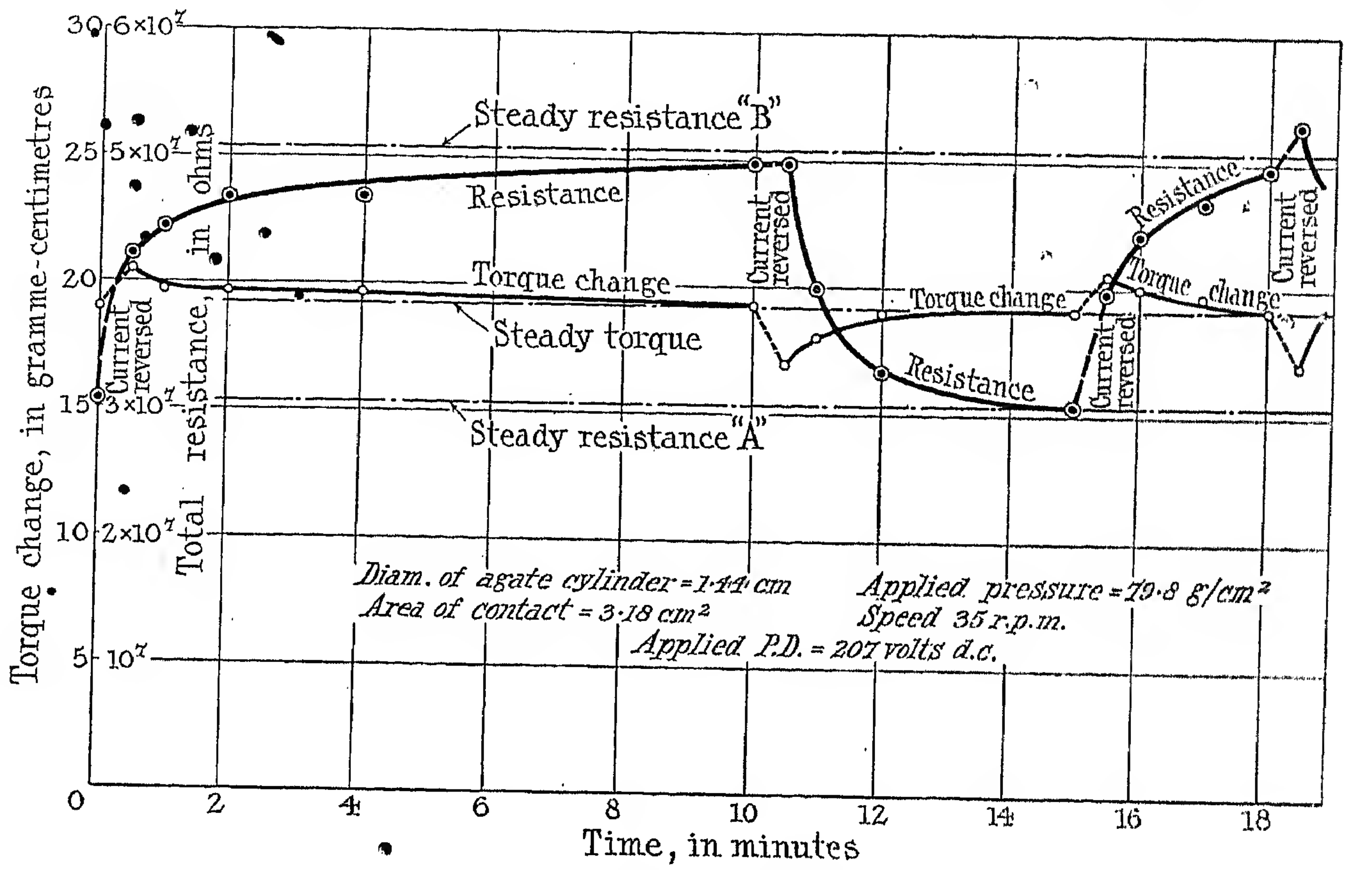

FIG. 22.—Variation of torque and resistance with time of application of P.D. between brass and agate, as measured by steelyard apparatus.

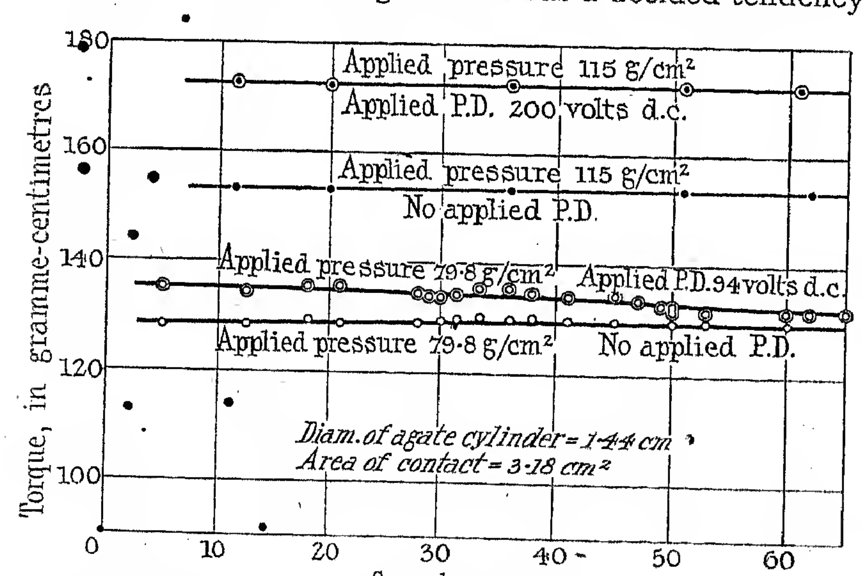

FIG. 23.—Variation of torque with speed, for brass-agate, as measured by steelyard apparatus.

Some experimental figures were taken for silver-lithographic stone and wrought iron-lithographic stone, and are given in Fig. 24. It will be observed that the change in resistance due to motion gets smaller as the applied P.D. is increased, exactly in the same way as for good conductors.

(7) *Comparison between the effects of alternating and direct currents.*—In order to ensure comparative conditions, alternating- and direct-current P.D.'s of the same value, as indicated by an electrostatic voltmeter, were applied alternately to a given contact. The torque-changes in each case were observed, but the instruments available were only suitable for measuring the direct-current resistance.

The results for brass-agate and brass-lithographic stone are given in Figs. 19 and 21. They are very similar to those obtained for wrought iron-wrought iron. The alternating P.D. caused the brake blocks to vibrate on the cylinder.

Some more precise information about the wave-form of the alternating-current supply was obtained in these tests. An oscillograph was used to record the E.M.F. curve at several different R.M.S. voltages (Fig. 25). With the aid of a planimeter the "form factor" was deduced in each case. It appears that the higher the R.M.S. voltage the smaller is this ratio.

(8) *Influence of body and contact resistances.*—Two thicknesses of celluloid were tested in the torsion apparatus under the same conditions. The results are shown in Fig. 17. Unfortunately, the samples must have been rather different in composition, because the total resistance was less for the thick piece.

With certain contacts, the application of P.D.'s up

to 550 volts produced no measurable change in the friction torque. This applied to the following cases :—

(*a*) *Copper-glass* (0·28 *cm thick*).
Torsion apparatus ($\frac{1}{16}$ in. diam. suspension) calibration 24·4 gramme-cm per degree.
Outside diam. of copper ring = 10·18 cm.
Inside diam. of copper ring = 7·6 cm.
Area = 36 cm^2.

(*b*) *Copper-ebonite* (0·22 *cm thick*).
Torsion apparatus ($\frac{1}{16}$ in. diam. suspension) calibration 24·4 gramme-cm per degree.
Outside diam. of copper ring = 10·18 cm.
Inside diam. of copper ring = 7·6 cm.
Area = 36 cm^2.

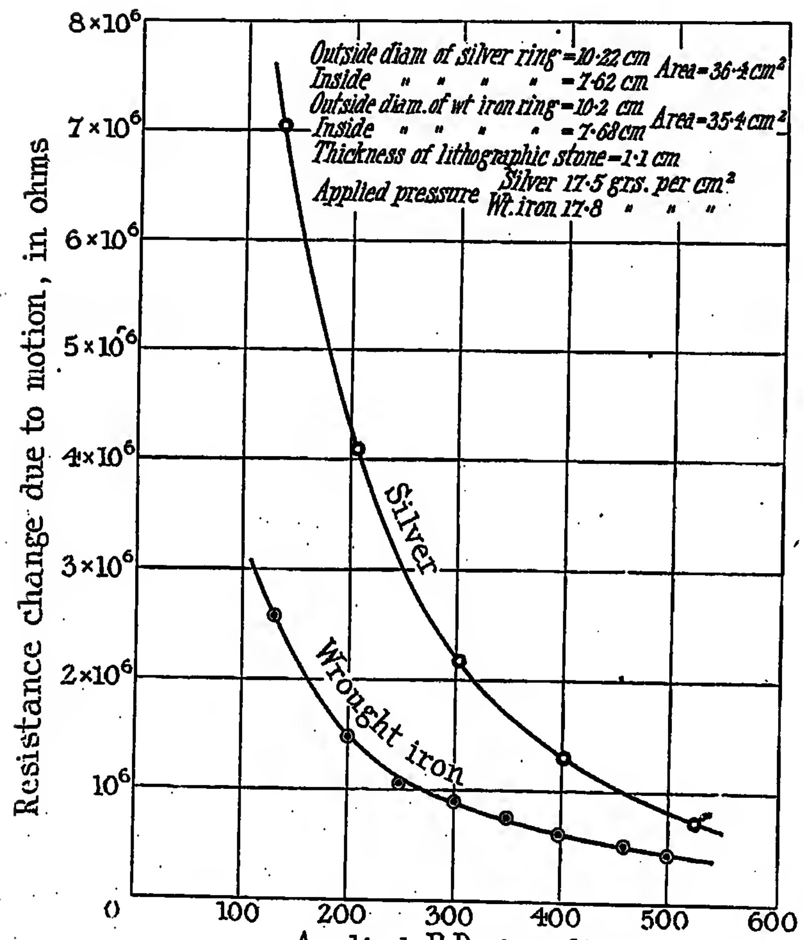

FIG. 24.—Change in resistance due to motion, with various applied voltages, as measured by torsion apparatus.

(*c*) *Copper-micanite* (0·2 *cm thick*).
Torsion apparatus ($\frac{1}{16}$ in. diam. suspension) calibration 24·4 gramme-cm per degree.
Outside diam. of copper ring = 10·18 cm.
Inside diam. of copper ring = 7·6 cm.
Area = 36 cm^2.

In the last case, (*c*), the contact was not very good, but sufficient to indicate any appreciable changes.

THEORY.

(1) *Pressure-changes and their relation to the contact resistance.*—When dealing with semi-conductors the analysis of the results is much simpler. The "stiction" effect persists over the whole range of currents considered. The application of a steady P.D. does not alter the coefficient of friction but merely adds to the applied pressure.

Our observations on semi-conductor contacts give very substantial support to the view that the "stiction" has its origin in electrostatic forces acting between the two surfaces. The currents employed were usually of the order of milliamperes, so that according to our theory any repulsion effect is quite negligible. The

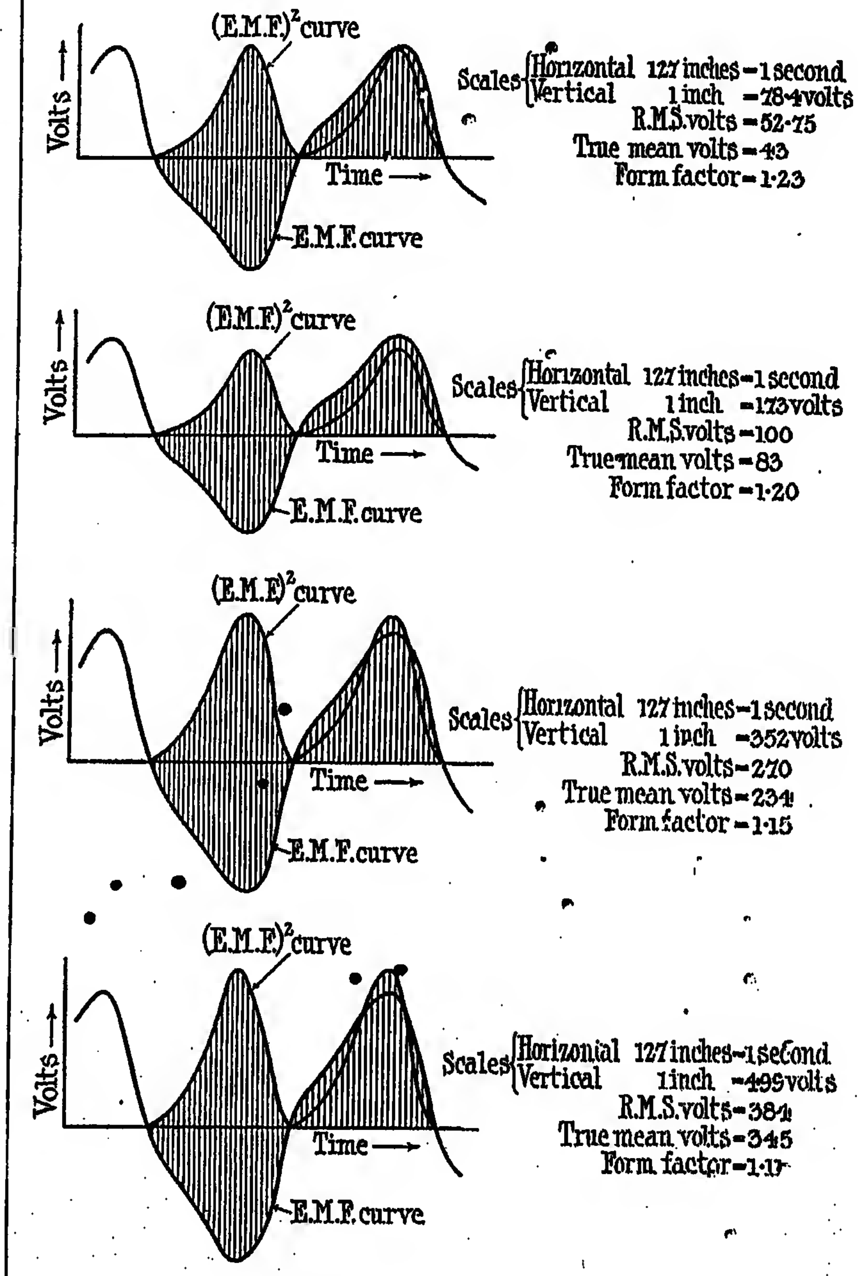

FIG. 25.—Oscillograph curves.

curves show that the rate of increase of pressure with applied potential generally begins to fall off about 350 to 400 volts. The total resistance of the circuit also drops rapidly as the terminal P.D. is increased. If we may assume that the body of the conductors follows Ohm's law, this conductivity change must occur at the two contacts with the semi-conductor. We conclude that the reduced stiction at the higher applied voltages is due to the decrease in the interface P.D. by reason of the coherer action. Although the current increases, the potential between the sliding surfaces becomes a smaller proportion of that applied to the terminals of the apparatus. If the contact was wet, the friction remained unaltered by the passage of a current, and the total resistance of the circuit was much lower. These are all significant facts. In most cases the

friction was greatest when the resistance had reached a maximum, but the brass-agate contact was an exception. In this instance the steady pressure-change corresponding to a certain applied P.D. was unaffected by the direction of the current, suggesting that the drop across the interface finally attained the same value. This is consistent with the supposition that the interface P.D. is partly determined by the magnitude of the current passing.

(2) *Comparison between different areas of contact.*—The comparison between different areas of contact carried out for copper-celluloid leaves little room for doubt that the "stiction" is directly proportional to the extent of the surface. The same sample of celluloid was used throughout the test.

(3) *Comparison between the effects of alternating and direct currents.*—Figs. 19 and 21 show the relative pressure-changes corresponding to various R.M.S. applied voltages. The "form factor" of the alternating E.M.F. wave is given in Fig. 25. Taking the true mean or time average of the applied P.D.'s, we see that the "stiction" is practically the same whether the supply be steady or varying, again confirming the view that the effect is due to electrostatic forces.

(4) *The significance of body and contact resistance.*—The friction between metal and either glass, ebonite, or micanite, was not measurably altered by a current passing across the junction. We conclude, therefore, that the body resistance of these semi-conductors, or perhaps more appropriately dielectrics, is large compared with the resistance of the contact. Not more than a fraction of a volt could have been absorbed at the interface without being detected.

The condition for stiction is simply that the insulating property of the semi-conductor is furnished by the contact rather than by the mass of the material. Some experiments which we shall describe on the direct-current conductivity of lithographic stone and slate, as measured between mercury electrodes, indicate the importance of the contact in these cases.

As far as we are aware, no attempt has been made to distinguish between body and contact resistances. It seems to have been taken for granted that the transition resistance from electrode to dielectric was always relatively negligible, particularly if the connection was made with mercury. This is far from the truth in many cases. Some suggestive experimental results are given by Addenbrooke * for the direct-current resistivity of celluloid as measured between mercury electrodes. Samples of different thickness were tested under similar conditions. The figures are reproduced in Table 3.

It is clear that the total resistance per unit area must have been very nearly the same for all three samples, both when ordinarily dry and specially dried. To us the conclusion is irresistible that a large proportion of the resistance must have been in the mercury contact, but Addenbrooke attributes the apparent irregularity to variations in the amount of absorbed moisture.

It is significant that merely to wet the metal-lithographic stone surfaces employed in the friction tests reduced the effective resistance of the circuit to about a quarter of the original value.

This somewhat remarkable correlation of facts can have only one interpretation : many substances must rely largely on the contacts for their insulating properties. Under standardized conditions, the magnitude of the pressure-increase produced at the junction of a semi-conductor and a metal conducting a current, is an excellent basis for comparing the real value of different substances as insulators. By testing various thicknesses of a particular sample of semi-conductor the body and contact resistances are easily separated.

Such an investigation is not confined to direct current. Some observations with high-frequency currents might lead to very important results, and supply us with more information about the variation in the apparent conductivity of a dielectric with frequency. It is not unlikely that the change really occurs in the contacts.

To distinguish properly between body and contact resistances it would be necessary to employ mercury

TABLE 3.

Thickness	Specific resistance	
	Room dryness	Dried
mm	ohms per cm cube	ohms per cm cube
0·62	$1 \cdot 7 \times 10^{10}$	—
0·4	$3 \cdot 2 \times 10^{10}$	$2 \cdot 9 \times 10^{12}$
0·23	$5 \cdot 7 \times 10^{10}$	$4 \cdot 4 \times 10^{12}$

electrodes on both sides of the semi-conductor, and to do away with the necessity for grinding the contact. A simple and satisfactory arrangement might be made by passing a stream of mercury under pressure through a pipe of the semi-conductor immersed in mercury and measuring the fall in the head over a definite length, with and without a P.D. applied between the inside and outside electrodes. Alternatively an apparatus of the form used by Heyl for metal-metal contacts might give good results. In classifying different materials, allowance would have to be made for the increased resistance of the contacts due to relative motion, but this should not be a difficult matter.

Our experiments are sufficient to show that such materials as slate, red fibre, paxolin and celluloid can only be classed as dielectrics in virtue of their high contact resistance, and that the true body conductivity of these semi-conductors cannot be measured with mercury electrodes.

ELECTRICAL EFFECTS AT STATIONARY CONTACTS.

EXPERIMENTAL WORK.

(1) *Transition resistances of metal-metal contacts.*—In order to estimate the transition resistance at standstill of the annular metal contacts employed

* *Journal I.E.E.*, 1919, vol. 57, "Institution Notes," p. (13); and *Proceedings of the Physical Society of London*, 1915, vol. 27, p. 291.

in the friction tests, the apparatus shown in Fig. 26 was employed.

Electrical connection was made with the upper and lower surfaces of the rings by means of ebonite-mercury troughs. In this way the nature and area of the contact were rendered definite, so that any given conditions could be repeated. Great care was taken to clean the surfaces.

By a process of elimination, figures were obtained

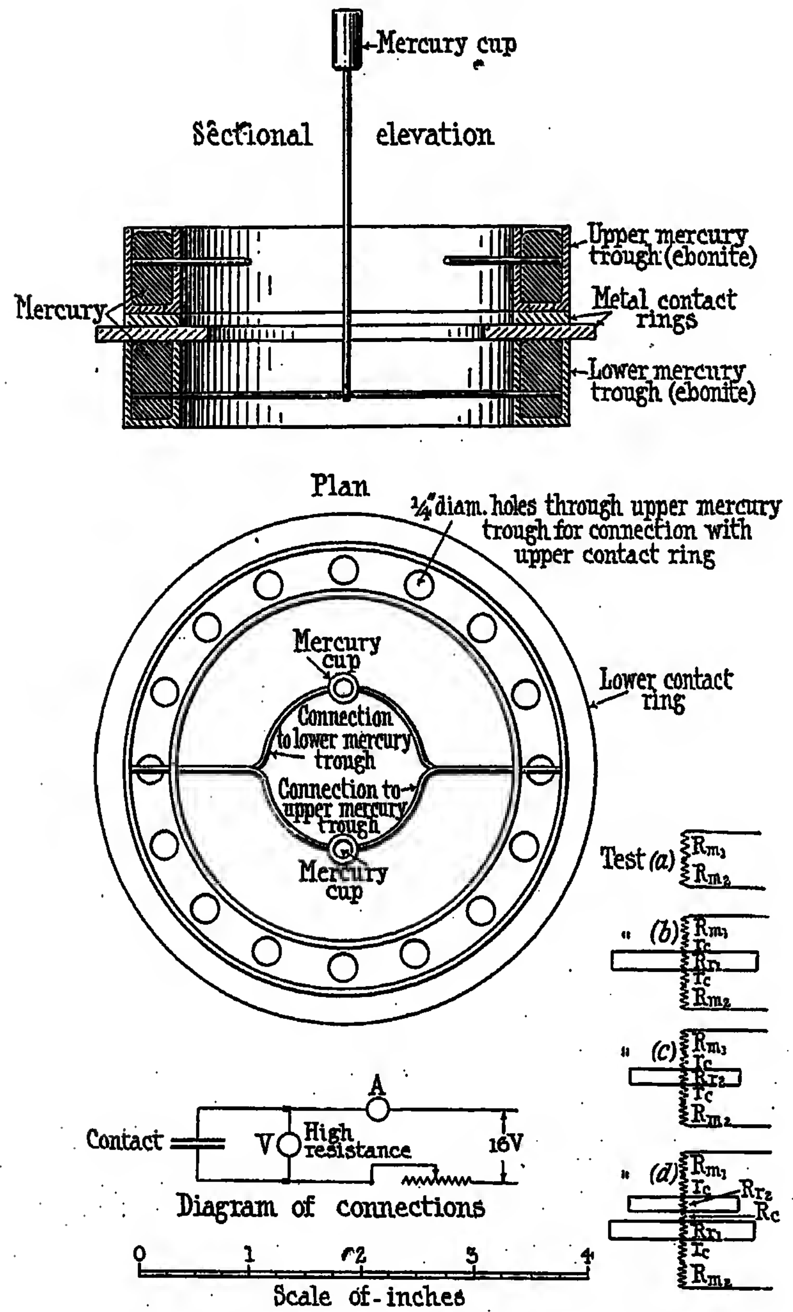

FIG. 26.—Apparatus for measuring the resistance of metal-to-metal contacts.

for the actual interface resistances, but these were not of much value because the contact between mercury and ring was supposed perfect.

The experiments showed, however, that the mercury contacts very nearly followed Ohm's law, so that an indication was given of the interface resistance characteristics. These correspond in a rather remarkable manner to the friction-changes associated with the passage of a current across a sliding metal-metal contact.

When the rings had been ground together, washed and dried in the usual way, the initial resistance of the circuit, test (*d*), as measured by a small current, was generally very high. As the current was increased, the P.D. also increased simultaneously in direct proportion, but periodically it fell suddenly to lower values. Sometimes the deviation from Ohm's law took a second or two to operate. This was not due to the inertia of the voltmeter needle or lack of damping.

Usually one of the resistance-changes was more marked than the others. At a certain critical current the P.D. might fall to half its original value. After the current had been increased to about 30 or 40 amperes the conditions became more or less stable, although there were always minor fluctuations, which continued when the applied P.D. was maintained constant. If now the experiment was repeated, the resistance for small currents was found to be only a little greater than that for large currents, and this condition was practically unaltered by further tests, and therefore corresponded to the "final state."

After washing and drying the surfaces again, the "initial state" was invariably restored. Merely to re-dry them produced no effect. If the contact was left untouched in the final state for some hours, the initial state was never completely re-established, although there was always a tendency to recovery. Continually tapping the rings produced a semi-sensitive condition.

(2) *The direct-current conductivity of lithographic stone and slate.*—Samples of the semi-conductor were cut in the form of a cylinder and were tested between mercury electrodes as shown in Fig. 27. The current corresponding to a steady applied P.D. of about 500 volts was observed at intervals after the circuit was

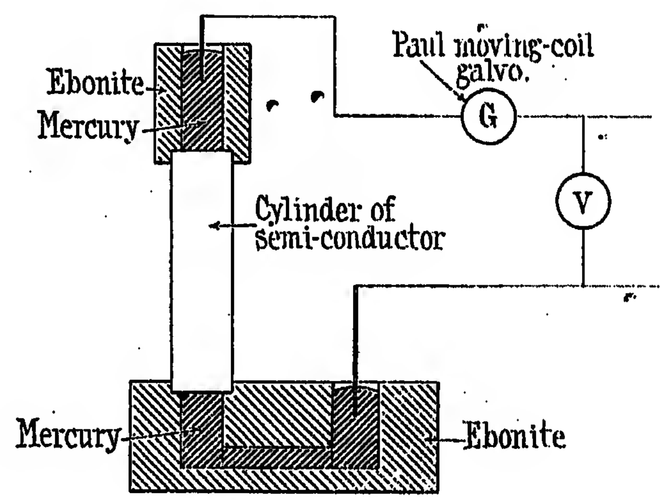

FIG. 27.—Arrangement of direct-current conductivity test.

closed. When the current had become approximately constant the P.D. was reversed and the observations were repeated.

About a dozen such tests were made on each of three cylinders of the same material, having a diameter of 1·05 cm and lengths of 0·55 cm, 2·6 cm and 10·8 cm respectively. No two series of readings for a given specimen were exactly alike, but typical curves are represented in Fig. 28 for lithographic stone and in Fig. 29 for slate. The figures for lithographic stone were by far the more consistent, and the "residual charge," which sometimes has an important influence,

was comparatively small in this case, even after a prolonged application of the P.D. The magnitude of the "residual charge" was estimated by the value of the current produced when the system was short-circuited through the galvanometer.

been in the body of the material, according to the ordinary laws of conduction we should have expected the shortest cylinder to have a conductivity about 20 times as large as that of the longest.

Whatever allowance be made for the influence of

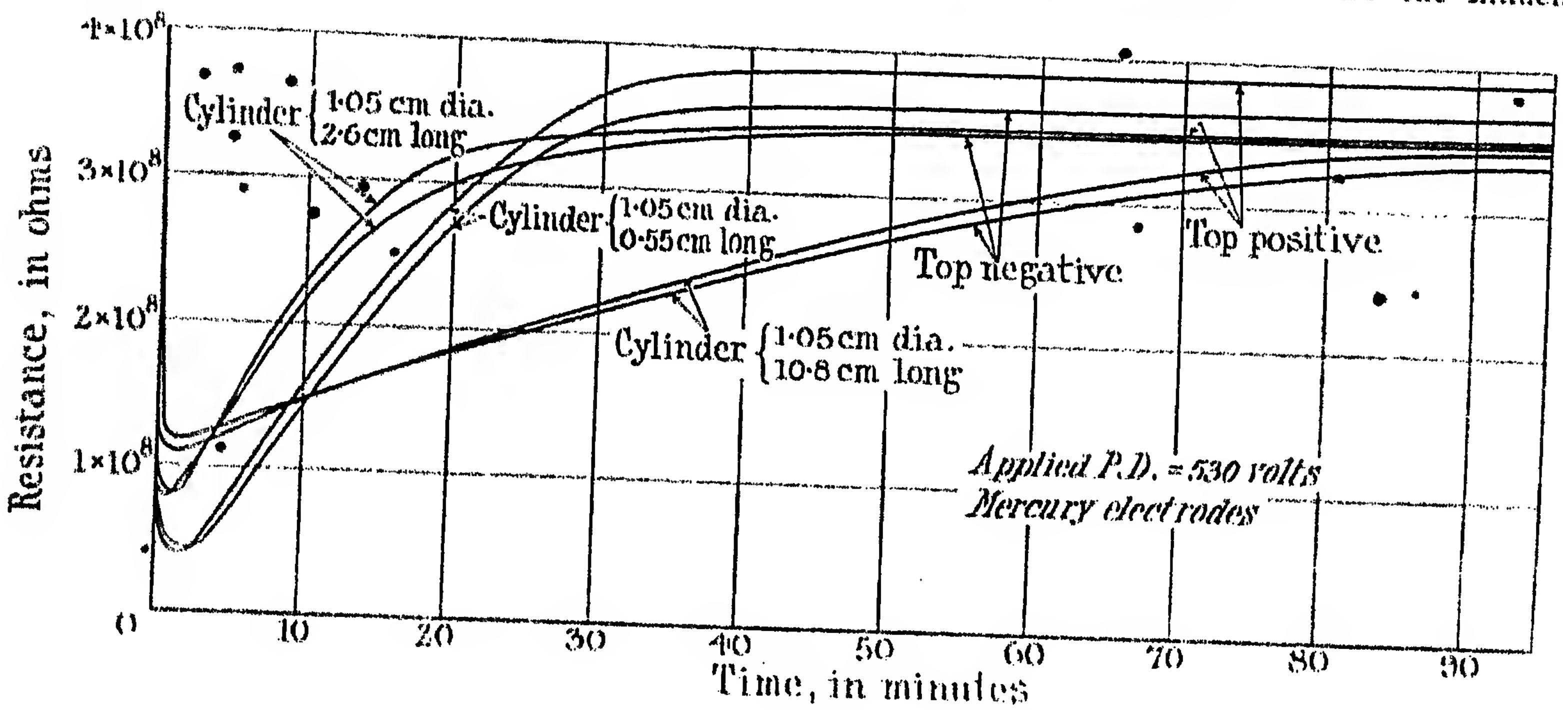

FIG. 28.—Direct-current conductivity of lithographic stone.

The three different cylinders were cut from the same piece of material in both cases, and care was taken to subject them all to the same treatment. After washing with soap and water they were dried in a

the residual charge, variations in the amount of moisture present, surface leakage, etc., we cannot get away from the conclusion that by far the greater part of the resistance must be in the contacts between

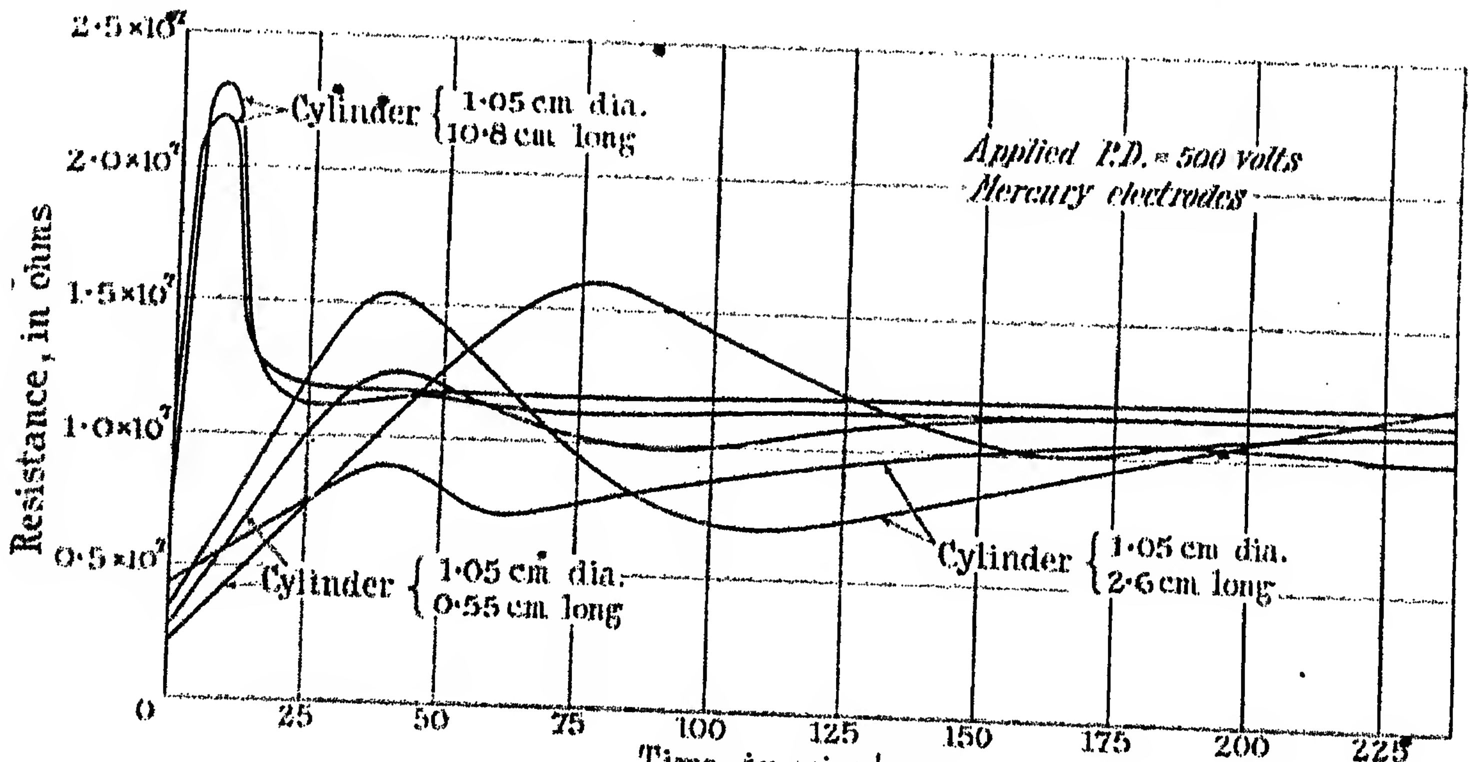

FIG. 29.—Direct-current conductivity of slate.

stream of hot air for about an hour, and then allowed to cool.

It is remarkable that the final apparent resistance of all three cylinders was about the same, both for lithographic stone and for slate. Had the resistance

mercury and semi-conductor. When two cylinders were connected in parallel the effective resistance was about halved, and when in series about doubled.

The arrangement behaved much in the same way as a leaky condenser. There was always an initial

rush of current when the P.D. was first applied. As the system became charged the current dropped, finally reaching a more or less steady value.

Absorption involves the establishment of a back E.M.F., which increases with the time of application of the external P.D. and adds to the apparent resistance of the circuit. By reversing the direction of the external P.D. the absorption E.M.F. is destroyed in a few minutes, and then it gradually builds up in the opposite direction.

In the case of slate the resistance reached a maximum soon after switching on, and at this point the residual charge was found to change its sign. There is little doubt that the curious variations in the conductivity of slate were largely due to the effect of the residual charge.

The initial rush of current was always greatest with

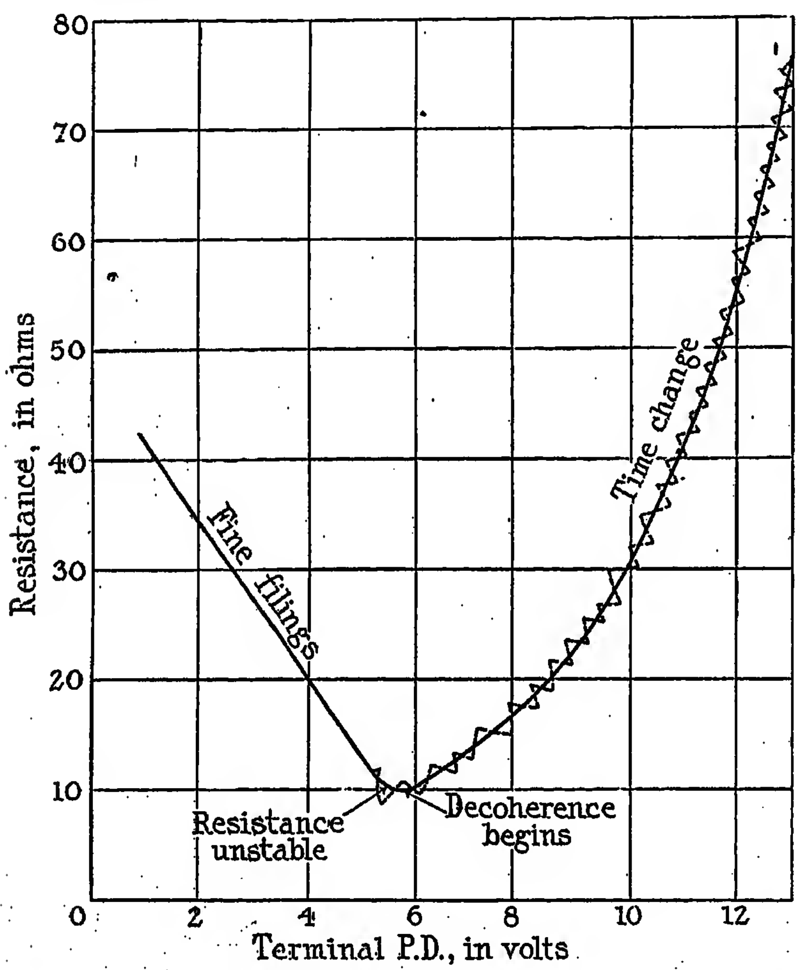

FIG. 30.—D.C. resistance characteristic of copper-filings coherer.

Copper electrodes; fine filings.

the shortest cylinder, and the characteristic resistance instability of solid imperfect contacts was not very apparent in these experiments.

(3) *Coherer characteristics.*

(*a*) *Metal filings.*—Only comparatively small voltages and currents are required to produce the so-called coherence phenomenon, but in the following experiments as much as 13 volts was applied to the terminals of some of the coherers tested, and currents up to 10 amperes passed through them.

The apparatus consisted of a glass tube about ¼ in. internal diameter having metal plugs in the ends, enclosing loosely packed filings. The plugs were connected to insulated terminals and were always made of the same metal as the filings.

It is unfortunate that in a great many researches carried out on this subject the active materials employed have been a mixture of two or more different substances. We must bear in mind that the contacts between plug and filings also have a share in producing the observed resistance-changes, and may in certain cases have a controlling influence.

Most of the common metals and graphite were tested in the manner described, the resistance being deduced from measurements of the terminal P.D. corresponding to a given current. A high-resistance voltmeter was used, so that it did not by-pass any appreciable current.

Typical curves for silver and copper are shown in Figs. 30 and 31. As the P.D. is increased, the resistance falls rapidly at first and then tends towards a minimum value. This stage corresponds to what has been called

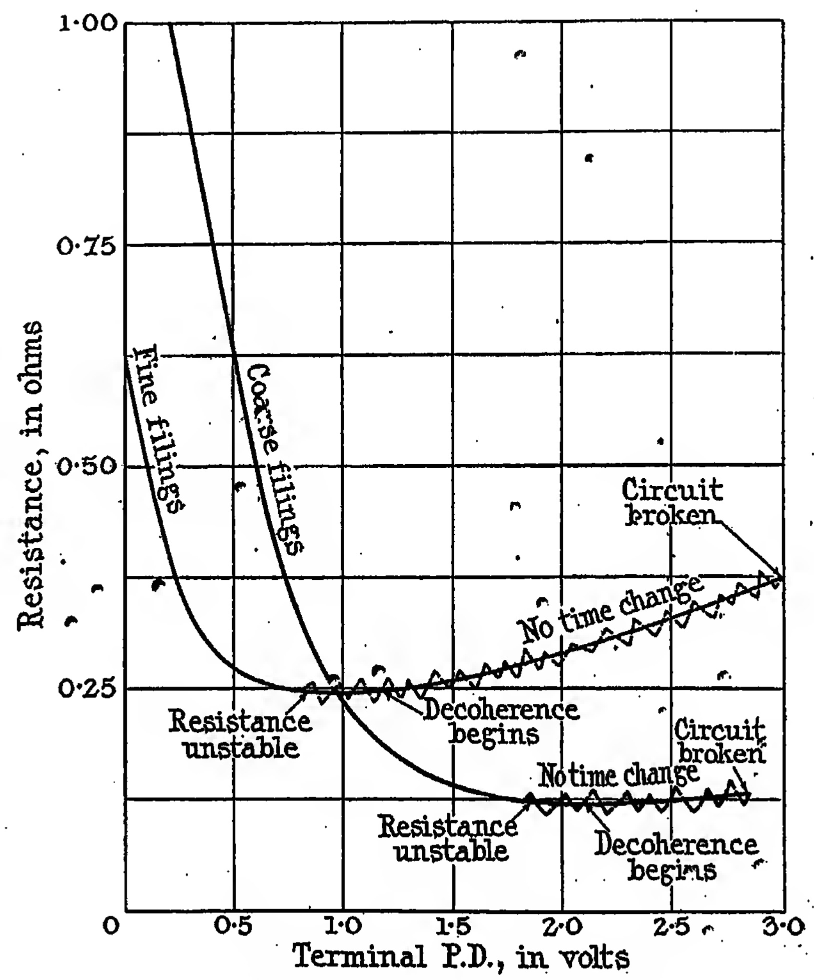

FIG. 31.—D.C. resistance characteristic of silver-filings coherer.

Silver electrodes.

"coherence," and is the normal working range of the commercial instrument. Further increase in the applied potential produces a sudden, very marked instability of the resistance, the average value of which begins to get larger again. In the case of copper, the filings had obviously become warm by this time and were beginning to discolour. The resistance-change became automatic, the current slowly falling and the P.D. rising as the oxidation of the particles spread from the positive to the negative electrode. This process continued for some hours until finally the conditions became very nearly steady.

If, however, during the time-change the external resistance of the circuit was suddenly altered so as to increase the current, there was generally a simultane-

ous complete rupture between the particles in the tube, followed by a spark. This effect occurred more easily when the filings were loosely packed.

The gradual decoherence action which proceeded automatically was found to be independent of the direction of the current and took place in a series of little jumps.

After the filings had become well oxidized the initial conditions were not easily restored by shaking the tube, especially if a P.D. was maintained across the terminals. But if continuity was successfully re-established, the first stage in the resistance-changes was always repeated. When the minimum value of the resistance was reached it became exceedingly unstable, and a further increase in the applied P.D. caused an interruption in the circuit.

The characteristic curve for silver is very much the same, except that the time-change does not appear in this case. The tube first of all coheres and then decoheres, completing the process with a sudden rupture between the particles. As the test proceeded there was very little discoloration of the active material and the temperature-rise was comparatively small.

The size of the filings had a noticeable influence. With small particles loosely aggregated, the minimum resistance is reached with a smaller applied P.D., and the decoherence can be followed more easily without causing a premature break in the circuit. An examination of the filings after the test showed that there could not have been any welding in the ordinary sense of the word. They fell apart immediately if touched.

Any sudden changes in the applied P.D. during the final stages of the resistance-changes invariably produced a simultaneous rupture in the circuit. The conditions were anything but stable during this phase. The ammeter and voltmeter needles were constantly wobbling up and down in opposite directions, whilst the increase in resistance as the terminal P.D. was raised was accompanied by a series of sparks among the filings.

After the filings had been used once, the sulphide film formed on their surface appeared to increase the sensitivity of the arrangement, so that the cycle of resistance-changes could be repeated with considerably smaller currents.

A number of other metals were tested in the same way and always with the same general results. Lead, tin, aluminium and zinc all interrupted the circuit soon after the coherence was complete. In one case there was a small time-change, but it was not easily followed.

The characteristic curves for copper and silver were selected as being fairly representative of the non-magnetic metals.

Nickel and wrought iron only interrupted the circuit when sufficient current was passed to make the filings red hot. If finely-divided wrought iron was placed between brass plugs the system behaved in the ordinary way. Judging from the position of the sparks, the rupture occurred between the filings and the electrode.

A tube containing powdered graphite was found to cohere slightly, but could not be induced to decohere.

(*b*) *Lead peroxide.*—Fig. 32 represents a typical direct-current characteristic for compressed lead peroxide contained between metallic lead electrodes. In practically every detail it corresponds exactly to that obtained for copper.

THEORY.

(1) *Coherence and decoherence.*—Although the resistance-changes at an imperfect contact may, in many cases, be largely due to a readjustment of its parts by the interface forces, there must also be other considerations involved.

A circuit including two rigid metal plates pressed together gives a small deviation from Ohm's law, as our experiments on stationary ring contacts showed. On the other hand, a mercury connection has a relatively constant resistance. We conclude that the gaps between the surfaces are chiefly responsible for the change. Our hypothesis regarding the action of the interface film at once offers an explanation. For a given P.D. the gaps assisting in the conduction of electricity will all be within a certain maximum length, the selection being made according to the potential gradient. As the applied P.D. is increased, the ionization of the gas between the surfaces will be extended and, consequently, the effective resistance of the contact will be reduced. The change will actually occur in little jumps, but the "critical" potentials may be so close together that the effect appears gradual. The fit of the surfaces is the determining factor, and if there is one particularly pronounced drop in the resistance it simply means that a large number of gaps have become active together. When the two parts of the contact are in relative motion the spacing is averaged, and consequently there is always one very marked critical P.D., which we have seen corresponds to the transition from the initial to the final state. Moreover, the small interval of time required to effect the increase in conductivity is consistent with the mechanism we are describing.

As soon as a gap becomes ionized it also becomes susceptible to electromagnetic striction, which will produce mechanical forces tending to separate the surfaces. The electrostatic attraction will temporarily cease to operate on account of the relatively low interface resistance. But if the parts of the contact are free to move they will do so in such a manner that the distance between them is increased and the conductivity of the system correspondingly reduced. At the same time the contraction of the conducting veins due to the pinch effect will become more pronounced as the current rises, so that their effective resistance will also become larger by this means.

The various effects we have described can be more or less followed from the coherer characteristics (Figs. 30 to 32). The decoherence in the cases of copper and lead peroxide must have been largely due to a chemical change in the nature of the surface, produced by heating. As we should expect, the accompanying resistance-change was automatic. But the silver-filings coherer gave very similar results without any appreciable suggestion that they were complicated by an alteration in the state of the surfaces. Moreover, all the metals tested ruptured the circuit when the current was sufficiently increased or the external resistance suddenly changed. The effect worked more easily when the

filings were loosely packed, and sometimes occurred in stages if the particles were small. All these observations might have been predicted from our theory. The thickening and extension of the interface film would also assist in the concentration of the current stream-lines and the striction would gradually interrupt the various parallel paths through the tube. The action is obviously cumulative, because a break in one contact means that more current has to pass through the others, and ultimately complete discontinuity will be established.

That the coherence of iron and nickel is partly a magnetic effect was proved by our experiments. The fact that iron loses its high permeability at about 800° C.,

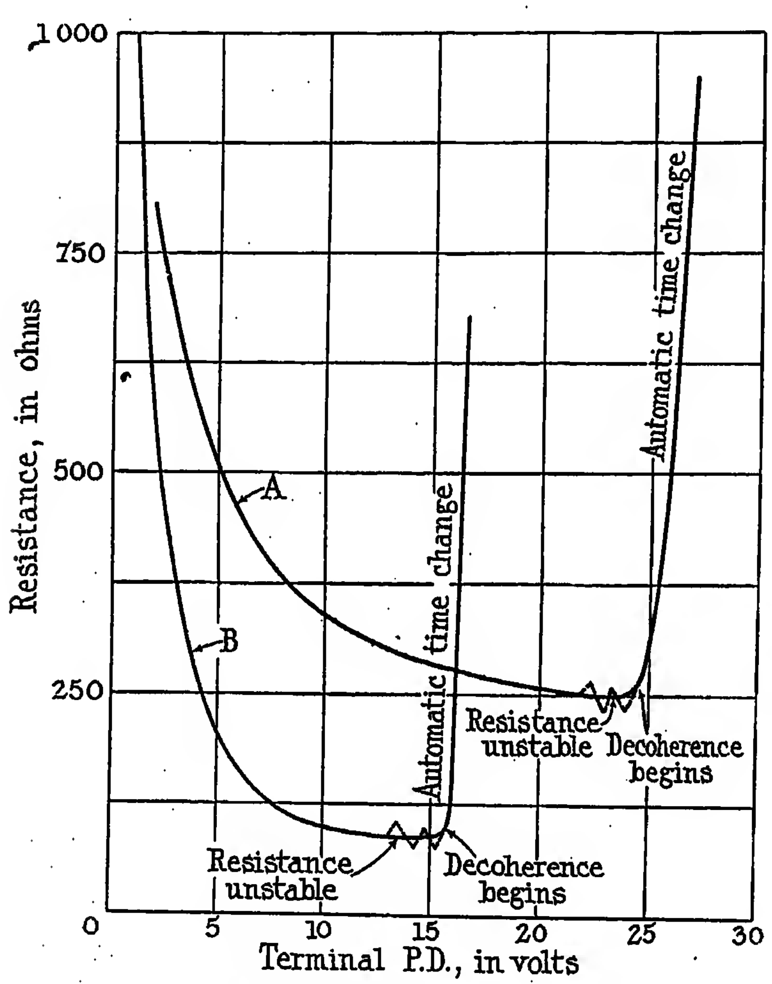

FIG. 32.—D.C. resistance characteristic of lead-peroxide coherer.

Metallic lead electrodes.

and nickel at about 370° C., and that an interruption in the circuit through tubes containing filings of these metals could only be brought about at red heat, is very significant. Again, a mixture of iron and brass decohered immediately.

(2) *The instability of the resistance of an imperfect contact.*—We have remarked that in all the imperfect contacts with which we have been concerned, except perhaps where mercury forms one of the electrodes, the interface resistance manifests a curious instability, which is quite independent of mechanical vibration.

If we consider once again the operation of the film between the surfaces, we see that the magnitude of the current conducted by the gaps may vary even when the applied P.D. remains constant. The area of active surface depends upon the voltage-drop across the contact. An extension of the number of conducting gaps is simultaneously accompanied by a reduction in the interface P.D., because the total current must remain approximately constant. Consequently, such a change will be very quickly arrested, and then continued again as soon as the contact resistance has risen sufficiently. It is clear that the conductivity of the junction, and the voltage across it, are interdependent, producing very unstable conditions. The striction of the conducting veins of mobile conductor in the interfaces may also exert an influence. A small increase in current will tend to reduce the section of these veins and therefore increase their effective resistance.

Correlation of Facts and a General Theory of Imperfect Contacts.

When reading through the literature of this subject, one notices an unfortunate tendency to keep the various theories in watertight compartments. Where we are concerned with processes of such an involved nature, we cannot afford to limit our attention to one particular point of view.

Our experiments have shown that the mechanical pressure at an imperfect contact of good conductors is first increased and then decreased as the applied P.D. is raised. The conductivity of the system has been proved to follow a similar cycle of changes, and is known to be exceedingly sensitive to the interface forces. It follows that if the active material (including the interface mobile conductor) is capable of readjustment under the influence of small alterations in these forces, the principal characteristics at once become more or less intelligible. We have already discussed in detail the influence of the interface film. Here it will be sufficient to point out that coherence and decoherence would be impossible without it, and that when the solid boundaries are incapable of displacement the mobile conductor between them alone determines the conductivity changes by variations in its distribution and the degree of ionization.

Although the resistance of a sliding contact is always greater than that of a similar stationary one, the evidence suggests that the same considerations apply in both cases.

Conclusion.

In conclusion the author wishes to express his sincere thanks to Prof. J. A. Fleming, M.A., D.Sc., F.R.S., for placing the resources of the Laboratory at his disposal and for advice during the course of the work; and to the Department of Scientific and Industrial Research for financial assistance.

APPENDIX 1.

The paper recently published by Messrs. Johnsen and Rahbek * dealing with the adhesion set up between a metal plate and a semi-conductor with which it is in close contact, contains several statements which are apparently in conflict with the results of our observations on this subject.

* *Journal I.E.E.*, 1923, vol. 61, p. 713.

In the first place, it is asserted that the contact resistance, which plays so important a part in the "stiction" phenomenon, is absent with mercury electrodes. Our experiments on the direct-current conductivity of lithographic stone and slate suggest that this is extremely unlikely, but in order to clear up the matter we have carried out the following tests.

A disc of polished lithographic stone was suspended horizontally by a flexible wire from one end of the arm of a balance so that it just touched the surface of a pool of mercury (see Fig. 33). The wire was electrically connected to the stone, in some cases by a piece of tinfoil spread over it, and in others by a layer of mercury enclosed in wax. On account of the exclusion of the atmosphere at the contact and the cohesion operating across the interface, about 12 to 13 grammes per square inch was required to raise the semi-conductor from the mercury. When, however, a P.D. was applied across the contact the force necessary to separate the

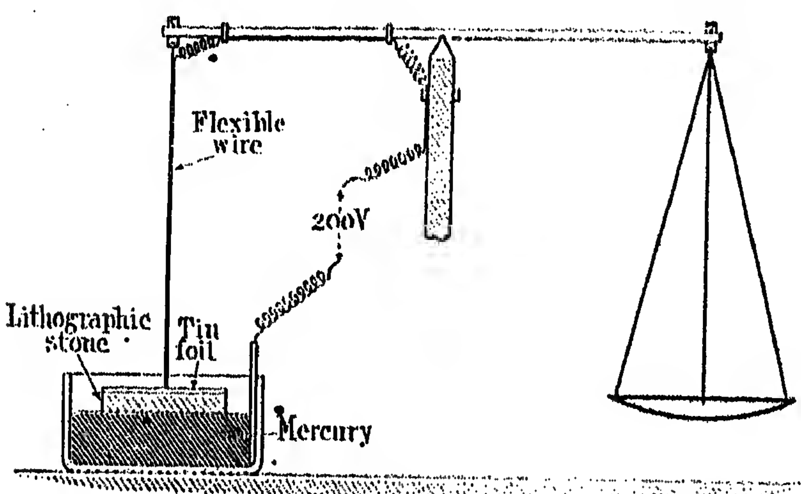

FIG. 33.—Apparatus for observing the electro-adhesion at a mercury-semi-conductor contact.

two parts was considerably increased. With a lithographic stone disc of about ¾ square inch area, and 200 volts (a.c.) supply, about 2 to 3½ grammes extra weight had to be added to the scale pan to upset the equilibrium. If, say, 2 grammes were added to the scale pan when the current was on, as soon as it was switched off the lithographic stone disc came right away from the mercury. Moreover, if the disc was tilted slightly so that it only made contact at one corner, the application of the P.D. immediately brought the two surfaces together over the whole area. This process could be observed quite easily. Great care was taken to secure perfectly clean mercury, and the lithographic stone was washed and dried before using. With a very thin film of petroleum oil covering the mercury surface the "initial pressure" fell to about 7 or 8 grammes per square inch whilst the superimposed stiction effect accompanying the application of a P.D. of 200 volts increased to 3 or 3½ grammes for an area of ¾ square inch. The results were exactly the same whether the connection to the upper surface of the semi-conductor was made with tinfoil or mercury.

Some tests on xylonite and slate in contact with clean mercury gave similar observations. In the case of xylonite the average "initial pressure" was 10 grammes per square inch, and the average additional adhesion effect due to 200 volts was 0·2 gramme per square inch. For slate an "initial pressure" of 8 grammes per square inch was increased to 10 grammes per square inch when the current was passing.

These facts show definitely that a very considerable "stiction" effect exists at a contact between a semi-conductor and mercury. The phenomenon is by no means confined to the case of solid electrodes. Since the adhesion is electrostatic in origin, it follows that the resistance of the interface film between the mercury and the semi-conductor is far from negligible; in fact it must be a large proportion of the total resistance of the circuit. It is significant that the nature of the contact on the upper side of the semi-conductor made no observable difference to the increase in the adhesion due to an applied P.D.

We should be interested to know how Messrs. Johnsen and Rahbek measured the distribution of potential over a circuit including a metal plate in contact with a piece of lithographic stone, curves for which are given in their paper.

It would appear that it is only possible to secure a really low-resistance contact when the liquid electrode wets the surface of the semi-conductor, and then the junction ceases to be what we call "imperfect." The supposition that mercury exactly follows the contour of the semi-conductor and thus eliminates air-gaps, is a fallacy.

Our experiments on the "slipping" effect observed in certain types of contact show that this is generally due to a reduction in the pressure between the surfaces, and not to a change in the coefficient of friction. Exceptions to this rule were only found in the cases of copper-graphite and graphite-graphite, and even in these instances the change was principally in the forces across the interface. The effect which altered the coefficient of friction did not operate simultaneously with the application of the current. The Edison electromotograph could not have worked by the part of the "slipping" action with which any appreciable time-lag is associated, and therefore, unlike Messrs. Johnsen and Rahbek, we conclude that the main function of the current was to produce a reduction in the mechanical pressure between the surfaces. The theory of electrolytic dissociation of the moisture at the interface receives little support from the facts. On the other hand we venture to believe that our hypothesis, that the "pinch effect" is responsible for the phenomenon, explains all the experimental observations, and at the same time satisfactorily accounts for the rapidity of the friction-changes.

APPENDIX 2.

The electrostatic forces which, we have shown, are produced by the application of a potential difference between a liquid metal, such as mercury, and a semi-conductor in contact with it, have been utilized by us in several instruments.*

* Patents have been applied for.

A telephone receiver can be made by simply floating a thin disc of lithographic stone, having its under side slightly concave, upon a pool of mercury so that only part of the surface is normally in contact. Electrical connection is made to the upper side of the stone disc by tinfoil cemented to it. The application of a varying potential difference between the tinfoil and the mercury causes a corresponding vibration of the semi-conductor. The attraction set up at the interface by the passage of the electric current across it pulls the semi-conductor periodically into more intimate contact with the mercury. The sound is produced either by the direct action of the vibrating disc on the surrounding air, or by the compression and rarefaction of the air partially enclosed between the mercury and the under side of the semi-conductor, a small hole, through which the air is forced in and out, being provided in the centre of the disc.

A very simple galvanometer for an oscillograph can be made by employing a piece of semi-conductor oscillating on the surface of mercury, so that its motion corresponds to the wave-form of the applied E.M.F.

DIRECTIONS FOR THE STUDY OF VARNISH-PAPER AND VARNISH-FABRIC BOARDS AND TUBES.

[REPORT (REF. A/S6) RECEIVED FROM THE BRITISH ELECTRICAL AND ALLIED INDUSTRIES RESEARCH ASSOCIATION.]

CONTENTS.

PREFACE.

For some time the Association has been engaged in the study of varnish-paper and varnish-fabric boards and tubes. In the past no standard method of testing materials of this class has been recognized, and therefore methods of test were developed. As the result of the investigations which have been carried out the tests described in this Specification are recommended for the purpose of ascertaining the electrical, mechanical and chemical characteristics of varnish-paper and varnish-fabric boards and tubes.

The tests contained in Section II of the Specification are essentially of a thorough research nature, whilst the abridged tests given in the Schedule are intended for use when a complete investigation of all the characteristics of the material is not required.

The Director of the Electrical Research Association will value comments and criticism from those who have occasion to use any of the tests given in this Specification.

I. DEFINITIONS AND CLASSIFICATION.

(a) Definition of Varnish-paper and Varnish-fabric Boards and Tubes.

The term "Varnish-paper (Fabric) Board (Tube)" denotes a board (tube) made from superimposed layers of paper (fabric) treated with varnish.

(b) Classification of Varnish-paper and Varnish-fabric Boards and Tubes.

The following classes and grades are recognized:—

Class I. Synthetic Resin Varnish-paper and Varnish-fabric Boards and Tubes.

Grade A.—This includes synthetic resin varnish-paper (fabric) boards (tubes), the principal characteristics of which are low water absorption, high resistivity, and good machining properties. This class of material does not necessarily possess a high electric strength at high temperatures, and is generally used for radio work and electrical apparatus where the dielectric is not subjected to a high electric stress at a high temperature.

Grade B.—This includes synthetic resin varnish-paper (fabric) boards (tubes), the principal characteristic of which is a high electric strength at high temperatures. This grade, in general, has not as good machining properties as Grade A, and is generally used in electrical machinery where high electric strength is required at a high temperature, as, for example, in oil-immersed plant.

Grade C.—This includes synethetic resin varnish-paper (fabric) boards (tubes) made from an inorganic paper or fabric (such as asbestos). The principal characteristics of this material are its ability to withstand a high temperature without serious loss of mechanical properties. This grade in general has not as high an electric strength as either Grade A or Grade B, is more hygroscopic and of lower resistivity. Its machining properties, although sufficiently good to permit of its being drilled, sawn, etc., are not in general as good as those of Grade A or Grade B.

Class II. Natural Gum or Resin Varnish-paper and Varnish-fabric Boards and Tubes.

Grade A.—This includes natural gum or resin varnish-paper (fabric) boards (tubes) possessing relatively high electric strength, and able to withstand temperatures up to 95° C. without softening. This material is generally used for transformer insulation.

Grade B.—This includes natural gum or resin varnish-paper (fabric) boards (tubes) possessing relatively high electric strength and able to withstand temperatures

up to 70° C. without softening. This material is generally used where the temperature-rise is small.

NOTE. It is recognized that special materials are obtainable which do not fall into any of the grades given above, as, for instance, bitumen-paper board and linseed oil varnish-paper board.

(c) *Terminology.*

(i) The term "Longitudinal" denotes the direction parallel to that in which the material travelled during manufacture.

(ii) The term "Transverse" denotes the direction at right angles to that described in (i) above.

(iii) The term "Perpendicular" denotes the direction normal to the surface of the material.

NOTE.—When the material is built up of superimposed layers having the "grain" at right angles, there is no definite longitudinal or transverse direction.

II. METHODS OF TEST.

1. Conditioning of Specimens previous to Test.

(a) *Electrical Tests.*

The Electric Strength, Clause 3, the Resistivity, Clause 4, the Surface Resistivity, Clause 5, and the Internal Resistance, Clause 6, shall be determined for as many as possible of the following conditions:—

(i) "Normal" Condition
(ii) "Dry" Condition
(iii) "Damp" Condition
(iv) "Tropical" Condition
(v) "Recovered" Condition

See Technical Publication Ref. A/S2, Directions for Determining the Electric Strength of Fibrous Insulating Materials.

(b) *Mechanical and Physical Tests.*

Before determining the mechanical and physical characteristics as specified in the respective clauses, the specimens shall be dried at a temperature from 75° C. to 80° C. for 18 to 24 hours, except in the case of Class II, Grade B materials, the temperature for which shall be from 55° C. to 60° C. The test shall be conducted as soon as the temperature of the specimen has fallen to 20° C. (± 5° C.) except where otherwise specified.

(c) *Chemical Tests.*

The chemical tests shall be carried out on the material as received without conditioning.

2. Determination of Thickness.

The specimen shall be conditioned in accordance with Clause 1 (b) before the thickness is determined.

(a) *Boards.*

Measurements of thickness shall be made by means of a suitable micrometer at ten points equally spaced around the sides of the board. The maximum, minimum and mean values of the thickness shall be stated.

(b) *Tubes.*

The internal and external diameters of the tube shall be measured at each end, two measurements being made on diameters at right angles in each case. The measurements shall be made by means of a suitable micrometer. The maximum, minimum and mean values of the diameters shall be stated.

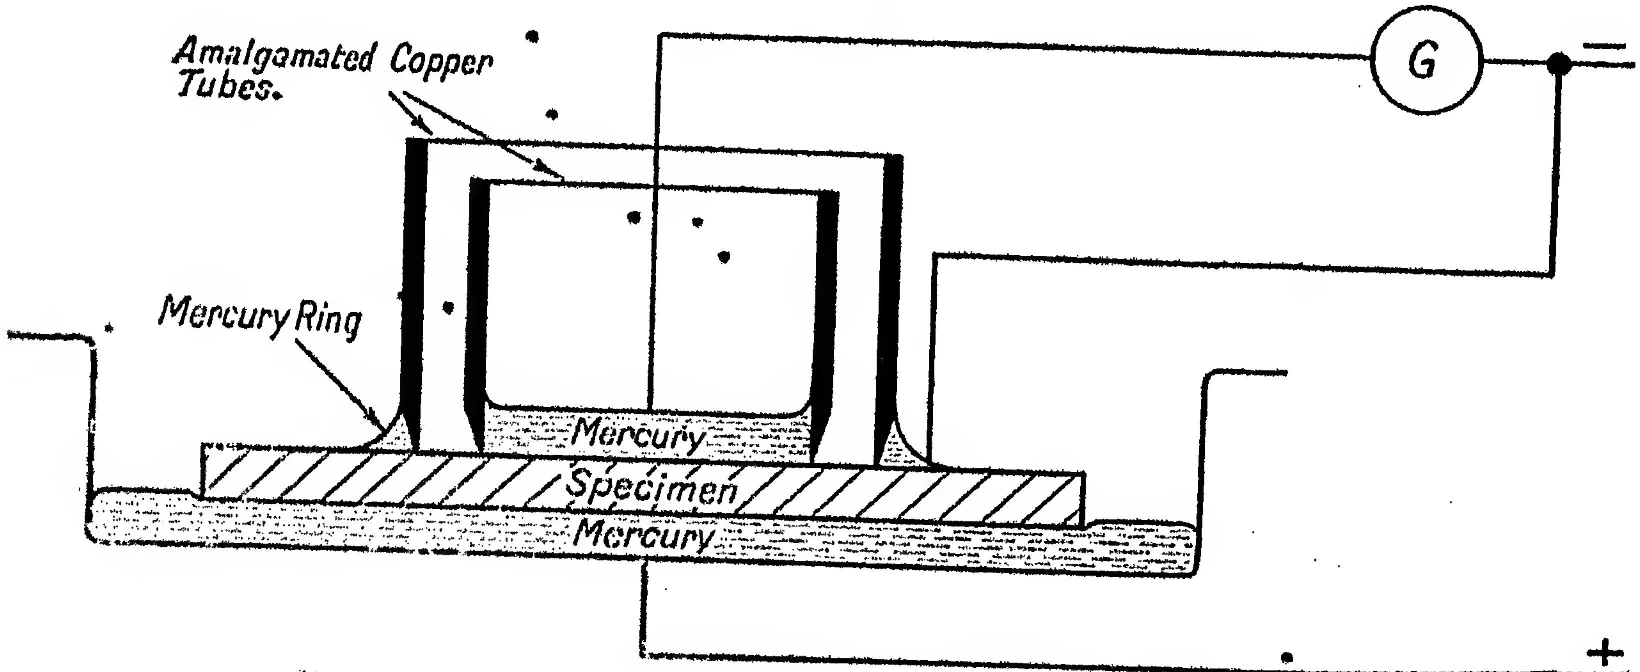

FIG. 1.—Diagrammatic Arrangement of Apparatus for Volume Resistivity Test.

3. Electric Strength.

The electric strength shall be determined in accordance with Technical Publication Ref. A/S2, Directions for Determining the Electric Strength of Fibrous Insulating Materials.

4. Resistivity.

The specimen shall be conditioned in accordance with Clause 1 (a) before the resistivity test is carried out

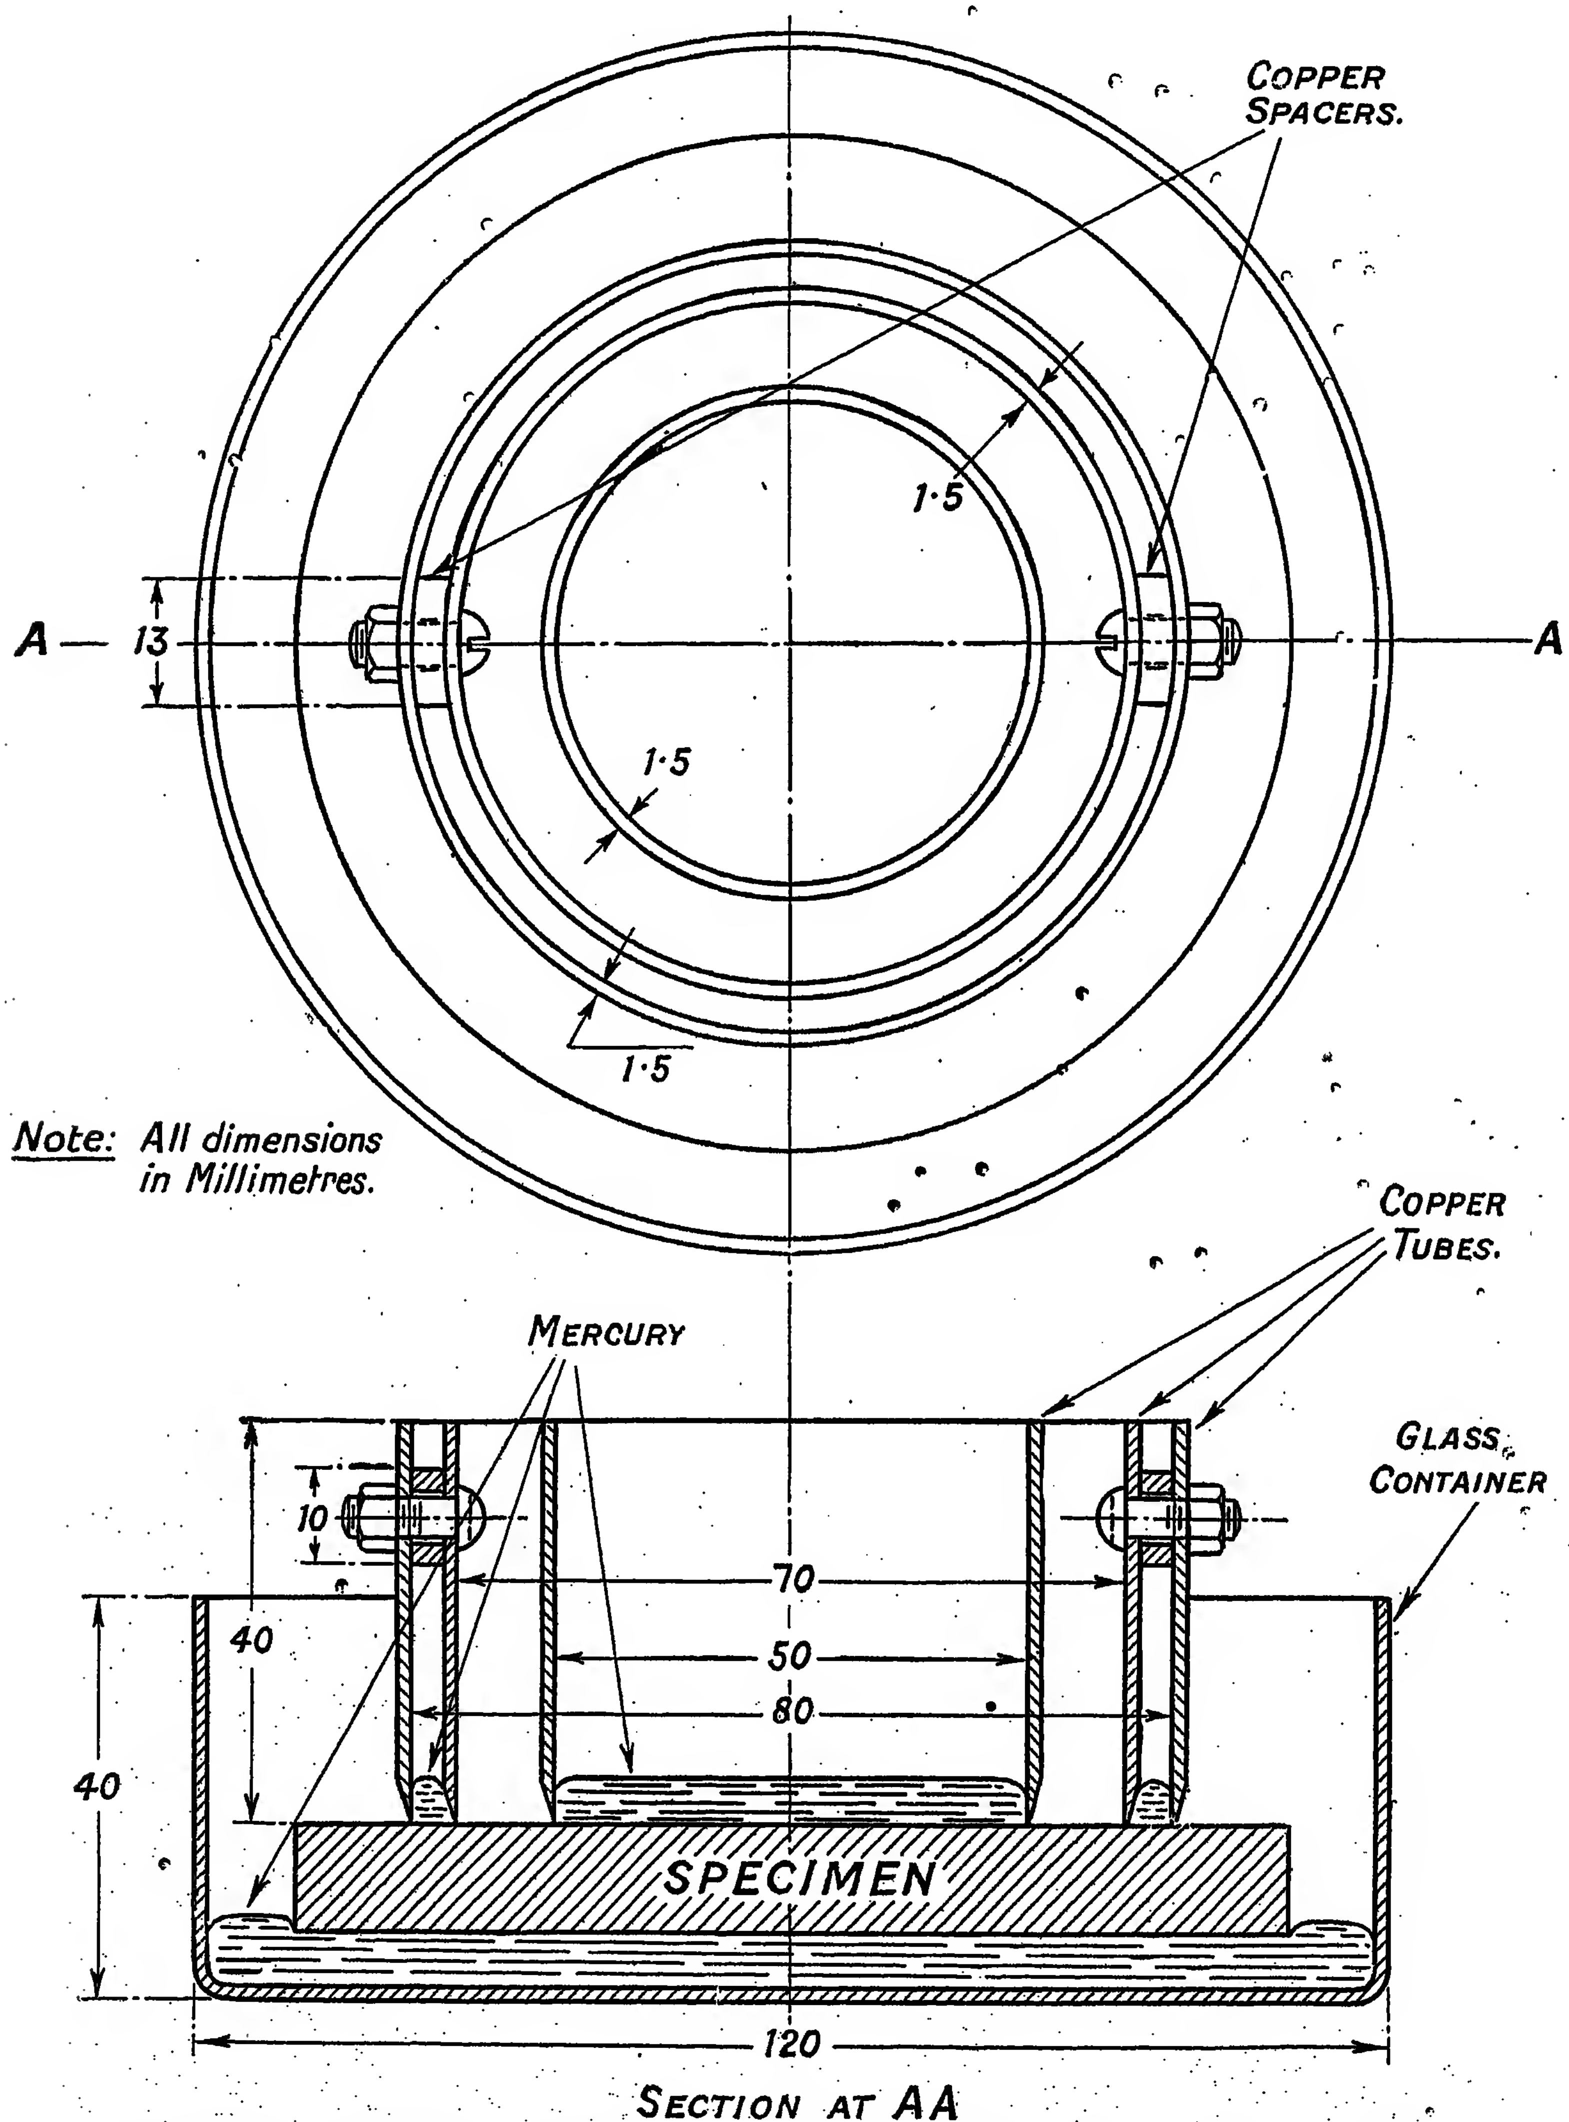

FIG. 2.—Form of Apparatus for Volume Resistivity and Surface Resistivity Tests (U.S. Bureau of Standards).

Measurements shall be made at various temperatures, including the maximum temperature at which the material is to be studied.

The specimen and the electrodes shall be exposed to the "normal" atmosphere as defined in Technical Publication Ref. A/S2, Directions for Determining the Electric Strength of Fibrous Insulating Materials, for 18 to 24 hours prior to the measurement of the resistance, and in the case of tests at room temperature whilst the test is being carried out.

A specimen 4 inches diameter shall be set up for test as shown in Fig. 1.

The resistance shall be measured at the end of each minute, over a period of ten minutes' electrification at a potential difference of 500 volts. The resistivity shall be expressed in megohms for a centimetre cube, and a curve shall be plotted showing the relationship between resistivity and time.

NOTE.—The dimensions of a suitable apparatus are shown in Fig. 2.

5. Surface Resistivity.

The specimen shall be conditioned in accordance with Clause 1 (*a*) before the surface resistivity test is carried out.

Measurements shall be made at various temperatures, including the maximum temperature at which the material is to be studied.

The specimen and electrodes shall be exposed to the "normal" atmosphere as defined in Technical Publication Ref. A/S2, Directions for Determining the Electric Strength of Fibrous Insulating Materials, for 18 to 24 hours prior to the measurement of the surface resistance, and in the case of tests at room temperature whilst the test is being carried out.

A specimen 4 inches diameter shall be set up for test as shown in Fig. 3.

The surface resistance shall be measured at the end of each minute, over a period of ten minutes' electrification at a potential difference of 500 V. The surface resistivity shall be expressed in megohms for a centimetre square, and a curve shall be plotted showing the relationship between surface resistivity and time.

NOTE.—The dimensions of a suitable apparatus are shown in Fig. 2.

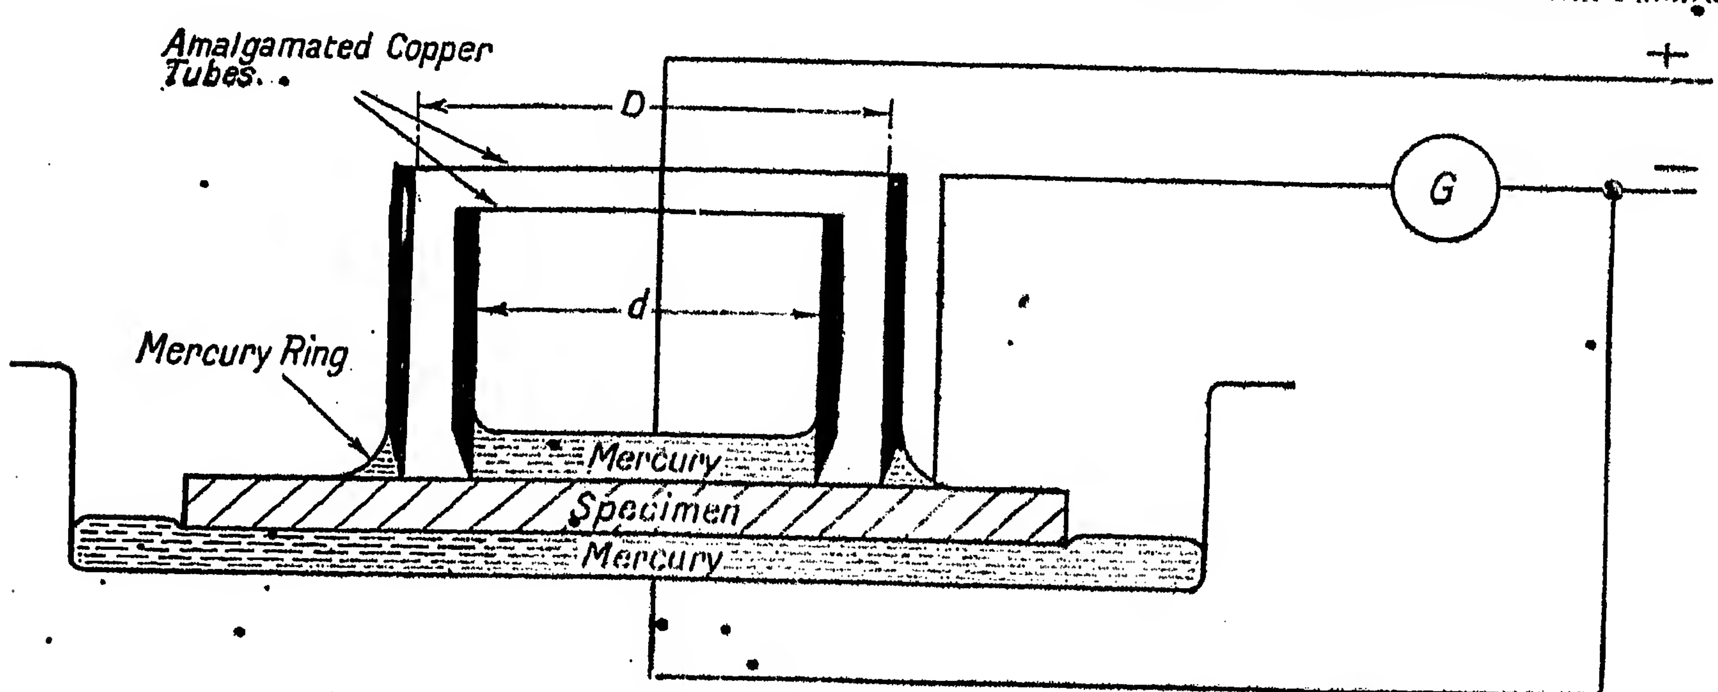

FIG. 3.—Diagrammatic Arrangement of Apparatus for Surface Resistivity Test.

6. Internal Resistance.

The specimen shall be conditioned in accordance with Clause 1 (*a*) before the internal resistance is determined.

Measurements shall be made at various temperatures, including the maximum temperature at which the material is to be studied.

The specimen and electrodes shall be exposed to the "normal" atmosphere as defined in Technical Publication Ref. A/S2, Directions for Determining the Electric Strength of Fibrous Insulating Materials, for 18 to 24 hours prior to the measurement of the internal resistance, and in the case of tests at room temperature whilst the test is being carried out.

Two holes 5 mm diameter shall be drilled to a depth equal to two-thirds of the thickness of the board. The distance between the centres of the holes shall be 15 mm. The holes shall be filled with mercury, and the resistance between them shall be measured at the end of each minute over a period of ten minutes' electrification at a potential difference of 500 volts.

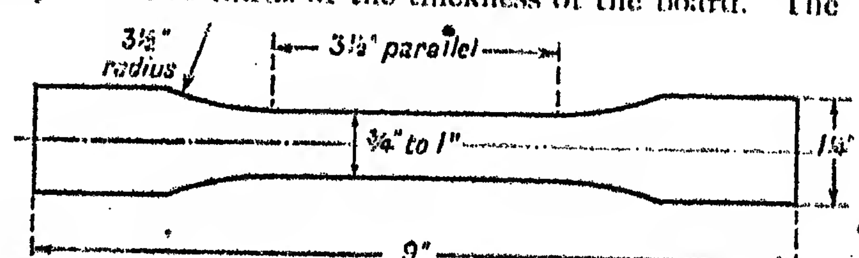

FIG. 4.—Specimen for Tensile Strength and Extension Tests on Boards.

The resistance shall be expressed in megohms, and a curve shall be plotted showing the relationship between resistance and time.

In reporting the results of the tests the thickness of the specimen shall be stated.

7. Tensile Strength and Extension.

The specimens shall be conditioned in accordance with Clause 1 (*b*) before the tests for tensile strength and extension are carried out.

The form of the specimen shall be as follows:—

(*a*) Boards, in accordance with Fig. 4.

(*b*) Tubes, in accordance with Fig. 5 (which also depicts a suitable form of grip for holding the tube in the testing machine).

The extension shall be measured on a 3-inch gauge length.

In all cases the specimens shall be tested to ascertain the ultimate tensile strength. The load shall be increased steadily at such a rate that the specimen breaks in approximately two minutes from the time of the application of the load.

The ultimate tensile strength shall be expressed in lb. per sq. in.

The test shall be carried out under the following conditions:—

(i) At a temperature from 15° C. to 25° C.

(ii) At the appropriate temperature given in Table 1, after the specimen has been immersed in the oil specified in Table 1, at the high temperature for 24 hours.

Table 1.

Temperature of Specimen in Tensile Strength and Extension Tests.

Material	Limits of Temperature, ° C.	Class of Oil
Class I, Grades A and B	90 to 95	B.S.S. No. 148 for light grade oil
Class II, Grade A..	90 to 95	
Class II, Grade B..	65 to 70	
Class I, Grade C ..	145 to 150	Mineral oil, closed flash point not less than 250° C.

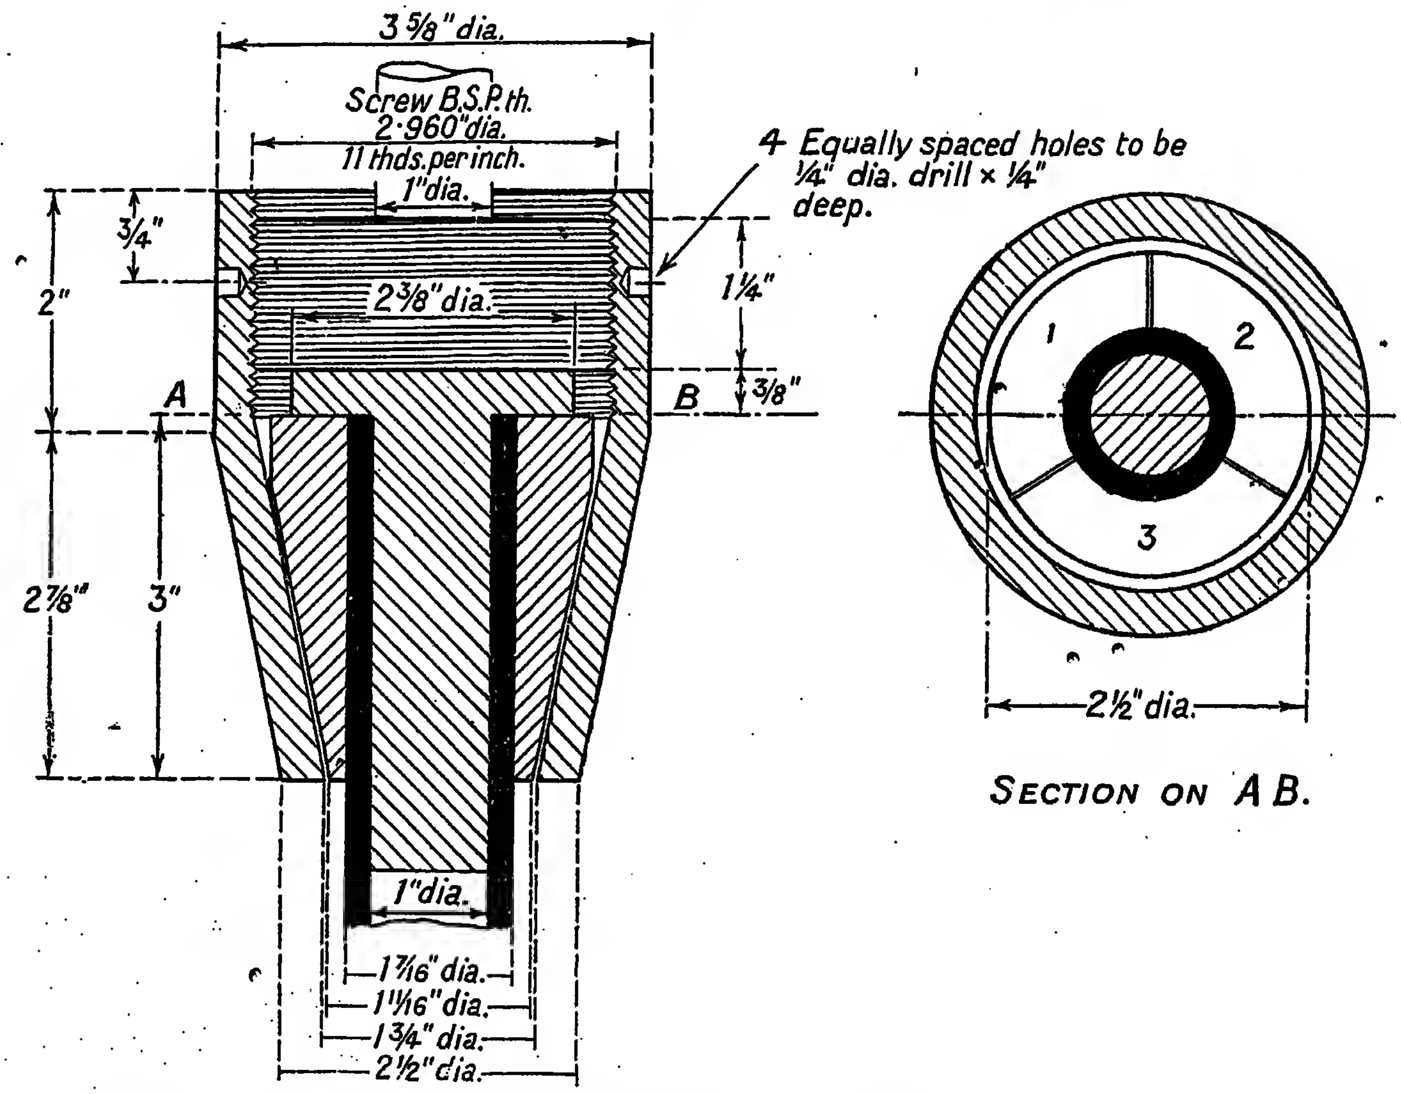

Fig. 5.—Form of Grip for holding Tube in Testing Machine for Tensile Strength and Extension Tests.

8. Compression Strength.

(Not to be applied to Class II, Grade B, material.)

(*a*) *Boards.*

The compression test shall be carried out at the appropriate temperature given in Table 2, after the specimen has been immersed in the oil specified in Table 2 at the high temperature for 24 hours.

The dimensions of the specimen shall be 1 inch cube, the specimen being built up with several layers of the material when necessary. The layers of the material shall be bedded together by the application of an initial

TABLE 2.

Temperature of Specimen in Compression Test.

Material	Limits of Temperature, °C.	Class of Oil
Class I, Grades A and B	90 to 95	B.S.S. No. 148 for light grade oil
Class II, Grade A	90 to 95	
Class I, Grade C ..	145 to 150	Mineral oil, closed flash point not less than 250° C.

load of 300 lb. per sq. in. The first measurement of the length of the specimen shall be taken under this load, which shall be included in the load registered in each case.

The load shall be applied in increments of 1 500 lb. per sq. in., each of which shall be maintained for one minute, and the yield of the specimen shall be measured at the end of each period.

The test shall be continued until the specimen has yielded 10 per cent of its original length when measured as stated above, or when the load has reached about 6 tons per sq. in.

(*b*) *Tubes.*

The form of the specimen shall be a tube, the thickness of the wall being not less than ⅛ inch, and the length equal to the external diameter of the tube. The end faces of the specimen shall be truly plane, square and parallel.

An initial load of 300 lb. per sq. in., computed on the cross-sectional area of the material, shall be applied, and the first measurement of the length of the specimen shall be taken under this load, which shall be included in the load registered in each case.

The specimen shall be heated prior to test and tested as specified in (*a*) above.

(*c*) *Cylinders.*

The form of the specimen shall be a cylinder not less than 8 inches internal diameter.

The length of the cylinder shall be equal to the internal diameter and the thickness of the wall shall be equal to 1/64th of the internal diameter.

The specimen shall be heated prior to test and tested as specified in (*b*) above.

9. SHEARING STRENGTH OF BOARDS.

The specimen shall be conditioned in accordance with Clause 1 (*b*) before the shearing test is carried out.

Materials up to and including ⅛ inch (3·2 mm) thick

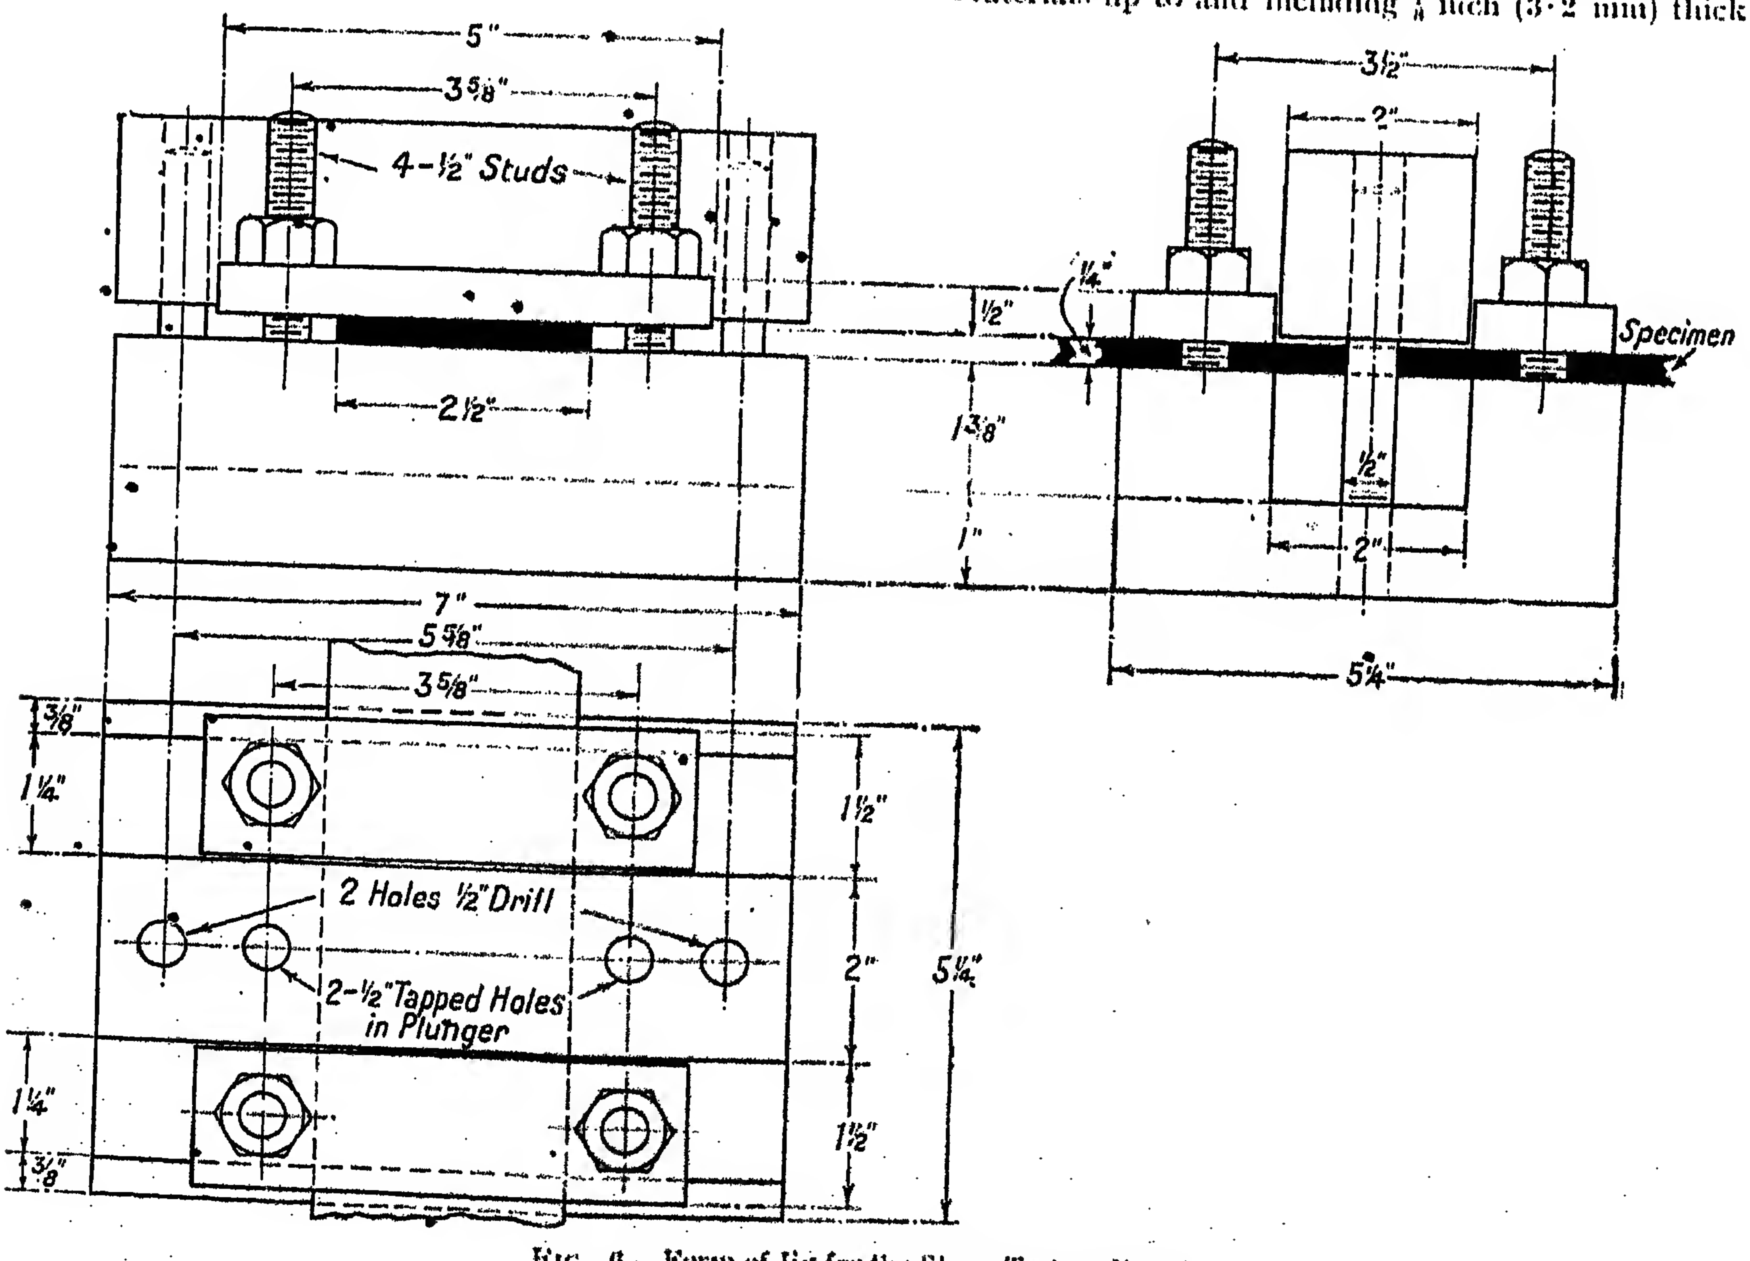

FIG. 6.—Form of Jig for the Shear Test on Boards.

shall be tested to ascertain the force required to punch a hole $\frac{1}{2}$ inch in diameter.

The load shall be applied steadily, and shall be increased at a rate of approximately 100 lb. per minute for each 1/32 inch thickness of specimen.

The clearance between the punch and the hole shall

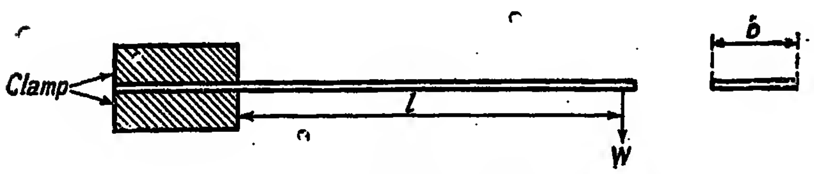

FIG. 7.—Form of Test for Stiffness or Rigidity.

be negligible, as obtained by trimming the punch with the die.

The force required to punch the hole shall be expressed in lb. per sq. in.*

Materials above $\frac{1}{8}$ inch (3·2 mm) thick shall be tested as follows:—

A load shall be applied centrally on the specimen and increased until failure occurs. The load required to cause failure and the nature of the fracture shall be stated.

(*b*) *Tubes.*

A specimen of tube shall be cut of length equal to the external diameter, and shall be subjected to a crushing load perpendicular to the axis of the tube. The load required to cause failure and the nature of the fracture shall be stated.

11. STIFFNESS OR RIGIDITY.

The specimen shall be conditioned in accordance with Clause 1 (*b*) before the stiffness test is carried out.

(*a*) *Boards.*

Materials shall be tested for stiffness or rigidity by the cantilever method as follows:—

The form and arrangement of the test shall be in accordance with Figs. 7 and 8.

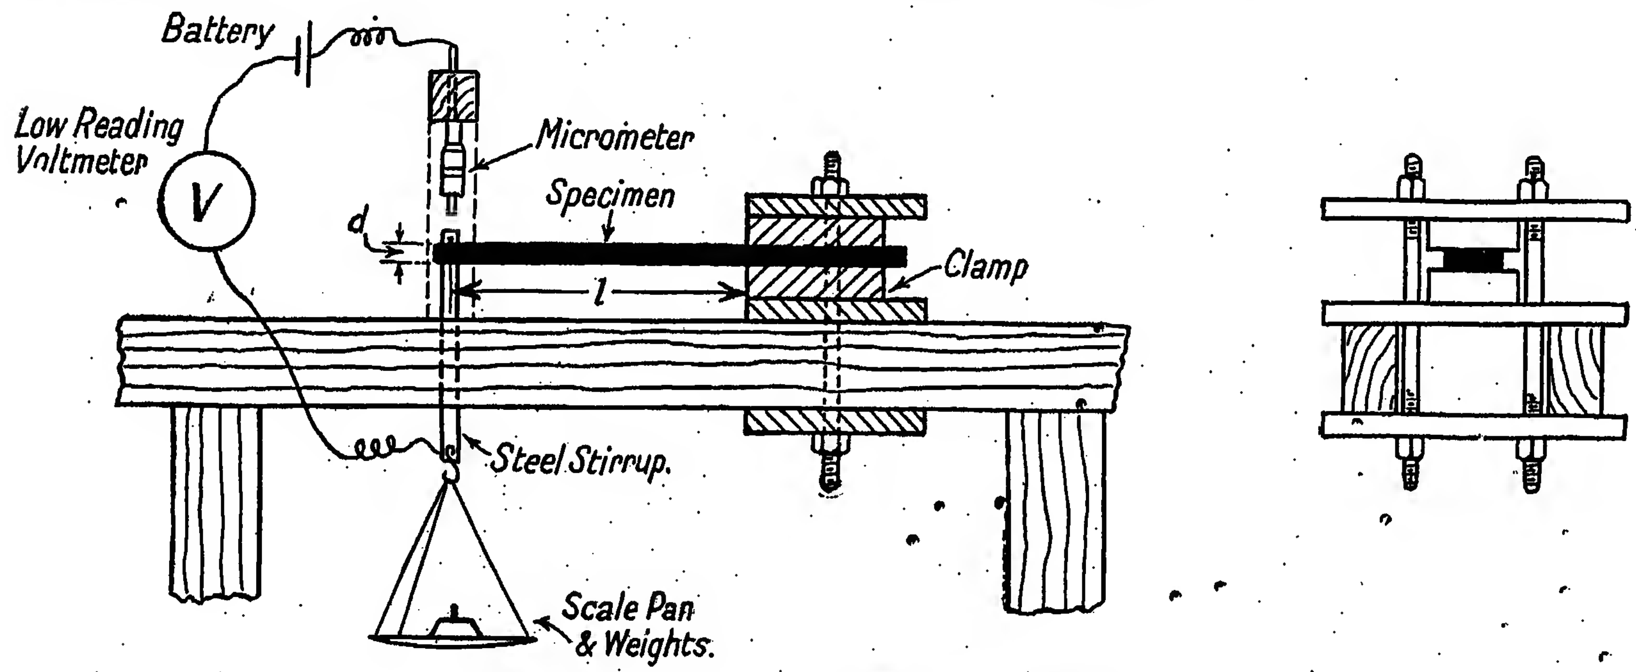

FIG. 8.—Arrangement of Cantilever Test for Boards.

A specimen, the dimensions of which shall be 5 inches (127 mm) long and $2\frac{1}{2}$ inches (64 mm) wide, shall be clamped in a shear testing jig, so that both ends of the specimen are sheared off simultaneously. The pressure required to produce shear, computed on the total area of the sections sheared, shall be expressed in lb. per sq. in.

A suitable form of jig for the shear test is shown in Fig. 6.

10. COHESION BETWEEN LAYERS (SPLITTING TEST).

The specimen shall be conditioned in accordance with Clause 1 (*b*) before the test for cohesion between layers is carried out.

(*a*) *Boards.*

A specimen 1 inch wide and of a length equal to four times the thickness of the material, plus $\frac{1}{2}$ inch, shall be supported on vee-blocks spaced apart at a distance equal to four times the thickness of the material under test.

The specimen shall be firmly fixed in clamps and the stirrup and scale pan placed in position as shown in Fig. 8. A measurement shall be made of the unsupported end below datum as follows:—

An inside micrometer shall be clamped above the stirrup. The electric circuit shall be as shown in Fig. 8. The micrometer screw shall be turned until the circuit is closed (as indicated by the voltmeter), and the micrometer reading shall then be taken.

Small equal increments of load shall be applied and the corresponding increments in deflection measured immediately. Each increment of load shall be applied as soon as the deflection for the previous load increment has been read. Readings shall only be taken for the range during which the increment of load is proportional to the increment of deflection.

The dimensions of the specimen shall be as follows:—

For specimens not exceeding 1/6 inch thick:

Cantilever length = 2 inches
Breadth = $\frac{3}{4}$ inch

The increments of deflection shall not exceed 0·010 inch.

* In a future edition of this Specification it is probable that the shear stress will be substituted for the pressure required to punch the hole.

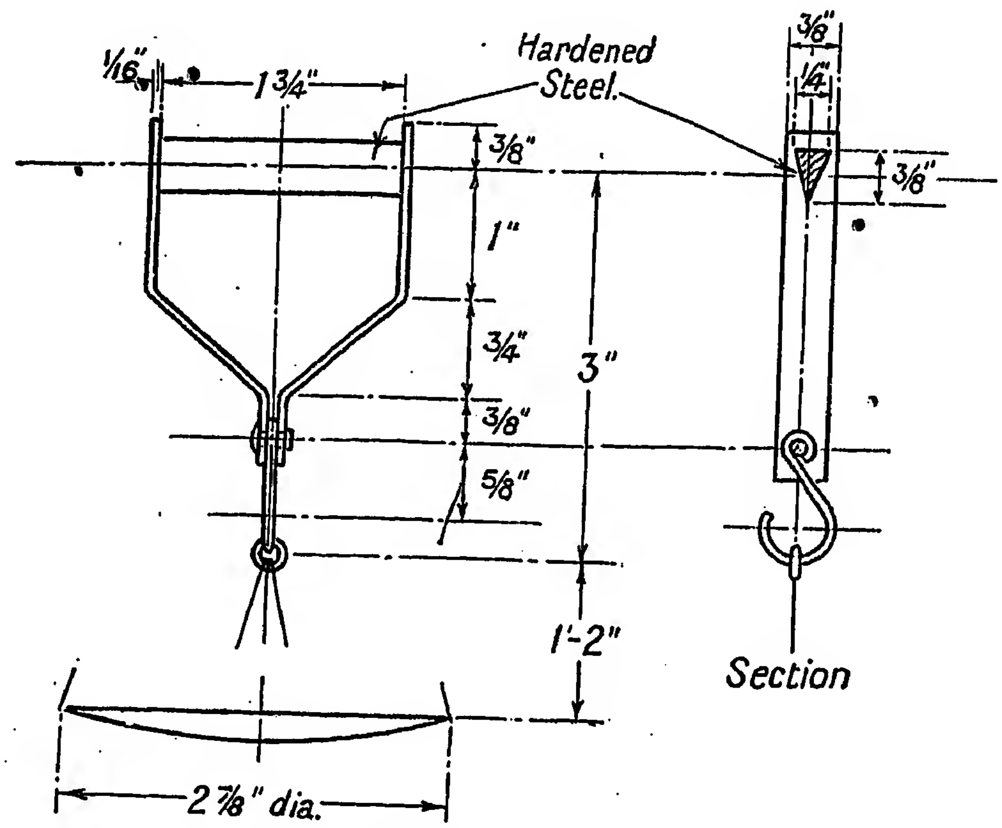

FIG. 9.—Form of Knife-edge Balance for Cantilever Test.

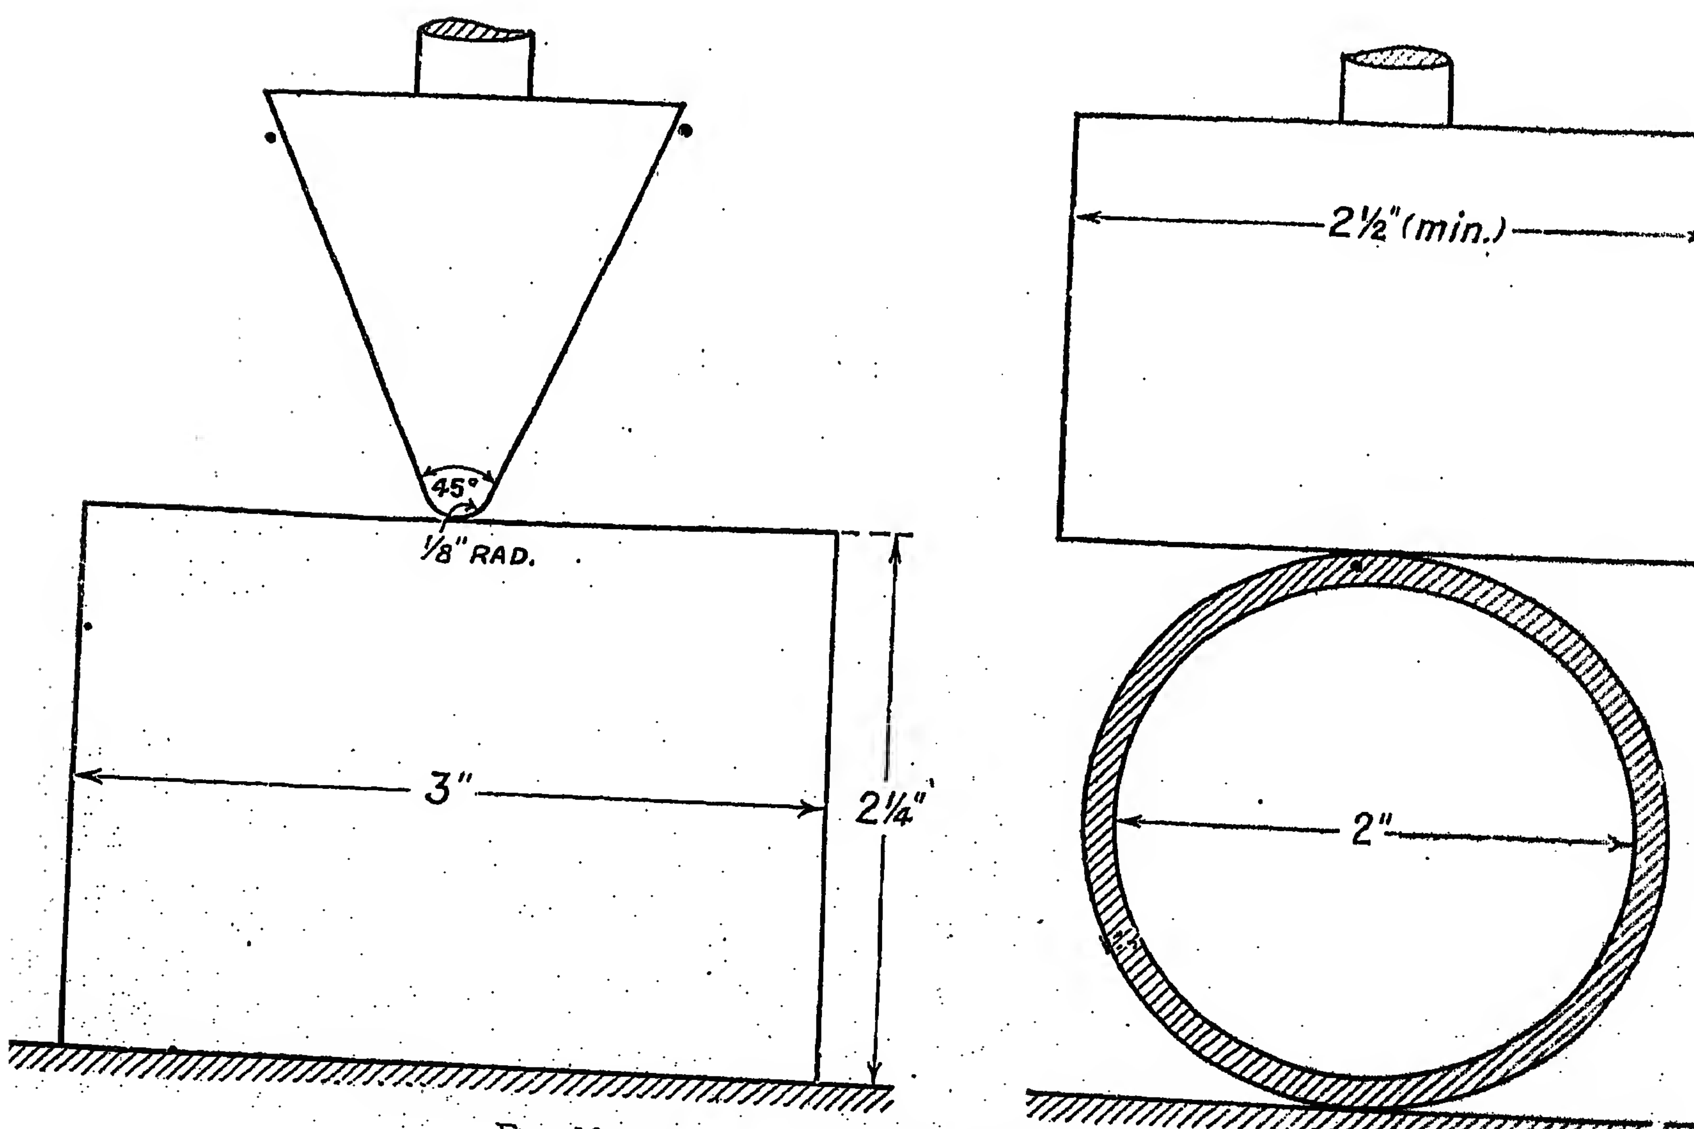

FIG. 10.—Arrangement of Stiffness Test for Tubes.

For specimens exceeding 1/16 inch thick the cantilever length shall be from 3 inches to 9 inches according to the stiffness of the material.

The breadth of the specimen shall be one-fifth of the cantilever length.

The increment of deflection shall not exceed 0·015 inch.

Young's Modulus E shall be computed from the following formula :—

$$E = \frac{4Wl^3}{bd^3y}$$

where W = average increment of load, lb.,
l = cantilever length, inches,
b = breadth of specimen, inches,
d = thickness of specimen, inches,
y = average increment of deflection, inches.

When the final increment of deflection has been measured as described above, the load shall not be removed. The increment of deflection shall be re-measured after 1 minute, 10 minutes, 1 hour and 18 hours respectively.

After the 18-hour test has been completed, tests at loads of 0·66 and 1·5 times, respectively, the value of the load employed in the 18-hour test shall be applied to the specimen, and the increments of deflection shall be re-measured as before in the prolonged test.

NOTE.—A suitable form of knife-edge balance for use in the cantilever test is shown in Fig. 9.

(*b*) *Tubes.*

A tube 3 inches long, 2 inches internal diameter and 2¼ inches external diameter shall be set up in a compression testing machine as shown in Fig. 10.

The load shall be applied to the top of the specimen and midway between the ends, by means of a wedge-shaped plunger not less than 2½ inches wide, the bottom edge of which is rounded to a radius of ⅛ inch. The angle of the wedge shall be approximately 45 degrees, and its axis shall be at right angles to the axis of the tube as shown in Fig. 10. The load shall be increased by steps, and sufficient readings of the load and travel of the plunger taken up to the load at which failure occurs to enable a stress-strain curve to be plotted.

12. SHRINKING, WARPING AND SWELLING.

The following tests shall be conducted after the specimens have been exposed for 18 to 24 hours to the "normal" condition as defined in Technical Publication Ref. A/S2, Directions for Determining the Electric Strength of Fibrous Insulating Materials.

(*a*) *Shrinkage.*

(i) *Test in Air.*

In the case of boards, the test for shrinkage shall be carried out on a specimen about 4 inches square.

The length and width respectively of the specimen shall be measured at ten points equally spaced along each of two edges at right angles. The thickness of the specimen shall be the mean of ten measurements of thickness taken at points equally spaced around the edges. The measurements shall be made by means of a micrometer or other suitable method.

In the case of tubes, the test for shrinkage shall be carried out on a specimen the length of which shall be not less than three times the external diameter.

The internal and external diameters of the specimen shall be measured in two directions at right angles. The measurements shall be made by means of a micrometer or other suitable method.

The specimen shall be dried for 48 hours by heating uniformly in an oven at the appropriate temperature given in Table 3, and the dimensions shall then be measured at the same points as before at atmospheric temperature.

TABLE 3.

Temperature of Specimen in Shrinkage Test in Air.

Material	Limits of Temperature, ° C.
Class I, Grades A and B	105 to 110
Class I, Grade C	160 to 165
Class II, Grade A	105 to 110
Class II, Grade B	80 to 85

Comparison shall be made between the mean values of the dimensions before and after the heat treatment, and the percentage difference, computed on the original mean values respectively, shall be stated, the original mean values being given.

(ii) *Test in Oil* (*not to be applied to Class II, Grade B Material*).

In the case of boards, the diameters of a ring approximately 4 inches internal diameter and 6 inches external diameter shall be measured longitudinally and transversely. The ring shall be immersed in the oil specified in Table 4 for 120 hours at the appropriate temperature given in Table 4. The diameters shall then be measured again as before at atmospheric temperature. Comparison shall be made between the values of the diameters before and after the immersion in oil, and

TABLE 4.

Temperature of Specimen in Shrinkage Test in Oil.

Material	Limits of Temperature, ° C.	Class of Oil
Class I, Grades A and B	115 to 120	B.S.S. No. 148 for light grade oil
Class II, Grade A	115 to 120	
Class I, Grade C ..	170 to 175	Mineral oil, closed flash-point not less than 250° C.

the percentage differences computed on the original values shall be stated.

In the case of tubes, the internal and external diameters of a specimen, the length of which shall be not less than three times the external diameter, shall be measured in two directions at right angles. The tube shall be heated in oil as specified above, and the diameters shall then be measured again at the same points as before at atmospheric temperature.

Comparison shall be made between the mean values of the internal and external diameters respectively before and after the immersion in oil, and the percentage differences computed on the original mean values shall be stated, the original mean values being given.

(b) Warping.

Warping shall be determined by the following method :—

(i) *Boards.*

A specimen 6 inches square shall be dried for 48 hours at the appropriate temperature given in Table 3. It shall then be placed on a flat surface not less than 7 inches square, and a flat metal plate 6 inches square shall be placed on the specimen, so that the edges of the plate and the specimen coincide. The weight of the upper plate shall not exceed 8 ounces. The distances between the four corners of the under surface of the upper plate and the corresponding points on the upper surface of the lower plate shall be measured. The sum of the four readings shall be compared with four times the original mean thickness of the specimen before drying, and the percentage increase computed on four times the original thickness shall be stated.

(ii) *Tubes.*

A straight tube, the length of which shall be 24 times the internal diameter, shall be dried for 48 hours at the appropriate temperature given in Table 3. The tube shall then be tested by means of a straight-edge or other suitable method, and the maximum deviation from straightness shall be stated, the internal and external diameters of the tube being given.

13. Machining Properties.

The specimen shall be conditioned in accordance with Clause 1 (*b*) before the machining tests are carried out.

The machining properties of the material shall be determined by turning, milling, drilling, countersinking and punching specimens. The effect on the material with respect to cracking, splitting or chipping shall be stated.

Boards shall be tested by being tapped with a No. 0 B.A. tap. Tubes shall be tested by being screwed, externally and internally, with 11 B.S.W. threads per inch, cut with a tool by an operator experienced in working with this class of material. The effect on the material with respect to cracking, splitting or chipping shall be stated.

Note.—The manufacturer of the material should be asked to state the cutting speed, depth of cut, rate of feed and lubricant, if any, to be employed in carrying out the machining tests.

14. Freedom from Chemical Reaction.

The chemical tests shall be carried out on the material as received without conditioning.

The material shall be tested * for the presence of the following :—

Ammonia. (Does not apply to Class II material.)
Phenol. (Does not apply to Class II material.)
Free Mineral Acids.
Organic Acids. (Does not apply to Class I material.)
Alkalis.
Lime.
Chlorides.

The tests shall be carried out as follows :—

(a) Free Ammonia.

Two grammes of the material are pulped with 200 cm^3 of distilled water free from ammonia and boiled for a short time under reflux condensation. The filtrate is distilled until 100 cm^3 have come over, and the distillate is made up to 250 cm^3. Varying aliquot amounts from 5 cm^3 to 100 cm^3 are tested with Nessler's reagent until a suitable coloration is found. This is then matched by means of standard ammonium chloride solution by the usual colorimetric method as employed in water analysis.

(b) Combined Ammonia.

The distillation residue from the above determination is made up to 200 cm^3 with water free from ammonia. A little caustic soda is added, and the processes of distillation and Nesslerization are repeated as above.

(c) Phenol.

Ten grammes of material are pulped with 200 cm^3 of water, and the whole mixture distilled until about 100 cm^3 have come over.

To the distillate so much dilute iodine solution is added as is needed just to give a faint coloration with starch-paste. Phenol is then determined by the Koppeschaar method, i.e. sodium bromate solution and acid are added, and after tribromophenol has separated out, the unused bromine is titrated back with KI and thiosulphate.

(d) Acids or Alkalies.

Ten grammes of the material are pulped with 200 cm^3 of distilled water and gently boiled for one † hour. The cooled liquid is filtered perfectly clear by the aid of a pump. The filtrate is tested with phenolphthalein.‡

* It is important to reduce the material to as finally divided a condition as possible, since fully-stoved synthetic resins cannot be brought into solution except by the most destructive solvents. In some cases soaking in water and subsequent pounding in a mortar will reduce the material to a pulp in which the synthetic resin is in a sufficiently fine state of division. In more refractory cases it will be necessary to pulverize the material in a laboratory mill. A suitable method is wet grinding in a cone mill, after the material has been cut into the smallest possible pieces.

† It has been found that alkali is sometimes difficult to remove from pulp. It is recommended that if on testing after one hour's boiling alkalinity is indicated, the pulp should be re-boiled with another 200 cm^3 of distilled water, and further boilings given if considered necessary.

‡ If the solution to be titrated is not coloured, methyl orange has been found reliable.

If acid, it is titrated with $\frac{N^*}{100}$ caustic soda; if alkaline, with $\frac{N^*}{100}$ hydrochloric acid. Should the filtrate be very dark, alkali blue 6B may be used as indicator. If alkali blue 6B is not available, and phenolphthalein is used, the solution must be suitably diluted with a neutralized diluent, or alcoholic or ethereal extracts must be employed. When a large amount of free acid or alkali † is found, it is advisable to boil the residue with fresh water, titrate again, and repeat as requisite.

The acidity or alkalinity shall be expressed as—

"Equivalent to — per cent of SO_3," or
"Equivalent to — per cent of NaOH."

(e) *Organic Acids.*

Ten grammes of the conditioned sample shall be extracted to exhaustion with 100 cm^3 of methylated spirit in a soxhlet apparatus. The alcoholic extract thus obtained shall be cooled, and to it shall be added 50 cm^3 of benzene and a considerable excess of N/2 sodium hydroxide (e.g. 50 cm^3); the mixture shall be well shaken for about five minutes, and then the excess of alkali back titrated with N/2 H_2SO_4 and phenolphthalein.

(f) *Lime and Chlorides.*

The lime and chlorides shall be determined by the usual laboratory methods from the ash after the incineration of the material.

15. Effects of Acid and Alkali.

The tests for the effect of acid and alkali shall be carried out on the material as received without conditioning.

Specimens, the dimensions of which shall be similar to those specified in Clause 10, shall be immersed in the following reagents:—

(a) A sulphuric acid solution, specific gravity 1·25, for 24 hours at a temperature of 40° C.
(b) A 5 per cent solution of caustic soda, for 24 hours at a temperature of 100° C. (Not to be applied to Class II material.)
(c) A 10 per cent solution of common salt, for 24 hours at a temperature of 100° C.

After removal from the reagents, the specimens shall be tested for cohesion between layers in accordance with Clause 10, and their condition with respect to disintegration, blistering, warping, splitting or other deterioration shall be stated.

16. Effect of Oil.

(Not to be applied to Class II, Grade B, material.)

The specimen shall be conditioned in accordance with Clause 1 (b) before the effect of oil is determined.

A specimen shall be immersed in the oil specified in Table 4 for seven days continuously at the appropriate temperature given in Table 4. At the end of this period the condition of the specimen with respect to disintegration, warping, splitting, blistering, softening or other deterioration shall be stated.

17. Effect of Prolonged Heating at High Temperature.

(Not to be applied to Class II material.)

The specimen shall be conditioned in accordance with Clause 1 (b) before the effect of prolonged heating at high temperature is determined.

A specimen shall be heated at the appropriate temperature given in Table 5 for seven days continuously

TABLE 5.

Temperature of Specimens in Prolonged Heating at High Temperature Test.

Material	Limits of Temperature, °C.
Class I, Grades A and B	150 to 155
Class I, Grade C	200 to 205

in air, and another specimen shall be heated at the same temperature for seven days continuously in mineral oil having a closed flash-point not less than 250° C. After the heat treatment, the condition of the specimens with respect to disintegration, warping, splitting, blistering, softening or other deterioration shall be stated.

18. Water Absorption.

The specimen shall be conditioned in accordance with Clause 1 (b) before the test for water absorption is carried out.

A sample of board $1\frac{1}{2}$ inches square, or a tube $1\frac{1}{2}$ inches long, shall be weighed. The board specimen shall have the four edges, and the tube specimen the two ends, freshly cut before being used for the test. The specimen shall then be immersed in water at a temperature from 15° C. to 25° C. After 24 hours' immersion it shall be taken from the water, and, after removing the surface moisture by wiping, weighed again.

The specimen shall then be replaced in the water, and after six days' immersion re-weighed with the same precautions as before. The weight shall be taken to the nearest milligramme in each case.

The percentage absorption of water in each case shall be computed on the original weight of the specimen, and the orginal dimensions of the specimen shall be stated.

When it is desired to distinguish between the absorption in the longitudinal, transverse and perpendicular directions respectively, the appropriate surfaces of the specimen shall be coated with a waterproof varnish before the test for water absorption is carried out.

* When a large amount of acid or alkali is present $\frac{N}{10}$ solution may be used.

† It has been found that alkali is sometimes difficult to remove from pulp. It is recommended that if on testing after one hour's boiling alkalinity is indicated, the pulp should be re-boiled with another 200 cm^3 of distilled water, and further boilings given if considered necessary.

SCHEDULE.

Service Conditions*				Conditioning of Specimen for Test	Test recommended to determine the Suitability of the Material
Electric Stress	Frequency	Mechanical Stress	Temperature		
(1) Low	Power	Low	Low	Normal (Clause 1 (a))	Electric strength
Low	Power	Low	Low	Dry (Clause 1 (b))	Machining properties
(2) Low	Power	Low	High	Normal (Clause 1 (a))	Electric strength
Low	Power	Low	High	Dry (Clause 1 (b))	Machining properties
Low	Power	Low	High	Dry (Clause 1 (b))	Effect of prolonged heating at high temperature, followed by test for cohesion between layers
(3) Low	Power	High	High	Normal (Clause 1 (a))	Electric strength
Low	Power	High	High	Dry (Clause 1 (b))	Machining properties
Low	Power	High	High	Dry (Clause 1 (b))	Effect of prolonged heating at high temperature, followed by test for cohesion between layers, in which transverse modulus of elasticity should be determined.
(4) High	Power	High	High	Normal (Clause 1 (a))	Electric strength, with special reference to its value at high temperature
High	Power	High	High	Dry (Clause 1 (b))	Machining properties
High	Power	High	High	Dry (Clause 1 (b))	Effect of prolonged heating at high temperature, followed by test for cohesion between layers, in which the transverse modulus of elasticity should be determined
(5) Low	Radio	Low	Low	Normal (Clause 1 (a))	Power factor and permittivity at radio frequencies
Low	Radio	Low	Low	Dry (Clause 1 (b))	Machining properties
(6) High	Radio	High	High	Normal (Clause 1 (a))	Power factor and permittivity at radio frequencies
High	Radio	High	High	Dry (Clause 1 (b))	Machining properties
High	Radio	High	High	Dry (Clause 1 (b))	Effect of prolonged heating at high temperature, followed by test for cohesion between layers, in which the transverse modulus of elasticity should be determined
For use in a very damp atmosphere ..				Damp (Clause 1 (a))	Electric strength
				Tropical (Clause 1 (a))	Electric strength
				Dry (Clause 1 (b))	Water absorption
When subjected to considerable tensile stress				Normal (Clause 1 (a))	Electric strength
				Dry (Clause 1 (b))	Tensile strength and extension
				Dry (Clause 1 (b))	Machining properties
When subjected to considerable compression stress				Normal (Clause 1 (a))	Electric strength
				Dry (Clause 1 (b))	Compression strength
				Dry (Clause 1 (b))	Machining properties
When subjected to considerable shearing stress				Normal (Clause 1 (a))	Electric strength
				Dry (Clause 1 (b))	Shearing strength
				Dry (Clause 1 (b))	Machining properties
When high resistivity is required				Normal (Clause 1 (a))	Resistivity
				Normal (Clause 1 (a))	Internal resistance
				Normal (Clause 1 (a))	Electric strength
				Dry (Clause 1 (b))	Machining properties
When high surface resistivity is required ..				Normal (Clause 1 (a))	Surface resistivity
				Normal (Clause 1 (a))	Internal resistance
				Normal (Clause 1 (a))	Electric strength
				Dry (Clause 1 (b))	Machining properties

* Typical examples of the use of material under these conditions are as follows:—

(1) Terminal boards for use under oil.
(2) Insulating parts of resistances for use on low pressure circuits.
(3) Spacing pieces, etc., on rotating fields of alternators.
(4) Spacing pieces, etc., of large oil-immersed transformers.
(5) Insulating parts of wireless receiving apparatus.
(6) Insulating parts of wireless transmitting apparatus.

19. Determination of Density.

The specimen shall be conditioned in accordance with Clause 1 (*b*) before the density is determined.

The density, expressed in grammes per cm^3, shall be ascertained by weighing and measuring a sample of board $1\frac{1}{2}$ inches square or a tube $1\frac{1}{2}$ inches long.

20. Power Factor and Permittivity at Radio Frequencies.

Methods of test suitable for synthetic resin varnish-paper (fabric) boards are being developed by the Association.

21. Softening Point.

The specimen shall be conditioned in accordance with Clause 1 (*b*) before the softening point is determined.

(*a*) *Boards.*

The softening point of the material shall be determined on a specimen of dimensions similar to those of the specimen employed in the Stiffness Test, Clause 11 (*a*). The specimen shall be set up for test in a manner similar to that described in Clause 11 (*a*).

A load equal to half the value of the load employed in the 18-hour test in Clause 11 (*a*) shall then be applied. The apparatus shall be arranged in a suitable heated chamber, the temperature of which shall be gradually increased at the rate of 10° C. per hour until the specimen fails completely. The initial temperature shall be as follows:—

(i) For Class I materials, 100° C.
(ii) For Class II materials, 60° C.

The deflection at each 5° C. increment of temperature shall be noted, and complete failure shall be deemed to have occurred when the rate of deflection of the specimen is seen to increase rapidly without appreciable increase of temperature.

(*b*) *Tubes.*

The softening point of the material shall be determined on a specimen of dimensions similar to those of the specimen employed in the Stiffness Test, Clause 11 (*b*). The specimen shall be set up for test in a manner similar to that described in Clause 11 (*b*).

A load equal to half the value of the load at which failure occurs in Clause 11 (*b*) shall be applied. The test shall then be carried out in the same manner as described in (*a*) above.

22. Effect of Vibration and Impact.

Note.—Methods of test are under consideration.

23. Effect of Electric Arc.

The specimen shall be conditioned in accordance with Clause 1 (*b*) before the test for the effect of electric arc is carried out.

The specimen shall consist of two strips of the material 6 inches long and 2 inches wide, which shall be clamped together with a piece of 0·036 inch diameter copper wire between them, laid centrally along their length.

The copper wire shall be fused by being connected across a 500-volt D.C. circuit in which there is a total non-inductive resistance of such a value as to limit the current to 100 amperes. The fuse may be short circuited by a switch whilst the current is being adjusted.

The test shall be repeated at intervals of two minutes until the carbonized surface of the material acts as a conductor and the arc does not extinguish itself. The number of times the copper wire can be fused before this state is reached and the condition of the surface of the material shall be stated.

Note.—This material is not of an arc-resisting character, and should not be used in service in such a manner that it will under normal conditions be exposed to an arc or flame.

Schedule.

When it is desired to study the materials covered by this Specification for specific purposes, and it is obviously unnecessary to apply the whole of the tests described in Section II, the abridged series of tests outlined in the Schedule on page 171 should be applied.

DIRECTIONS FOR THE STUDY OF VARNISHED COTTON CLOTH (EXCLUDING ADHESIVE TAPE).

[REPORT (REF. A/S7) RECEIVED FROM THE BRITISH ELECTRICAL AND ALLIED INDUSTRIES RESEARCH ASSOCIATION.]

CONTENTS.

PREFACE.

It has been found from experience that considerable differences exist in the electrical and mechanical properties of varnished cotton cloth supplied to electrical manufacturers from different sources. Hitherto it has been too commonly the practice to compare various samples of varnished cloth by a crude test for electric strength and perhaps a tensile strength test. It is clear that such tests by no means determine the relative merits of different samples with respect to their suitability for use in electrical machinery. This Specification has, therefore, been drafted, in which directions are given for a comprehensive study of the electrical and mechanical properties of varnished cloths with a view to the adoption by makers and users of uniform methods of test, and ensuring that the important properties of the material with respect to service conditions may be thoroughly investigated.

The ability of varnished cloth to withstand a relatively high alternating electric stress for a prolonged period without breakdown is of vital importance, but electric strength tests, as frequently carried out, are of little value towards securing this result. Appropriate tests will be found referred to in Clauses 10 and 11.

This Specification is not intended for use as a purchasing specification, but it is issued in the belief that it will lead to such improvements that all varnished cloth supplied to the electrical industry will be at least equal to the best now obtainable, and that there will be in time considerable further improvement.

With further experience in the use of the methods of test suggested herein, and after they have come into general use, the Association will be in a position to make recommendations to the British Engineering Standards Association for the issue of a Purchasing Specification for Varnished Cotton Cloth.

The Director of the E.R.A. will value comments and criticism from those who have occasion to use any of the tests given in this Specification.

I. DEFINITIONS.

(a) *Yarn.*

The term "yarn" denotes the spun cotton (see Clause 2).

(b) *Fabric.*

The term "fabric" denotes the woven yarn (see Clause 3).

(c) *Varnish.*

The term "varnish" denotes any substance, used alone or dissolved in a suitable solvent, that yields an insulating film when applied to the fabric.

(d) *Unvarnished.*

The term "unvarnished" denotes that the fabric has not been varnished or impregnated with insulating compounds, but embraces material which has been subjected to preparatory treatments such as those referred to in Clause 4.

(e) *Varnished.*

The term "varnished" denotes fabric that has been varnished or impregnated with insulating compounds.

(f) *Varnished Cloth.*

The term "varnished cloth" denotes the finished material suitable for use as a dielectric.

II. PREPARATION OF THE FABRIC BEFORE VARNISHING.

1. General.

The relative merits of various classes of cotton, various methods of spinning and weaving, and various treatments in manufacture before varnishing should be studied with respect to the electrical and mechanical properties and uniformity of the finished cloth.

2. Classification of Cotton.

The following classes of cotton should be investigated :

(*a*) Sea Island.
(*b*) Egyptian.
(*c*) American.
(*d*) Indian.

3. Spinning and Weaving.

The effect of the following should be ascertained :—

(*a*) Count of yarn.
(*b*) Twist of yarn.
(*c*) Type of weave.
(*d*) Closeness of weave.

4. Processes of Treatment during the Preparation of the Fabric.

The effect of the following processes should be ascertained :—

(*a*) Sizing.
(*b*) Bleaching.
(*c*) Parchmentising.
(*d*) Mercerising.
(*e*) Singeing.
(*f*) Dressing (nature and amount).
(*g*) Calendering.

5. Physical Tests on the Fabric before Varnishing.

Note.—The tests to be carried out on the fabric before varnishing will be given in another document.

III. VARNISH TREATMENT.

6. Classes of Varnish.

The relative merits of the following classes of varnish require investigation :—

(*a*) Oil, linseed or other drying oils.
(*b*) Oil and resin or gum resins.
(*c*) Shellac or other natural gums.
(*d*) Bituminous or asphaltic, including natural and artificial asphalt and pitches.
(*e*) Synthetic resins, of which phenol and formaldehyde condensation products are typical.

7. Method of Varnishing.

Note.—Instructions on the method to be employed in varnishing the fabric are under consideration.

IV. METHODS OF TEST.

When reporting the results of any test the thickness of the material, with the varnish removed, and the count of yarn, and number of threads per inch of warp and weft shall be stated.

8. Maturing of Varnished Cloth.

The varnished cloth shall be stored in a dry cool room, not artificially conditioned, for at least three months before the tests specified below are carried out.

9. Conditioning of Specimens for Test.

The varnished cloth shall be conditioned as described below.

(*a*) *"Normal" Condition.*

This is obtained by permitting the material to absorb its normal quantity of moisture by exposing it to an atmosphere of 75 per cent relative humidity at a temperature from 15° C. to 25° C. for 18 to 24 hours.

Note.—The specified relative humidity may be obtained by the use of a solution of sulphuric acid in water, specific gravity 1·223.

(*b*) *"Dry" Condition.*

This is obtained by removing from the material as much as possible of its free natural moisture, by heating it at a temperature from 75° C. to 80° C. for two to three hours.

(*c*) *"Damp" Condition.*

This is obtained by exposing the material to an atmosphere of not less than 95 per cent relative humidity at a temperature from 15° C. to 25° C. for 18 to 24 hours.

(*d*) *"Tropical" Condition (for use when required).*

This is obtained by exposing the material to an atmosphere of not less than 90 per cent relative humidity at a temperature from 45° C. to 50° C. for 18 to 24 hours.

(*e*) *"Recovered" Condition.*

This is obtained by heating the material at a temperature from 75° C. to 80° C. for 18 to 24 hours and subsequently exposing it to Normal Condition as in Clause 9 (*a*) for one week.

Note (i).—If in (*c*) or (*d*) the material is removed from the atmosphere of specified humidity before testing, precaution must be taken to prevent appreciable change in the condition of the material from this cause.

Note (ii).—When testing the electric strength of the material at the high temperatures the electrodes should be raised to the high temperature before the material is removed from the atmosphere of specified humidity.

10. Highest maintained Alternating Electric Stress.

The test shall be carried out in accordance with Technical Publication Ref. A/S2, Directions for Determining the Electric Strength of Fibrous Insulating Materials, Appendix II.

The test shall be carried out after the material has been conditioned as specified in Clause 9 (*a*), (*b*) and (*e*) of this Specification.

Under special circumstances the test shall also be carried out after the material has been conditioned as specified in Clause 9 (*c*) and (*d*) of this Specification.

11. Electric Strength.

The tests shall be carried out in accordance with Technical Publication Ref. A/S2, Directions for Determining the Electric Strength of Fibrous Insulating Materials, Part II, Abridged Tests.

The varnished cloth shall be tested under the states given in (*a*) and (*b*) below, at the temperatures specified in Ref. A/S2, Part II, Abridged Tests.

(*a*) *Test in Free State.*

The varnished cloth shall be tested in a free state, i.e. unstressed.

(*b*) *Test under Tension.*

The varnished cloth shall be tested in strips of convenient width whilst subjected to various values of tensile stress ranging from 0·5 to 1·5 lb. per mil thickness per inch width of strip. The load shall be maintained for 5 minutes before the electric stress is applied. The appearance of the varnish film when the electric stress is applied shall be stated.

Tests shall be carried out with the load applied in the direction of the warp, the weft and the bias at an angle of 45° respectively.

12. Tensile Strength.

The varnished cloth shall be brought to the normal condition as specified in Clause 9 (*a*), before the test for tensile strength is carried out.

Nine specimens shall be cut in such a manner as to be representative of the bulk of the cloth. Three specimens shall be cut in the direction of the warp, three in the direction of the weft and three on the bias at an angle of 45°. No two specimens cut in the same direction shall contain the same longitudinal threads.

The specimens shall be two inches wide and shall be placed evenly in the jaws of the testing machine so that the unstretched length of the cloth between the jaws is not less than 12 inches. The load shall be applied at a uniform rate and the time taken to reach the breaking load from the commencement of the application of the load shall be one minute. If the specimen breaks unevenly, or in or at the jaws, due to incorrect clamping, a duplicate test shall be carried out on another specimen including the same threads. The maximum, minimum and mean values of the three tests warp way, of the three tests weft way and of the three tests on the bias, respectively, shall be stated.

Tests shall be carried out at the following temperatures :—

20° C., 60° C., 90° C. and 120° C.

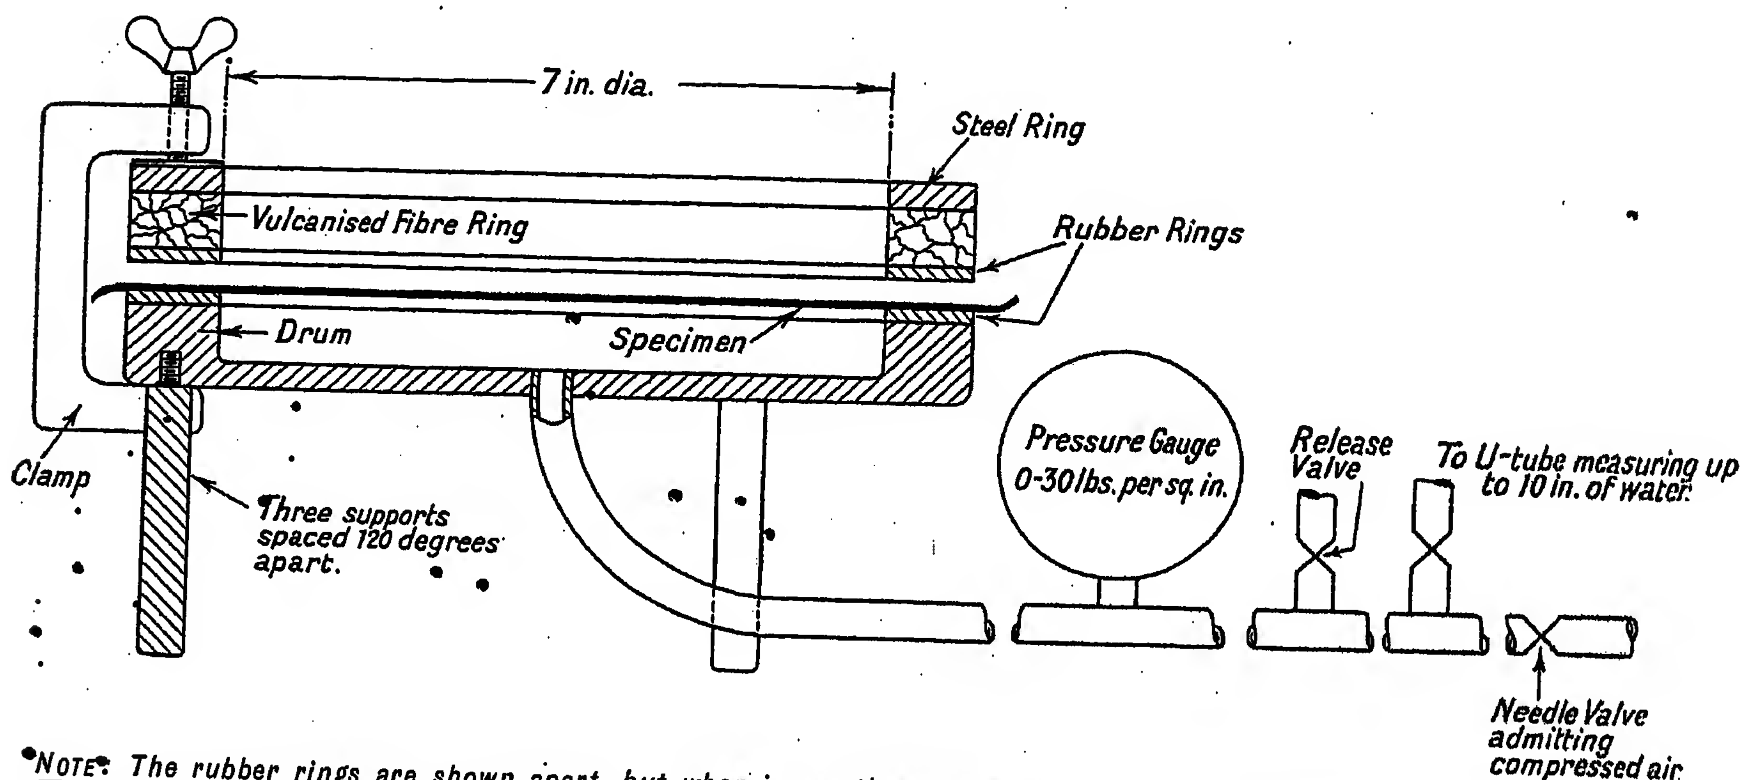
Note.—When testing at the high temperatures the specimen should be surrounded by a heated cylinder to maintain the required temperature.

13. Bursting Strength and Extensibility.

The bursting strength and extensibility shall be determined when the varnished cloth is in the Normal Condition as specified in Clause 9 (*a*).

The bursting strength test shall be carried out by means of the apparatus shown in Fig. 1 as follows :—

The varnished cloth shall be clamped between the



NOTE: *The rubber rings are shown apart, but when in use they are brought into contact with the specimen and fixed by clamps, one of which is shown in position.*

Fig. 1.—Apparatus for measuring the Bursting Strength of Varnished Cloth.

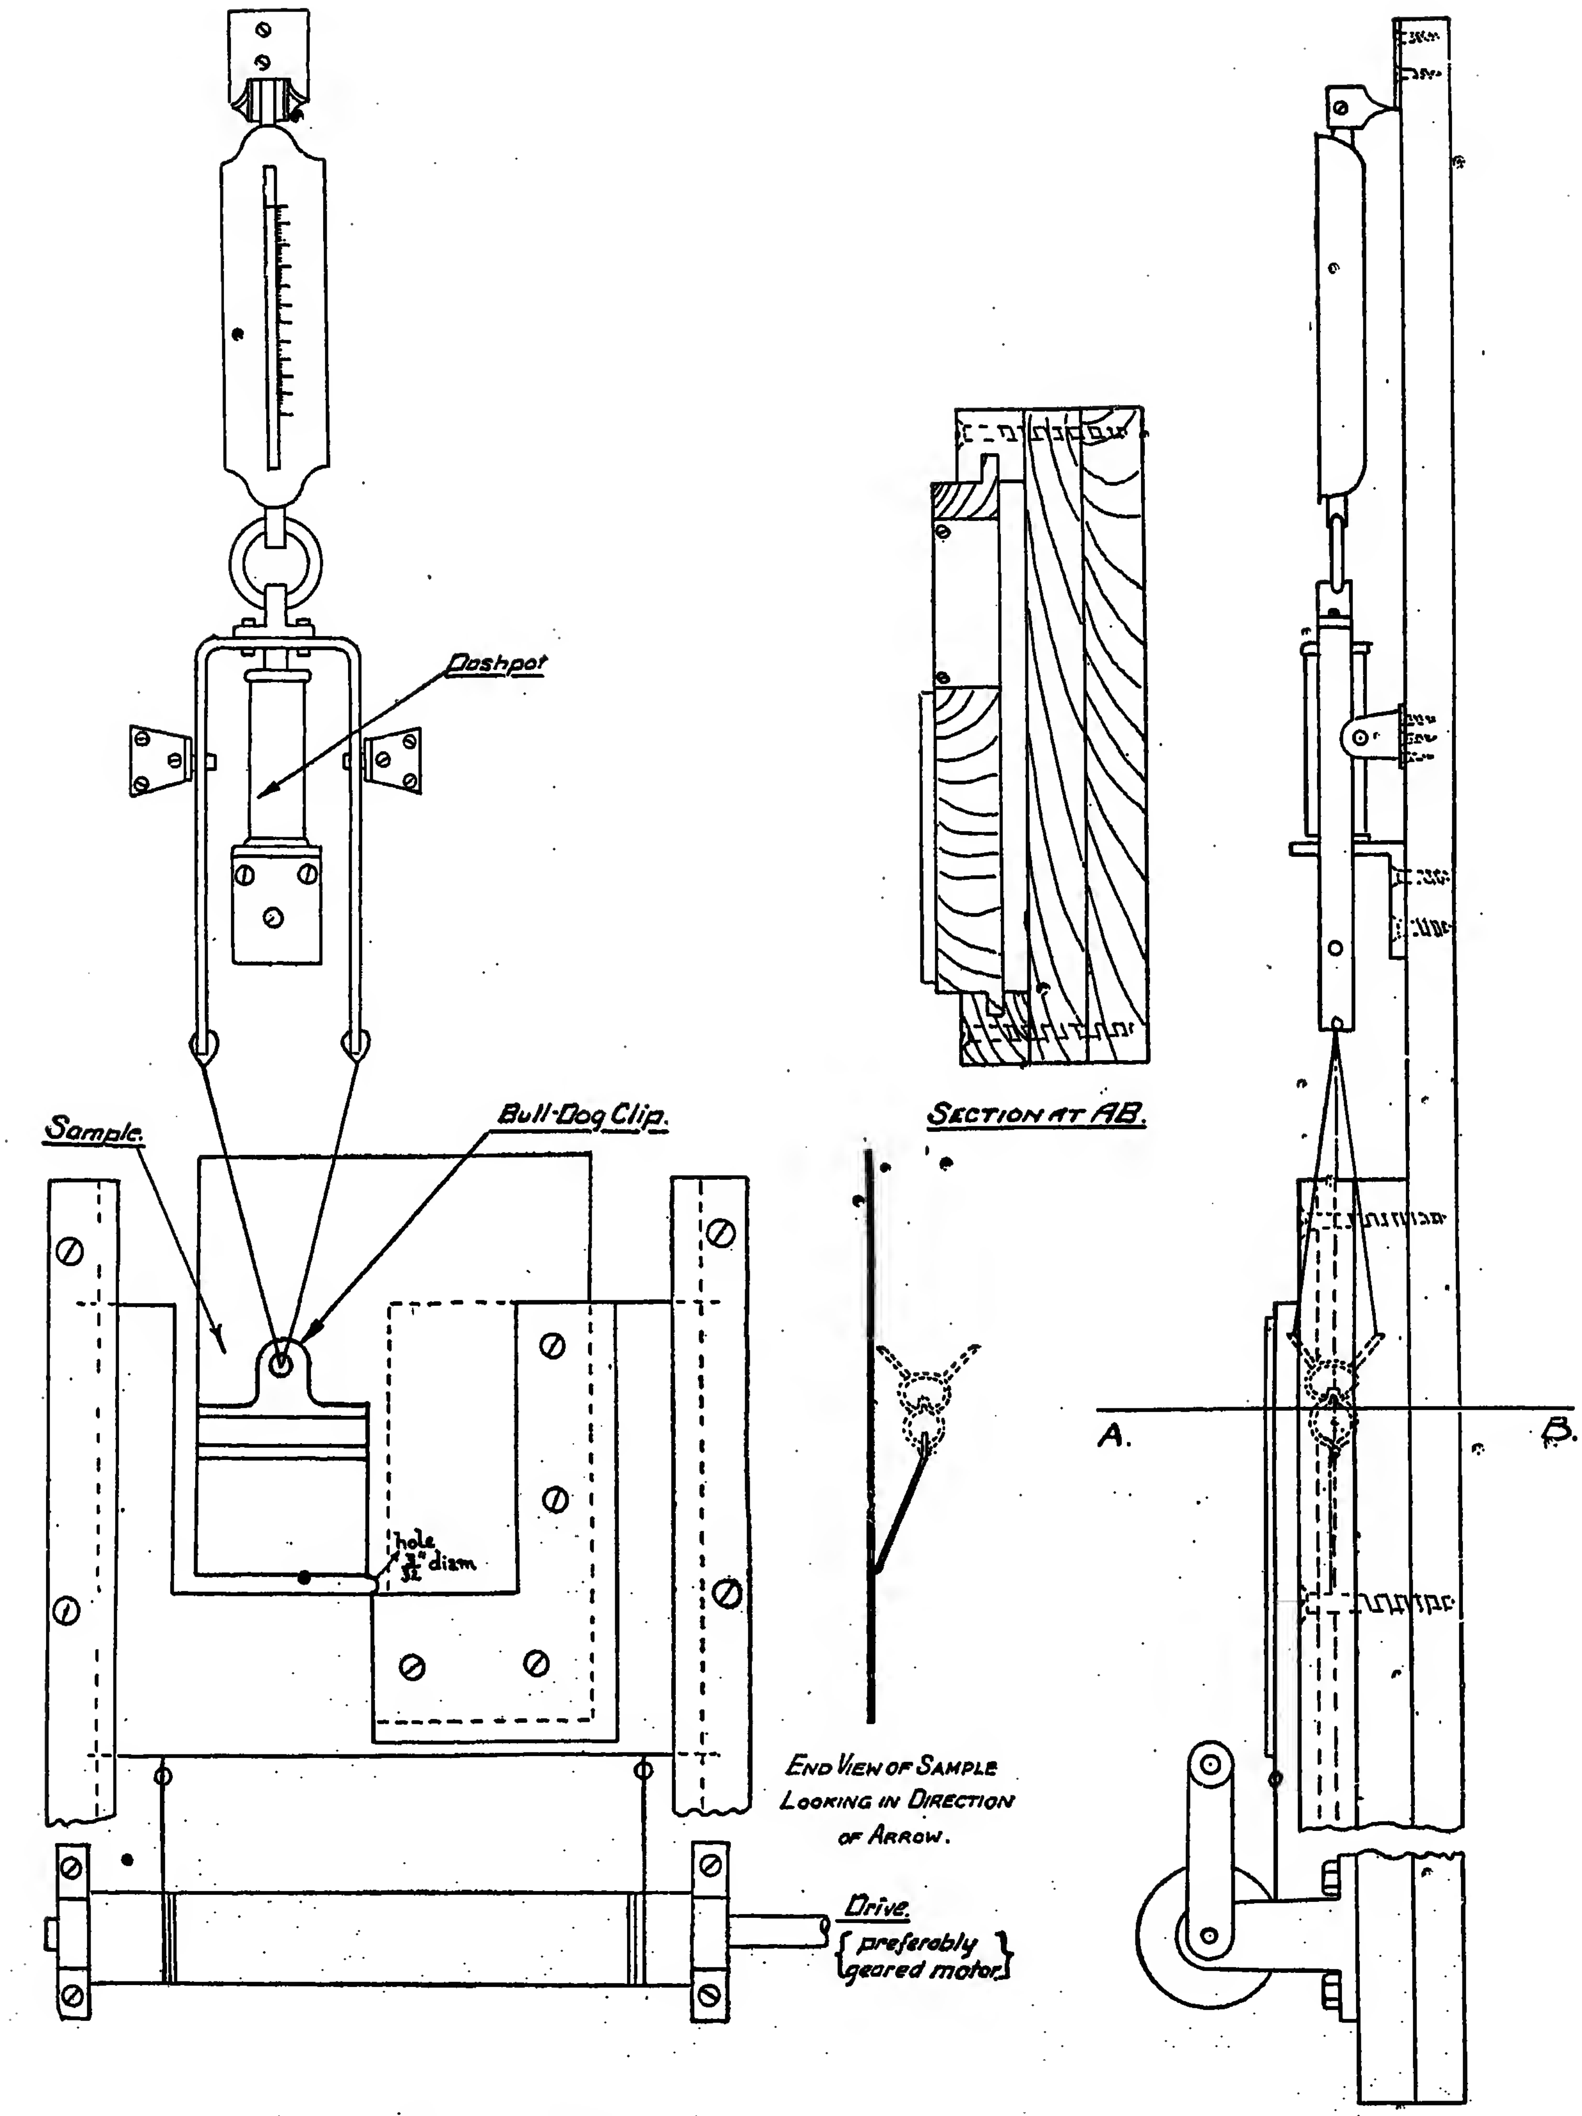


FIG. 2.—Apparatus for measuring the Tearing Strength of Varnished Cloth.

rubber insertion rings fitted on top of the drum so as to make an airtight joint. Air shall be pumped into the drum at such a rate that the pressure on the varnished cloth diaphragm is increased gradually at the rate of approximately 30 lb. per minute until failure occurs.

The test for extensibility shall be carried out on the apparatus shown in Fig. 1 as follows :—

The varnished cloth shall be clamped between the rubber rings as before. Air shall be pumped into the drum at such a rate that the radii of curvature of the varnished cloth diaphragm can be determined by means of a suitable spherometer. Sufficient readings shall be taken to enable a curve to be plotted showing the relationship between the air pressure and the radius of curvature of the diaphragm.

14. Tearing Strength.

The tearing strength shall be determined when the varnished cloth is in the Normal Condition as specified in Clause 9 (*a*).

The tearing strength test shall be carried out by means of the apparatus shown in Fig. 2 as follows :—

The resistance to tearing shall be proved by the load required to tear the varnished cloth commencing from a hole 3/32 inch diameter punched out of the cloth. The position of the hole and application of the load shall be as shown in Fig. 2.

The size of each separate specimen tested shall be 6 inches square.

(*a*) Three tests shall be made with the tear in the direction of the warp of the cloth. This shall be called the "Warp Tear Test."

(*b*) Three tests shall be made with the tear in the direction of the weft of the cloth. This shall be called the "Weft Tear Test."

The method of carrying out the tearing test shall be as follows :—

Prepare the varnished cloth specimen as shown in Fig. 2.

Swing the inverted L piece to the right.

Place the specimen in position, the punched hole being at the edge of the L piece as indicated.

Screw the L piece down. Bend over the cut piece and attach grip device—needle or clip—and secure to lower portion of balance.

Rotate the winding gear with steady movement at a rate of approximately 12 inches per minute until the 6-inch length is torn through. (A motor drive is recommended.)

Watch the balance and average the slightly varying values of the pull observed.

The maximum, minimum and mean values of the "warp" and "weft" tearing strengths respectively shall be stated.

15. Resistance of Varnish Film to Crushing.

The resistance of the varnish film to crushing shall be determined when the varnished cloth is in the Normal Condition as specified in Clause 9 (*a*).

The pressure required to damage the varnish film shall be ascertained by the following test, observation being made by visual inspection, assisted, if necessary, by a magnifying glass :—

The varnished cloth shall be compressed between a smooth metal plate and adjacent steel balls 1/8 inch diameter.

16. Ageing.

The tendency of the varnished cloth to deteriorate with age shall be determined by the change in the bursting strength after it has been heated at a temperature from 90° C. to 95° C. for four weeks.

Bursting strength tests shall be carried out as specified in Clause 13 as soon as the temperature of the specimen has fallen to 20° C. (± 5° C.), and also after the varnished cloth has been exposed to Normal Condition (Clause 9 (*a*)) for one week.

17. Resistance to Oil.

The varnished cloth shall be immersed in transformer oil, complying with British Standard Specification No. 148 for light grade oil, at a temperature from 115° C. to 120° C. for seven days, and the effect on the varnished film shall be stated.

18. Determination of Thickness.

The thickness of the varnished cloth shall be measured by means of a suitable micrometer.

Note.—In general, more reliable values of thickness can be obtained by measuring (say) 10 thicknesses and dividing the result by 10.

The average thickness of the varnished cloth shall be determined as follows :—

In the case of rolls, a test piece one foot long and the full width of the roll shall be taken sufficiently far from the end as to be representative of the bulk of the cloth. Ten measurements of thickness equally spaced diagonally across the test piece shall be made.

In the case of sheets, ten measurements of thickness equally spaced diagonally across the sheet shall be made.

The maximum, minimum and mean values of the thickness shall be stated.

19. Determination of Density.

The density shall be expressed in terms of weight in grammes per square metre. The varnished cloth shall be weighed in the Normal Condition as specified in Clause 9 (*a*).

DISCUSSION ON

"THE NATURE OF THE MAGNETIC FIELD PRODUCED BY THE STATOR OF A THREE-PHASE INDUCTION MOTOR." *

Dr. A. E. Clayton (*communicated*): The nature of the magnetic field produced by the armature windings of alternating-current machines is of importance, not merely in so far as it concerns induction motors, but with alternating-current machinery generally. It is not surprising, therefore, to find that the subject has attracted much attention during recent years.

Nomenclature.—The author raises the question—and it is important—of nomenclature. In this connection I have found it a great help, in dealing with all types of windings, to make use of the term "coil span" in cases where, apparently, the author would use "coil pitch." The term "coil pitch" may then be reserved to indicate the actual displacement between successive coils, the term thus having a meaning corresponding exactly to such terms as pole pitch, rivet pitch, and so on. Thus, for example, in the case of a commutator winding as in Fig. A, instead of using the terms "back

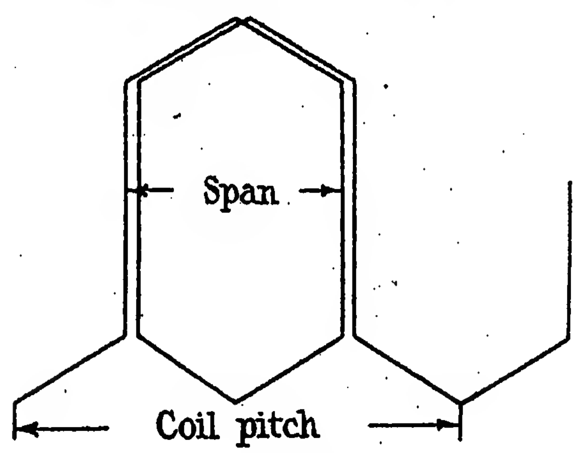

FIG. A.

pitch," "front pitch" and "total pitch," it only becomes necessary to use "coil span" and "coil pitch" as indicated in the figure. There is much to be said for this method, and as the effects of coil "span" and coil "pitch" are essentially different, it is a convenience to denote them by different terms. For example, with direct-current windings the pitch, as above defined, determines entirely the *type* of winding—simple lap, wave, etc. The coil span has no influence whatever upon the type of winding, but simply determines its suitability for any particular number of poles. This may be illustrated by the case of, say, a 39-slot, 4-pole, direct-current wave-wound armature having 117 commutator segments and armature coils. If the coil pitch, as above defined, is 58, the winding will form a two-circuit, simple wave winding for all values of the coil span, whether it be 8, 9, 10 or 11, etc., teeth. Incidentally, it may be noted that whereas it is necessary to express the coil pitch—or, what amounts to the same, the commutator pitch—in terms of the number of coils or commutator segments, the coil span is often best expressed as the number of teeth spanned by the coil. Similarly, with alternating-current windings it is the displacement between successive coils in the same series circuit which determines the nature of the winding. Thus, with 12 coils equally spaced around an armature and connected in series so as to carry current in the same direction, a 24-pole arrangement is formed quite irrespective of the value of the span—or, for that matter, of the spread—of the individual coils. The span of the coil simply determines the effectiveness of the coil for the particular number of poles for which the winding is suitable. To obtain maximum effect, the coil span must be an exact pole pitch, or some odd multiple of that amount. The term "full-pitch coil" has long been in use and, to my mind, is quite definite in indicating a coil which spans an exact pole pitch. In addition, to indicate a coil which does not span an exact pole pitch, the term "fractional-pitch coil" is much used; alternatively, the coil is often said to be "chorded." These terms all seem to me to be good, as they indicate definitely the feature characteristic of the coil. In the case of complete windings of the two-layer lattice type the terms "full-pitch winding" and "fractional-pitch winding" can at once be applied without any possibility of confusion to the cases where the individual coil spans an exact pole pitch or a fraction of the pole pitch, respectively. But with single-layer windings there is, as pointed out by the author, a possibility of confusion arising from the use of these terms in the case of windings of the "half-coiled" type, since the mean span of the component coils is then rather less than a pole pitch for the windings commonly referred to as "full-pitch." All difficulty can be removed if the winding is regarded as having a number of phases equal to the number of complete coils per pair of poles, as indeed is only logical. Thus a three-phase half-coiled winding is in reality a six-phase winding, and for the normal case of a concentric single-layer winding, the six-phase winding is slightly chorded. For analytical purposes I have found a great simplification to be possible by thus treating a winding having N coils per pair of poles as a symmetrical N-phase winding. But for normal commercial purposes it is naturally more convenient to regard a winding as having the same number of phases as the currents supplied to or by it, and it becomes necessary to consider the spacing of the actual conductors rather than the actual span of the component coils. Even in this case, however, I do not think that there is any difficulty in explaining what is meant by a full-pitch winding. A drawback to the use of the term "normal distribution" arises from the fact that it becomes necessary to explain what is meant by normal. If we regard the arrangement of the conductors in a twelve-phase, or a nine-

* Paper by Mr. F. J. Teago (see vol. 61, page 1087).

phase, or a six-phase synchronous converter as being normal, then that commonly used for three-phase machines must be regarded as abnormal. Or if the usual three-phase stator winding is regarded as normal, then all of the other cases must be considered to be abnormal. The term "super distribution" has, I think, but little to commend it, but that may be due to prejudice consequent upon the modern abuse of the word "super."

Reduction factor and chording factor.—The author correctly points out that the breadth factors in common use for E.M.F. calculations are numerically equal to the factors which he calls reduction factors for M.M.F. calculations. That being so, there appears to be no need to call them breadth factors in the one case and reduction factors in the other. I fail to see why the author, instead of evaluating the simple and well-known expression $(\sin \frac{1}{2}nm\psi)/(m \sin \frac{1}{2}n\psi)$, expresses the value of the coefficient as a series of cosines. When the number of slots per pole is large the waste of labour thereby caused is very considerable. With chorded windings it is simply necessary to introduce a chording factor numerically equal to the sine of half the angle spanned by the "coil," the angle being expressed in electrical measure to correspond to the particular harmonic under investigation.

Harmonics in supply current.—There are one or two minor points in the paper to which reference may be made. It is not quite correct to state, as on page 1087, that the harmonics are due to the windings being contained in slots; important higher harmonics will be present with surface windings. Again, in order that harmonics of the third order shall be absent from the resulting M.M.F., with a three-phase winding it is not necessary that the supply current shall be sinusoidal. These particular M.M.F. harmonics will disappear for all current wave-shapes other than those which contain harmonics of the third order.

Ratio of iron losses and magnetizing currents.—In comparing the performance of a particular induction motor as a 2-pole and as a 4-pole machine the author appears to omit one very important factor. He appears to neglect the effect of the armature core. As shown by the author, the ratio of the air-gap densities, neglecting leakage, for 4-pole and for 2-pole working is 1·46. This ratio is not in itself a complete criterion. It is necessary also to consider the ratio of the actual total flux per pole for 4-pole and for 2-pole working. In spite of the reduced air-gap density, the flux per pole with 2-pole connections will be 1·37 times as great as for 4-pole working. The relative values of the magnetizing current, and of the iron losses, for the two methods of connection will therefore depend entirely upon the degree of saturation in the teeth and in the core, and approximations which omit the effect of the core are not likely to be of much value.

Crawling.—In connection with Section 6 of the paper, it is perfectly true that saturation will cause increased fringing and round off the corners of the steps in the M.M.F. wave. Whether this will cause a reduced tendency to crawl depends entirely upon the number of slots per pole, as the spacing ripple harmonics may not be of orders likely to cause crawling. In the great majority of cases these ripple harmonics are of much higher orders than would cause trouble. On the other hand, saturation may introduce into the field form harmonics of low orders, which are quite unimportant in the unsaturated condition. For the case cited by the author, the evidence quoted in the paper fails to support his view that crawling on 2-pole connections is due to the reduction in the flux density in the air-gap. For he states that there is no tendency to crawl with 4-pole connections at half normal voltage. Under these latter conditions the flux density in the gap is much less than with 2-pole connections. With 2-pole connections crawling would appear to be due to the fact that the seventh harmonic in the M.M.F. distribution is far more pronounced than with 4-pole connections. On pages 1092 and 1094 the author appears to imply that crawling may be established by the fifth harmonic in the M.M.F. distribution, and suggests that it may be desirable to eliminate the effects of this particular harmonic. It does not seem to me that any tendency to crawl will be established by the fifth harmonic, for the resulting M.M.F. due to this particular harmonic rotates in an opposite direction to that due to the fundamental. As a result there will be a small braking action due to this harmonic, decreasing slightly as the motor speeds up, but it does not appear to me that there will be any tendency for the fifth harmonic to establish a definite crawling speed. The seventh harmonic gives rise to a field rotating in the same direction as the fundamental, and causes a pronounced "ripple" to occur in the graph representing the running-up torque plotted in terms of the speed. The crest of this ripple occurs at a speed rather less than one-seventh of normal synchronism, and the trough at a speed somewhat higher than this amount. Normally, the speed at which the motor may crawl will then be slightly in excess of one-seventh of synchronous speed. With two-phase machines, trouble may be expected from the fifth harmonic, as in this case the corresponding resulting field rotates in the same direction as that due to the fundamental.

Mr. F. J. Teago (*in reply*):

Nomenclature.—I quite agree with Dr. Clayton that it would have been better if I had used the term "coil span" rather than "coil pitch," because, as he points out, coil pitch is a most appropriate name for what is usually termed "coil creep." I do not, however, agree that full pitch, fractional pitch, chorded, etc., are definite terms, for the following reason: Alterations in the pitch, or span as it should be called, are made for very definite reasons and if such alterations fail to produce the desired results then the alterations in the span are not real. In alternating-current work, short spans are mainly used to eliminate harmonics. Figs. 4 and 7 (single and two-layer windings respectively) in my paper have, by all appearances, the right to be called short span, since the two sides of any one coil do not span one pole pitch, but with regard to the harmonics they produce in their M.M.F. curves they are identical with full-span coils. The problem then is what to call them. Geometrically they are short span. Electrically they are full span. I have tried to compromise by calling both normally distributed windings.

This suits both admirably, since "normal" distribution is one in which no slots containing conductors of any other phase are introduced between the slots containing the conductors of the phase under consideration. As Dr. Clayton points out, the terms "normal" distribution and "super" distribution may not be suitable for all classes of machinery, but for open-coil windings such as are used on alternators and induction motors they appear to have much to recommend them. Whatever the span of the coils, there is no change electrically from full-span coils unless the span is such as to cause the distribution to change from "normal" to "super."

Reduction factor.—I do not necessarily intend to imply that the expression $(\sin \frac{1}{2}nm\psi)/(m \sin \frac{1}{2}n\psi)$ should always be evaluated from its component parts (Table 1), but to be able to express any formula in its component parts is invaluable when one wants to ascertain the effect of a departure from the normal. Thus the component parts of the expression for any winding scheme of the types described can be readily written down as a trigonometrical series; some are given on pages 1092 and 1093, and have the advantage that the chording factor, as Dr. Clayton describes it, will be included.

Chording factor.—Dr. Clayton's remark, that the chording factor is numerically equal to the sine of half the electrical angle spanned by the coil, wants qualifying. Provided that the span alters the distribution and in the case of the two larger windings in Figs. 8 and 9, it is true, but occasionally the sign as well as the magnitude is required to be correct, so that it is much

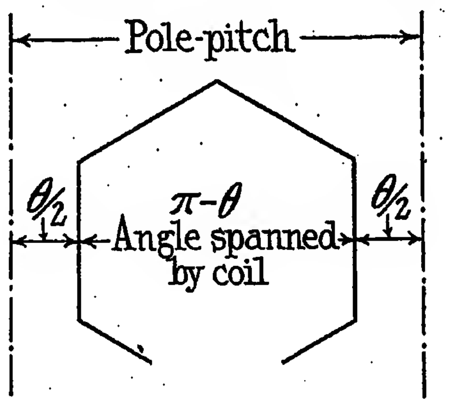

FIG. B.

better to use $\cos \frac{1}{2}n\theta$ than $\sin \frac{1}{2}n(\pi - \theta)$ (see Fig. B). For $n = 7$ and Fig. 9 (page 1091)

$$\cos \tfrac{1}{2}n\theta = \cos 210° = -\ 0{\cdot}866$$
$$\cos \tfrac{1}{2}\sigma n\psi = \cos 210° = -\ 0{\cdot}866$$
$$\sin \tfrac{1}{2}n(\pi - \theta) = \sin 420° = +\ 0{\cdot}866$$

This latter one is evidently wrong for sign. (See also Table 4, where the chording factor for the seventh harmonic is evidently negative.)

However, the expression $\cos \frac{1}{2}\sigma n\psi$, which I have suggested is correct both for sign and magnitude, also has the advantage that no mistake is likely to be made with windings which are apparently short span but not really so, since in these cases there is no super distribution, so that σ = zero and the chording factor $= 1{\cdot}0$. In the case of single-layer windings the chording factor is not, either in sign or magnitude, equal to the sine of half the electrical angle spanned by the coil. It is given by $(\cos \frac{1}{2}n\theta)/(\cos \frac{1}{2}n\psi)$ and is affected by both the span of the coil and the angle between successive slots. It is also given by $[\cos (\xi + 1)\frac{1}{2}n\psi]/(\cos \frac{1}{2}n\psi)$. This form, again, is not likely to cause mistakes, since where there is no super distribution ξ = zero and the chording factor $= 1{\cdot}0$.

Harmonics in supply current.—I quite agree with Dr. Clayton that harmonics would be present even with a surface winding, but this does not make my statement incorrect; it merely broadens it. Dr. Clayton is also quite correct in pointing out that, in reality, only the third harmonic need be absent from the supply current in order to suppress the third harmonic in the M.M.F. curve, but, again, this only broadens my statement. My chief aim is to prevent the idea that the supply current is producing the particular harmonics under consideration. However, if harmonics are present in the supply current then the system of waves of M.M.F. may contain stationary as well as rotating components of a complex character, the effect of which has not been included within the scope of the present paper.

Ratio of iron losses and magnetizing currents.—Dr. Clayton has evidently misread page 1095. I have not attempted to imply that if $\beta_4/\beta_2 = 1{\cdot}46$ then the ratio W_4/W_2 should be expected to equal $1{\cdot}46$, but for some reason is equal to $1{\cdot}6$. If $\beta_4/\beta_2 = 1{\cdot}46$, then the corresponding value of W_4/W_2 obviously depends upon the actual values of β_4 and β_2, since the curve connecting iron loss and β is not linear. I do not know the actual values of β_4 and β_2, but from iron-loss curves and probable values of the densities, I should have expected W_4/W_2 to be greater than $1{\cdot}6$. In obtaining the ratio of the magnetizing currents, I think Dr. Clayton must admit that I have at least made some allowance for the core and not neglected it as he suggests. My percentage allowances may not be strictly correct, but they are of the order one would expect, knowing the ratio β_4/β_2 and the probable, but not the actual, values of β_4 and β_2.

Flux density and crawling.—At half normal voltage, with the 4-pole connection, the density in the gap is $0{\cdot}73$ times that with full voltage and the 2-pole connection, so that if the reduction factors in Table 5 are assumed to be correct for the 4-pole case, they are on the high side for the 2-pole case; but the lower the density in the 2-pole case the more nearly are they correct. The crux of the matter is not the ratio of the gap densities but whether the density in the 2-pole case is low enough to cause the reduction factors to be sensibly as set out in Table 5.

Fifth harmonic.—I do not mean to imply that the fifth harmonic will establish a definite crawling speed, but the fifth harmonic has an influence on the tendency of the motor to crawl, as has been pointed out by Prof. J. K. Catterson-Smith in the paper referred to at the foot of page 1088. In conclusion, I am indebted to Dr. Clayton for his criticism, since it is apparent that parts of the paper have been so condensed that wrong conclusions may be drawn from the text, and it is only by the valuable aid of those who are prepared to study a paper in detail that the doubtful points are cleared up.

PERIODIC TRIGGER RECEPTION.

By E. V. Appleton, M.A., D.Sc., and F. S. Thompson, B.A., Royal Corps of Signals.

(*Paper received 26th September, and read before the* Wireless Section *21st November*, 1923.)

Summary.

The phenomenon of oscillation hysteresis exhibited by simple triode generators is discussed theoretically. A practical method of reception in which this phenomenon is utilized in a periodic manner is described. This method, which for convenience may be termed "periodic trigger reception," is suitable for continuous-wave and spark signals.

A low-frequency electromotive force is introduced in the grid circuit of a simple triode oscillator in such a way that high-frequency oscillations are not produced in the absence of an incoming signal. A small signal of high frequency is, however, sufficient to produce a train of free oscillations once every low-frequency cycle. Such free oscillations are rectified by the triode, and a signal of the impressed low frequency is heard in the receiver telephones.

The system differs fundamentally from the Armstrong super-regenerative receiver in the following respects:—

(*a*) The ordinary oscillation-hysteresis characteristic is followed in a "quasi-stationary" manner;

(*b*) No self-oscillations are produced in the system in the absence of an incoming signal; and

(*c*) The amplitude of the telephone signal is practically independent of the amplitude of the incoming signal and not proportional to it as in super-regenerative receivers.

It has been discovered experimentally that oscillations may be maintained in a simple triode generator with extreme negative grid potentials such as would cut off the anode current entirely under normal conditions. A simple theory for the conditions necessary for such maintenance is given. An oscillator of this type is very efficient in that anode and grid currents are only permitted to flow for a very small part of the cycle.

It is now becoming more and more generally recognized that, in order to account satisfactorily for the behaviour of many modern wireless circuits, proper account must be taken of the non-uniform conductances of the triodes used. Indeed, in many cases, no explanation at all, however approximate, is possible unless the non-linear nature of the triode characteristics is recognized. Various examples of this may be mentioned. Some time ago Dr. van der Pol and one of the present authors * found that, for a triode generator, there was often a pronounced difference between the limiting conditions for the starting and stopping of free oscillations. This difference was accounted for by the peculiar shape of the triode characteristics for the particular conditions used. An explanation of such a phenomenon in terms of straight characteristics is obviously impossible. The non-linear theory was also applied by Dr. van der Pol † to account for the discontinuities in phase and frequency which are encountered in coupled-circuit transmitters. Later one of the present authors * showed how a similar theory accounted for the main features of the synchronization phenomena met with when two triode assemblies with mutual interaction are adjusted so as to be nearly in resonance.

The above examples are cases of free oscillations, but similar phenomena are met with in cases of forced oscillations. For example, in continuous-wave reception by the auto-heterodyne method it is very often noted that there is a "silent interval" of receiver frequency in the region of resonance, within which no signal is heard. Such a phenomenon has been explained † in terms of the non-linear characteristics of the triode, and it has been shown that in such a case the presence of forced vibrations of amplitude greater than a certain critical value, due to the signal, automatically suppress the free vibration so that no beats occur and no combination tone is heard in the receiver telephone. Another interesting example of forced vibrations in a non-linear system has recently been described by E. H. Armstrong,‡ who has shown that a triode assembly may often be made more sensitive as a receiver of high-frequency oscillations if there is present in the system another forced vibration of quite different and uncorrelated frequency. In attempting to explain the action of the circuits described by Armstrong, one of the present authors found a non-linear triode system in which the interaction of the forced vibrations is such that the amplitude of one vibration is increased by the presence of the other, and it is with this scheme that the present paper deals. At first the mistake was made of concluding that such a scheme was necessarily the same as Armstrong's, but a practical investigation of the method (which for convenience may be termed the "periodic trigger" method), together with a closer examination of Armstrong's super-regenerative circuits, has shown that, while both methods depend on the interaction of two forced vibrations, there are many essential and fundamental differences between them. Such differences will be mentioned later in the paper.

The method of reception to be described is based on the difference (mentioned above) between the conditions for the building up of triode oscillations from an infinitesimally small amplitude and the conditions for the maintenance of an oscillation already existing. In this respect it is somewhat analogous to the trigger

relay described by L. B. Turner.* We shall therefore preface our account of some of the practical points connected with the working of this method with a short theoretical account of the fundamental points underlying trigger action in general.

Let us consider the case of the simple oscillator circuit shown in Fig. 1. For this circuit it is well known that, if the mutual inductance M between the coils L_1 and L_2 is of the correct sense, and is gradually increased from a low value, oscillations are spontaneously produced when M reaches a certain critical value. This value is given by the equation †

$$aM = -\left(RC_1 + \frac{bM^2}{L_1}\right) \quad . \quad . \quad . \quad . \quad (1)$$

where R and C_1 are respectively the resistance and capacity of the oscillatory circuit, and a and b are respectively the mutual conductance and the anode conductance of the triode. In most practical cases the second term on the right-hand side of Equation (1) is small compared with the first, so that the numerical critical value of the mutual inductance is given by

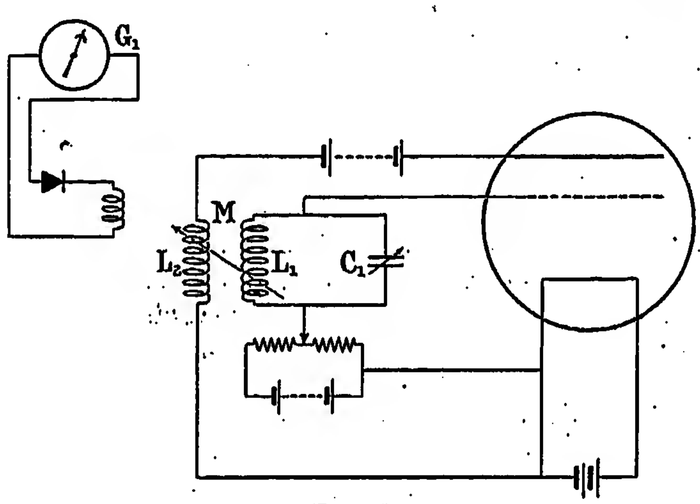

Fig. 1.

$$M = \frac{RC_1}{a} \quad . \quad . \quad . \quad . \quad . \quad . \quad (2)$$

Let us now consider the effect of varying the steady grid potential of the oscillator by means of the potentiometer shown in Fig. 1, and, in connection with this, let us imagine that the foot of the grid-voltage/anode-current characteristic of the triode is as illustrated in Fig. 2.

It is clear that oscillations will not start if the representative point of grid potential is to the left of − 8 volts, in which case no anode current flows. Oscillations are, however, spontaneously produced if the representative point is moved to the right of this value to a point such that the slope of the curve is equal to a, as defined by Equation (2). We thus know precisely the conditions for the starting of oscillations.

Let us now assume that the representative point is fixed first at − 20 volts by means of the potentiometer, and, further, let us assume that a large oscillation is temporarily induced in the oscillator so that the representative point now oscillates for a few periods about its new zero. It is clear that the induced oscillations will not be maintained if this induced voltage is insufficient to take the representative point into the region of finite anode current. But if the oscillatory grid potential is of sufficiently large amplitude, such as is illustrated by the sine curve below the characteristic shown in Fig. 2, there is the possibility that the anode current-changes may be such as to assist in maintaining the oscillations with constant amplitude. The conditions for this may be stated fairly precisely.

Let the induced oscillatory grid potential v be expressed by $v = A \sin \omega t$, where $\omega^2 = 1/(L_1C_1)$ (see Figs. 1 and 2). Then once every cycle the anode current will flow for a time. Let the fundamental component of these periodic anode-current changes be represented by ${}_1i_a$. Such an alternating component of anode current will produce by induction via M an electromotive force of magnitude $M\omega{}_1i_a$ in the oscillatory circuit. This electromotive force acting at resonance

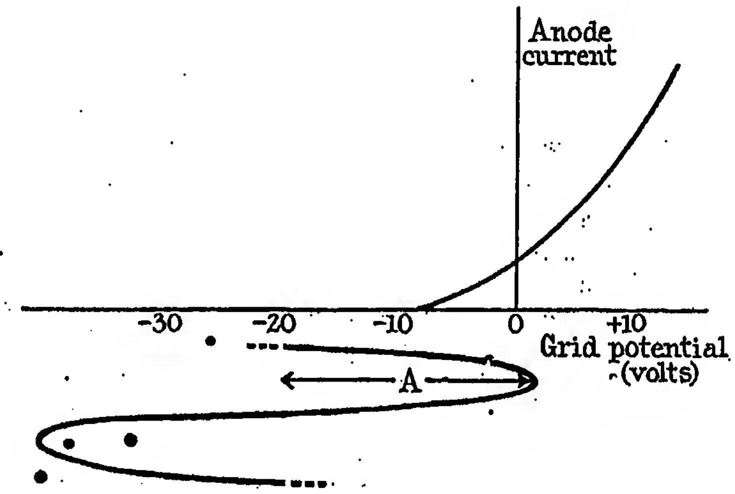

Fig. 2.

on the oscillatory circuit L_1C_1 (see Fig. 1) will, in itself, produce an alternating grid potential of maximum amplitude $M{}_1i_a/(RC_1)$, and a little consideration shows that this amplitude is in phase with the original grid potential-changes if M is of negative sign. We thus see that the oscillation of amplitude A is maintained if the result is equal to the cause, or if

$$A = \frac{M{}_1i_a}{RC_1} \quad . \quad . \quad . \quad . \quad . \quad . \quad (3)$$

The above explanation may perhaps be put a little more precisely as follows. With reference to Fig. 1 let us assume that Q is the charge on the oscillatory circuit condenser at any instant. We then have, as the expression of the electromotive forces in the circuit,

$$L_1\frac{d^2Q}{dt^2} + R\frac{dQ}{dt} + \frac{Q}{C_1} = -M\frac{di_a}{dt} \quad . \quad . \quad (4)$$

where i_a is the anode current and t is the time. Let us now write *

$$i_a = \phi(v) = \phi\left(\frac{Q}{C_1}\right) = av + \beta v^2 + \gamma v^3 + \delta v^4 + \epsilon v^5 \quad (5)$$

* British Patent No. 130408.

† Appleton: *Philosophical Magazine*, 1919, vol. 37, p. 134; and *Proceedings of the Physical Society*, 1921, vol. 33, pt. 2.

* We have here assumed, for simplicity, that the anode current is mainly controlled by the grid potential, and we have thus neglected the effect of change of anode potential due to induction between the coils L_1 and L_2 in Fig. 1.

where v is the departure of the grid potential from its stationary value and α, β, etc., are constants. Equation (4) thus becomes

$$\frac{d^2v}{dt^2}+\left[\frac{R}{L_1}+\frac{M\phi'(v)}{L_1C_1}\right]\frac{dv}{dt}+\omega^2v=0 \quad . \quad . \quad (6)$$

where ω^2 has been written for $1/(C_1L_1)$.

An approximate solution of an equation similar to (6) has been previously given,* so that only the final results of the solution need be stated here.

It may be shown that, if M is of negative sign and a solution of the type $v=a\sin\omega t$ is assumed, the possible stationary amplitudes are given by the real roots of

$$\left(\frac{RC_1}{M}-\alpha\right)a^2-\tfrac{3}{4}\gamma a^4-\tfrac{5}{8}\epsilon a^6=0 \quad . \quad . \quad (7)$$

These roots may be written

$$a_1^2=0$$

$$a_2^2=-P-\sqrt{(P^2-N)}$$

and $$a_3^2=-P+\sqrt{(P^2-N)}$$

where $P=\frac{3}{5}\gamma/\epsilon$ and $N=-(8/5\epsilon)[(RC_1/M)-\alpha]$, and the square roots are taken as having a positive real part. But such amplitudes, though possible, are not necessarily stable, and a criterion of stability is necessary for each of the three amplitudes given by (7).† These are respectively:—

$$\text{For } a_1;\ \left(\frac{RC_1}{M}-\alpha\right)>0$$

$$\text{For } a_2;\qquad \epsilon a_2^2>0$$

$$\text{For } a_3;\qquad -\epsilon a_3^2>0$$

We thus see that if $[(RC_1/M)-\alpha]$ and γ are positive and ϵ is negative,‡ oscillation hysteresis is possible in that the zero amplitude, a_1, is stable, as is also the finite amplitude a_3, while between the two an unstable amplitude of value a_2 is to be found. This unstable amplitude is really the "threshold" value, in that a temporarily induced amplitude greater than this value will automatically build up to the stable value a_3. One less than this value will finally reach the stable zero value a_1. The triode system is thus in a stable condition when not oscillating and when oscillating with amplitude a_3.

We thus see that the whole question of oscillation hysteresis and trigger action is definitely attributable to the shape of the triode characteristic and is not dependent on the presence of gaseous ionization in the triode, as has sometimes been supposed.

The relation between the above theoretical considerations and the practical working of the proposed method of reception may best be illustrated by what, for convenience, may be termed the oscillation-hysteresis (or "backlash") characteristic of a simple triode oscillator. This is obtained by plotting the relation between the current in the oscillatory circuit and the grid potential as controlled by a grid potentiometer. The circuit used for determining this relation is shown in Fig. 1, while a typical example of the results obtained for a standard "R" triode is exhibited in Fig. 3 (a).

The circuit of Fig. 1 is seen to be a simple oscillator to which is weakly coupled a detecting coil in series with a crystal detector and sensitive galvanometer, G_1. The grid potential is continuously variable by means of a potentiometer consisting of cells and a non-inductive resistance, and is calculable from a knowledge of the resistance and the grid battery voltage. The relation between the galvanometer readings (which are proportional to the square of the oscillatory current) and the grid potential is shown in Fig. 3 (a) together with the ordinary grid-potential/anode-current characteristic of the triode. It will be seen that on starting with a large negative grid potential (e.g. -35 volts) and reducing this gradually, oscillations do not start

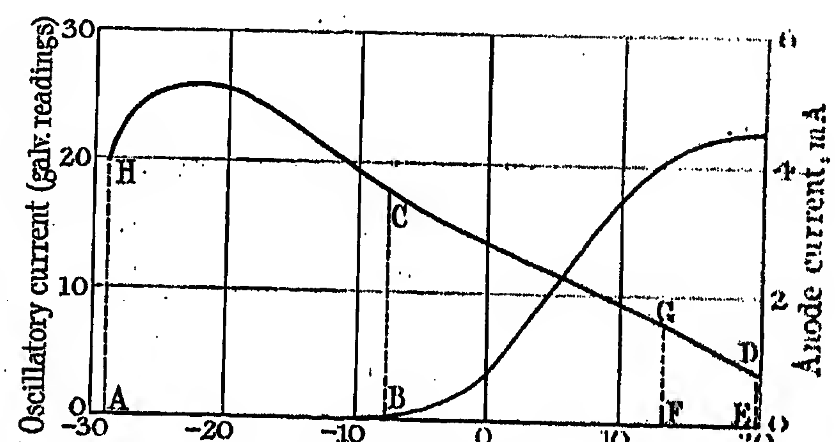

FIG. 3 (a).

until conditions represented by the foot of the ordinary static characteristic are reached (e.g. at $-7\cdot8$ volts), when an oscillation suddenly starts. Reducing the negative grid potential to zero causes this high-frequency oscillation to diminish somewhat in amplitude, but the grid potential must be increased to $+20$ volts before the oscillation finally and suddenly ceases. On now retracing these grid potential-changes the system remains in the non-oscillating condition until the grid potential becomes $+13\cdot2$ volts, when oscillations suddenly start again. On reducing the potential still further the old part of the curve is retraced, but now the grid potential must be made -29 volts before the oscillations can be finally stopped. In other words, if a continuous variation of grid potential is made from -30 volts to $+30$ volts and back again, two oscillation-hysteresis loops are obtained, the variation of oscillatory current being illustrated by the path ABCGDEFGCHA in Fig. 3 (a). The magnitudes of the positive and negative backlash regions [FE and AB in Fig. 3 (a)] are further illustrated in Fig. 3 (b), where the relation between these quantities and the back-coupling, M, is shown. We thus notice the remarkable fact that oscillations, if once started, can be maintained with strong negative grid potentials for

† APPLETON and VAN DER POL: *loc. cit.*, p. 183.

‡ It is easily seen that if we are working at conditions represented by the foot of the characteristic, and M is less numerically than the critical value, these conditions are usually fulfilled.

conditions represented by a region well to the left of the foot of the ordinary static characteristic. It is this region that we propose to utilize in a periodic manner for the reception of wireless signals. This discovery of the possibility of the maintenance of oscillations with extreme grid potentials (i.e. with potentials more negative than that required to cut off the anode current under normal conditions) leads to an understanding of the method of obtaining high efficiencies in a triode

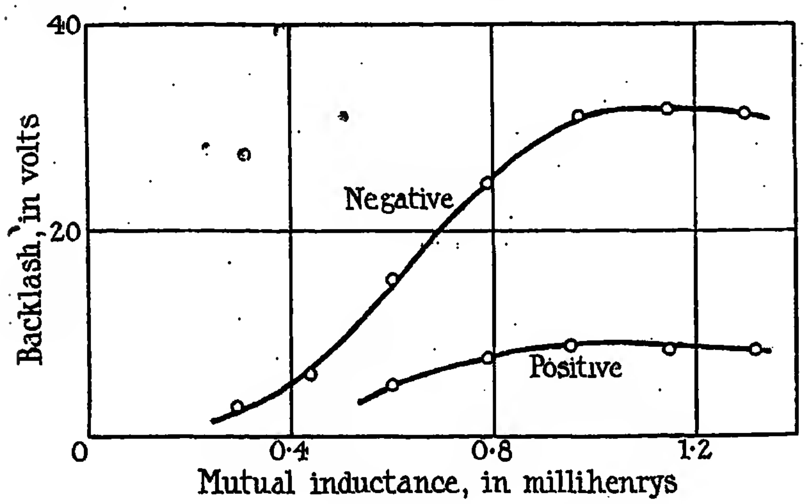

FIG. 3 (*b*).

transmitter, for in such cases the anode and grid currents flow only for part of the cycle. From the theoretical treatment given above we see that in the region represented by ABCH in Fig. 4, which represents the left-hand side of Fig. 3 (*a*), there are two stable states of the system, one quiescent (of amplitude zero) and the other oscillating (of amplitude given by the values HC). To make the system pass from the quiescent to the oscillating condition, oscillations have temporarily to be produced in the system of an amplitude greater

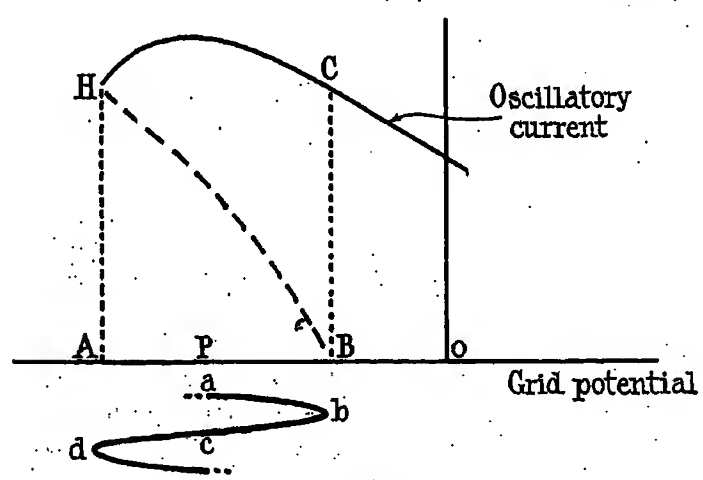

FIG. 4.

than the value indicated by the appropriate point on the broken line HB of Fig. 4, which represents the intermediate unstable values. Moreover, the amplitude of oscillations necessary to produce this trigger action is smaller the nearer we make the grid potential approach the point B from the left.*

Let us now consider the grid potential fixed at P and a cyclic potential of low frequency and of amplitude "ab" to be impressed about this point. A small high-frequency electromotive force impressed on the oscillatory circuit will now "trig" the system during the favourable conditions in the positive half of the low-frequency cycle (indicated by the point "b" in the figure) and the resulting oscillations will be maintained until the peak value of the other half-cycle (indicated by the point "d" in the figure) is approximately reached. The high-frequency oscillations thus produced in the triode system are rectified in the usual way, due to the curvature of the anode current characteristic, and a note of the impressed low-frequency cycle is heard in a telephone inserted in the anode circuit. In the absence of a high-frequency signal the system is not "trigged," and only a very feeble sound of the local low frequency is heard in the telephones. We thus have a method of receiving wireless signals based on periodic trigger action, the receiver being "trigged" by any signal strong enough to take the system over the threshold in the favourable parts of the low-frequency cycle.

In the cycle of operations indicated by Fig. 3 (*a*) the grid voltage-changes must be sufficiently slow to enable the oscillatory amplitude to reach its limiting value for the appropriate conditions. We may conveniently term such grid potential-changes "quasi-stationary." In order that the results obtained with a cyclic grid potential should be interpretable in terms of the above characteristic, the cycle "abcd" of Fig. 4 must also be sufficiently slow as to be "quasi-stationary." Experimentally we have found that the higher the radio-frequency used, the higher may be the impressed low frequency consistent with the above condition. Further mention of this point will be made later.

In testing some of the fundamental properties of this method of reception we have used a 90-period impressed low-frequency grid potential obtained from the Cambridge town supply. This was introduced into the grid circuit by means of a transformer as illustrated in Fig. 5. Here L_1C_1 is the main oscillatory circuit coupled to the anode circuit by means of the coil L_2. The town supply of 100 volts was transformed to 40 volts and then introduced by magnetic coupling into the grid coil L_3. The last-named coil had to be shunted by a condenser C_2 of about 1 200 $\mu\mu F$, which acted as a high-frequency by-pass.

The oscillatory current in L_1C_1 was indicated by the loosely coupled detector-galvanometer circuit, while the telephone signals were detected aurally by the telephone or measured by the detector-galvanometer G_2. The high-frequency signal was provided either by a small triode set a few metres away or by the signals of GLA from Ongar. Both signals were faintly audible (no aerial being used) when the receiver was made to function as an auto-heterodyne set.

In adjusting the receiver for periodic trigger reception the grid potential was adjusted to a value slightly more negative than the value corresponding to the centre of the negative "backlash" region. The magnitude of the cyclic grid potential was increased by increasing the coupling M_2 until, in the absence of signals, a very loud note of the impressed low frequency was heard. The coupling was then diminished until the loud note just disappeared. For these conditions it is obvious

* Note that the curves AB, HB and HC represent the three roots a_1, a_2 and a_3 of Equation (7).

that the cyclic variation just fails to reach the critical starting grid voltage, and thus the system is quiescent over the whole of the cycle. In the presence of a high-frequency signal of sufficient magnitude, however, the oscillator is "trigged" every cycle, and the system oscillates during the whole of the right-to-left transit of the representative point. It is evidently advantageous to make this oscillation occupy as large a portion of the cycle as possible. The best results are therefore obtained with a cyclic grid potential equal to about half the "backlash" voltage. Moreover, this is the minimum cyclic grid voltage with which the alternate trigging and quenching can be carried out as required in this method.

In the presence of a high-frequency signal the note heard with the above circuit was very loud and audible a few yards from a pair of low-resistance Brown telephones. The cessation of either the high-frequency input (incoming signal) or the low-frequency input (cyclic grid potential) stopped the loud signal entirely. Thus the loud signal must be regarded as the product of the interaction of two forced vibrations in the non-linear triode system.

With the above apparatus a study was made of the dependence of the telephone signal current on

(a) The amplitude of the incoming signal at resonance;
(b) The frequency of an incoming signal of constant magnitude; and
(c) The back-coupling of the receiver.

The relation between the signal telephone current as measured in G_2 (Fig. 5) and the oscillatory current in the transmitter as measured by a loosely coupled detector circuit, is shown in Fig. 6. It is there seen that the telephone signal is practically independent of the incoming signal. Such a relation is to be expected from the theory given above if we assume that the signal necessary to "trig" the receiver is small compared with the self-oscillation of the receiver when trigged. Still further confirmation of this view is afforded by the observation that the telephone received signal was practically the same when the cyclic grid potential was increased until periodic trigger action took place automatically in the absence of an incoming signal.

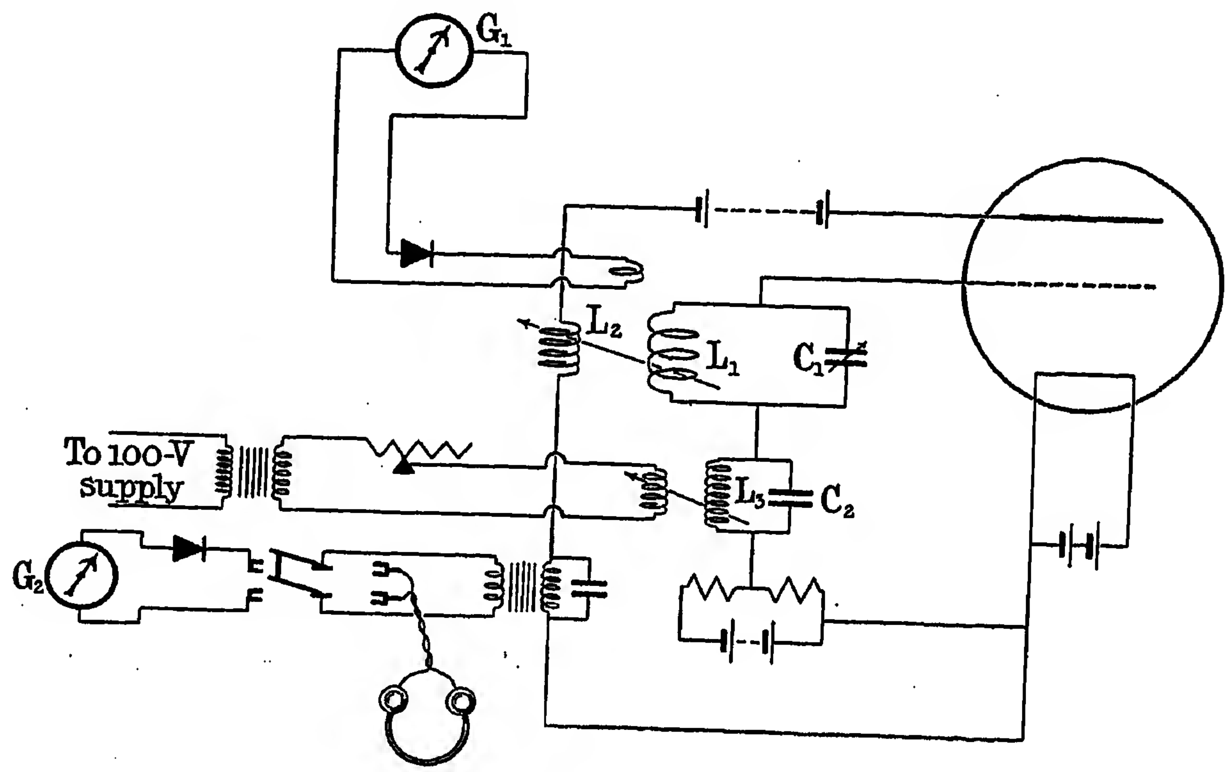

Fig. 5.

These observations show quite definitely the difference between periodic trigger action and the super-regeneration of Armstrong. In the first case the resulting telephone signal is practically independent of the amplitude of the incoming signal, whereas in super-regeneration, according to Armstrong,* "the free oscillations which are set up during the periods of negative resistance are directly proportional to the amplitude of the impressed E.M.F." Moreover, in periodic trigger reception there is no self-oscillation in the absence of a signal, whereas in super-regeneration there is always, according to Armstrong's oscillograms,†

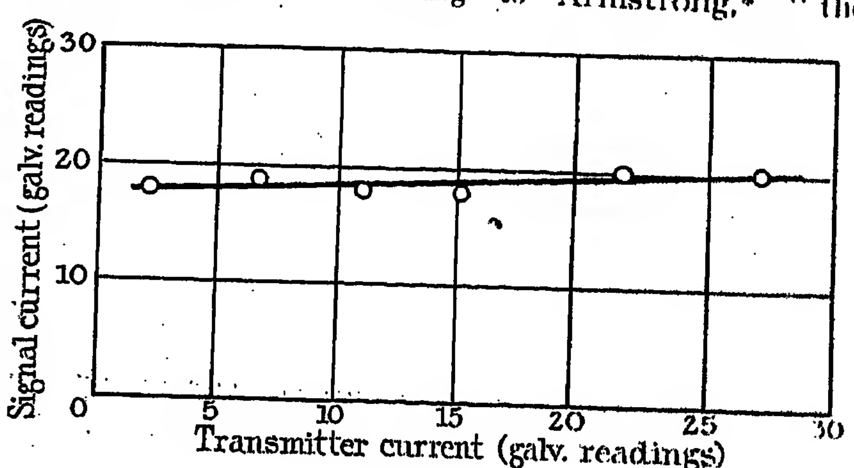

Fig. 6.

* Armstrong: *Proceedings of the Institute of Radio Engineers*, 1922, vol. 10, p. 244.

† Armstrong: *ibid.*, pp. 251 and 252.

a small self-oscillation in the absence of signals, which is enhanced by the signal.

The relation between the telephone current and the frequency of the incoming signal is illustrated in Fig. 7, where the galvanometer readings of G_2 are plotted as a function of the transmitter condenser readings. The transmitter amplitude was tested separately and found to be independent of the above-mentioned capacity alterations.

We again note that there is only a small alteration in the telephone current for these frequency changes. The telephone signal was found to start and stop abruptly at critical condenser values as the capacity was altered. There was not the slightest evidence of a gradual increase of signal strength from zero with gradual alteration of transmitter frequency, as is usual in ordinary receivers.

The strength of the telephone signal obviously depends on the magnitude of the high-frequency self-

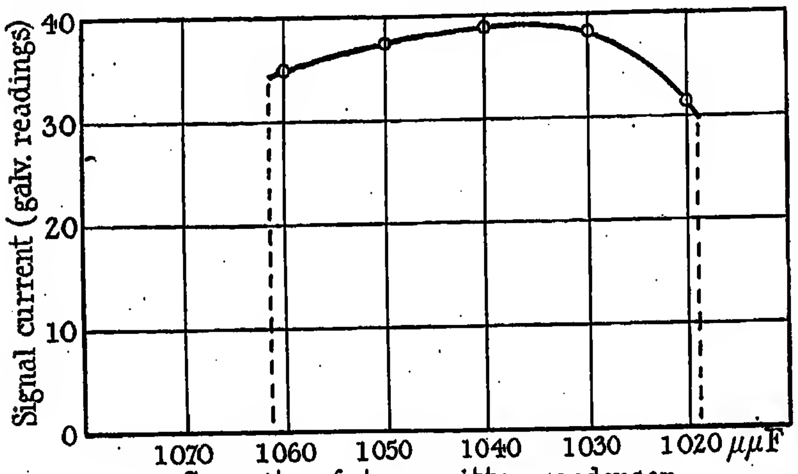

Fig. 7.

oscillations produced by the "trigger" action of the incoming signal. Thus any alteration made in the triode oscillator system which increases the amplitude of the self-oscillations (the detecting properties of the system being retained the same) will increase the telephone signal. This point is illustrated by some observations made on the effect of increasing the value of the mutual inductance on (1), the magnitude of the self-oscillation, and (2), the magnitude of the telephone signal in periodic trigger reception. In each case of (2) the cyclic grid potential was made approximately equal to half the "backlash" voltage, so that self-oscillations occupied half the cycle. The results are set out in Table 1. From these readings it will be seen that the values of the amplitudes of the self-oscillations and the telephone current increase together with increase of mutual inductance.

Further experiments made with cyclic grid potentials of frequency higher than 90 periods per second resulted in still louder signals as the low frequency more nearly approached the natural frequency of the telephones. But here considerable difficulty was encountered as it was found that once the cyclic grid potential had been increased to the value necessary for starting "trigger" action in the absence of an incoming signal, the voltage could be reduced considerably below the critical value before the trigger action stopped; and further, that within this region of hysteresis the receiver, once "trigged" by a signal, did not return to the quiescent state when the signal ceased. These phenomena, however, disappeared when the same receiver was used on smaller wave-lengths. It would therefore appear that, for satisfactory working, the ratio (radio frequency/low frequency) must not fall below a certain value determined by the constants of the circuit and the triode parameters. The authors found it possible to work satisfactorily between wave-lengths of 1 000 and 3 000 m with a range of low frequency from 250 to 90 periods per second, but further investigation of this point is to be desired.

As a matter of practical interest, and in view of the fact that the signals hitherto received had been exces-

Table 1.

0·97	22·0	18·0

sively loud, the system was tried with low values of anode voltage on the oscillator triode. With the anode connected to the positive end of the filament battery and the anode battery omitted, weak signals were received with the grid at about − 1·7 volts. With a further 2 volts on the anode the "backlash" region was about 0·3 volt, but it was found that in the middle of this region a small self-oscillation started, there being a further sudden increase of amplitude when the positive end of the region was reached. This necessitated the moving of the working point to the left of the centre of the backlash region, otherwise the signal was heard as a heterodyne whistle interrupted at the quenching frequency. In certain cases a state of absolute silence occurred at resonance, most probably due to the forcing of the feeble receiver oscillations by the incoming signal.* With the same connections and the anode at + 6 volts a nice loud signal was obtained and the effects enumerated above ceased to give trouble.

Discussion before the Wireless Section, 21 November, 1923.

Mr. L. B. Turner: The paper is a valuable contribution to the understanding of the type of receiver employing an unstable retroactive triode circuit. The authors, having set up an oscillation circuit of this type, have calculated, in terms of the shape of the static characteristic for the triode [α, γ, ϵ, in Equation (5)], the possible amplitudes of oscillation. Their mathematics makes possible a calculation of the relations obtained experimentally in Fig. 3 (a), but the authors do not appear to have checked the theory against the observed curve HCGD. They then superpose a low-frequency fluctuation of grid potential, thus constructing an electrically quenched trigger relay. Again, the theoretical formulæ might be used to calculate the behaviour when the quenching rate is low. I think it was my own "Oscillatory Valve Relay," described and demonstrated before the Institution in 1919,* which first directed attention to the method underlying the subsequent developments of Bolitho, Armstrong, Flewelling, and the present authors. Indeed, in turning up a volume of my laboratory notes of the winter 1917–18, I find that I covered experimentally a great deal of that ground. But while the authors certainly must not be criticized for ignoring unpublished matter, I do think they have presented as new some facts which were already common knowledge. Thus in introducing the trigger principle on page 181 they say that "Some time ago [viz. 1922] Dr. van der Pol and one of the present authors found that, for a triode generator, there was often a pronounced difference between the limiting conditions for the starting and stopping of free oscillations." This fact is the very basis of my valve relay, and was stated and explained in the paper referred to, wherein, too, the now familiar terms "backlash" and "threshold" were coined. The authors also announce, in the summary and at the foot of page 183, the "remarkable fact" that oscillations, once started, can be maintained with a mean grid potential so low as to be well to the left of the static anode current characteristic. Readers of my paper could hardly be unaware of this; and the condition is, indeed, that ordinarily found in triode oscillators working at high efficiency. The trigger relay described by me was produced in response to a demand for a device to close a local circuit, not actuate a telephone. The relay which had therefore to be embodied was utilized to carry out the quenching of the oscillation by means of a switching operation; and for relay work I continued to prefer this switching quench after experimenting with many electrical methods of quenching, including that used by the authors. I was trying then to obtain a very rapid, preferably ultra-audible, quenching rate, in order to use the trigger device as a powerful auditive receiver as in the authors' arrangement, but competent to reproduce the pitch of the incoming signals. The various methods I tried ran through the alphabet (I see in my notes) from A to P, and I did not succeed in obtaining what I wanted. But I experienced in acute form the difficulties the authors also have felt (see page 186) in attempting to raise the quenching frequency. In Fig. 5, the oscillation in L_1C_1 does not leap instantly to its final value, nor die instantly to zero, when the critical condition for the maintenance of oscillations is passed through. Major A. C. Fuller measured delays amounting to nearly 0·02 sec. in one of my instruments working at a wavelength of 1 500 m. In attempting really rapid quenching I found at once that it was necessary actively to damp the oscillation during quenching—as Bolitho and Armstrong do—and not merely to remove the retroaction as the authors do. There is nothing to prevent the authors from quenching partly or wholly by a damping process. Even so, if the speed and/or wavelength are then sufficiently increased, it will be found that the response no longer rises, as in Fig. 6, very slowly with the signal strength, but is more or less proportional to the signal strength. The sudden threshold will have vanished, and by a slight further change the trigger relay will have been converted into the Armstrong amplifier. On the other hand, if the low quenching rates—such as the authors' 90 250 p.p.s.—are retained, the electrical quenching appears to me, from the point of view of practical convenience, to be less desirable than the switching quench that I preferred. I should be glad if the authors would state what is the minimum practical signal strength required in their experiments. I do not see that a closer margin should be feasible with electrical quenching than with the switching quench, and with that I used to consider that about 0·05 volt was required.

* *Journal I.E.E.*, 1919, Supp. to vol. 57, p. 50.

Mr. E. B. Moullin: The authors' elegant analysis of the action of trigger relays is very welcome, for it enables us to calculate the amplification that can be obtained. Thus, using the authors' notation, if a marginal value a_2 is exceeded an oscillatory potential a_3 is produced, and the amplification for any stated margin may be defined by the ratio a_3/a_2. For satisfactory working the margin must have a lower limit greater than zero: the value of this lower limit depends on the steadiness of the valve batteries and other local conditions and probably is fairly definite for a given type of triode. I hope the authors will continue their analysis so that the amplification can be calculated more readily. The symbol v in Equation (5) is the departure of the grid potential from its mean value, and α, β, γ, etc., are different for each different grid potential. The present analysis allows us to calculate how the ratio a_3/a_2 depends on the circuit constants R, C and M when the mean grid potential is fixed, but it does not allow us to calculate how that ratio depends on the mean grid potential, because α, β, γ, etc., are unknown functions of this quantity. We do not know, therefore, how to design the circuit to suit the valve. If the characteristic can be referred to a fixed origin (say, zero grid potential) instead of a wandering one it will be a great advantage. I think that it is possible to leave the equations as they are and perform the transformation in P and N only; if that is so the alteration should not be difficult to make. I should be glad if the authors would calculate the slope of the

curve HB in Fig. 4 at a point very near to B. I hope that the analysis will be extended to cover the case where the grid potential is subjected to a part only of the fluctuations of potential occurring across L. In Fig. 3 (*a*) it is seen that when the grid is at -20V the oscillatory current is more than twice as great as when the grid is at $+ 6$V, and we might gain from this the impression that the output as well as the efficiency of a generator is greatest when the grid is made very negative. The explanation of the apparent anomaly is that the circuit of Fig. 1 was an unsuitable one with which to obtain a large output. If by choosing L_1 suitably the authors find that while still retaining the hysteresis loops they can get a curve connecting oscillatory current and grid potential which has a positive instead of a negative slope, they will be able to show us how to use the relay to much better advantage than it was being used when the observations shown in Fig. 3 (*a*) were made. If we attempt to combine the functions of a chain of amplifiers and of a rectifier in a single relay, then it must be both a good amplifier and a good rectifier. I think that the authors' method of quenching the relay may compare unfavourably with the mechanical method used by Mr. L. B. Turner, because it lessens the rectifying capabilities of the triode. In the authors' method the net change of mean anode current is the resultant of two opposing effects, viz. an increase of mean anode current owing to the rectification produced by the curvature of the characteristic, and a decrease of normal anode current and of rectified current resulting from the progressive decrease of mean grid potential. Let us trace these changes as the portion BCH of the cycle shown in Fig. 3 (*a*) is traversed by the grid potential. When oscillations begin at the point B there is an anode current due to the mean grid potential OB, and a net increase due to the oscillation BC. As the grid potential proceeds from B to A the anode current due to the mean grid potential falls to zero, and the net increase due to the oscillation decreases because no anode current flows during a portion of the positive half-cycle of high-frequency P.D. Just before arriving at H the mean anode current may be sensibly zero and remain so until the oscillation is restarted at B. With mechanical quenching all the rectification occurs at the same mean grid potential. To obtain the best results from a trigger relay quenched by the authors' system I think that it may have to be combined with a separate rectifier valve, and in this case part of the advantage inherent to a trigger relay is lost. The authors' system may possibly be advantageous for minimizing atmospheric disturbances, because the relay is sensitive for a small portion only of the cycle of grid potential. An atmospheric would not actuate the relay unless it occurred when the mean grid potential was near OB, and the disturbance would be independent of the strength of the atmospheric, but this advantage is gained only by waste of transmitter power, for signals occurring when the grid potential is far from OB are inoperative. I think that the periodic time of the local E.M.F. must not be greater than the time of duration of a Morse dot, otherwise a dot may begin and end without having had an opportunity of actuating the relay. An increase in the speed of signalling will, however, call for a more than proportionate increase in the frequency of the local E.M.F., because the signal may not have time to build up the marginal P.D. if given only one opportunity. But, as the authors point out, the ratio of radio frequency to local frequency must not fall below a certain amount or quenching ceases, presumably because the free oscillation left in the circuit after the point H has been passed must be given time to die down to a residuum which is less than the marginal value required for restarting. The critical ratio would be decreased by increasing R or decreasing L_1, the sensitivity being maintained by adding to the anode battery. Do the authors consider that if, when distuning their receiver, they had maintained the operating P.D. constant in value and frequency instead of keeping the transmitter current constant, they would still have obtained results similar to those illustrated in Fig. 7? Do they imply that an E.M.F. competent to actuate the relay must have not only a certain marginal value but also a frequency nearly the same as that of the receiver circuit? Does their analysis suggest that the receiver could not be actuated by moving it at a uniform speed across a constant magnetic field?

Mr. T. L. Eckersley: The chief value of the paper lies, in my opinion, not so much in its novelty (for

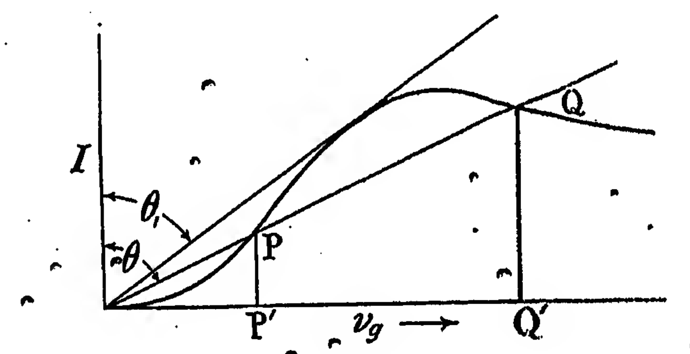

FIG. A.

Mr. Turner has previously used a very similar device) as in its clear mathematical exposition. The authors use a method in which they express the valve characteristics as a series of powers of what we might call the characteristic voltage V, i.e. $(V_A + mV_g)$, where V_A is the anode voltage, V_g the grid voltage, and m the magnification constant of the valve. There is another method in which the anode-current/grid-voltage characteristic can be expressed as a Fourier function of the characteristic voltage. Two or three years ago I attacked the problem of what the authors call "oscillation hysteresis" from this point of view. A tuned anode circuit was assumed in which the harmonics are supposed to be small compared with the fundamental, so that a practically sinusoidal voltage is impressed on the grid. Under these conditions we plot the actual oscillatory current in the plate circuit against the grid voltage, and get a curve of the form shown in Fig. A, which may be calculated from the characteristic as follows: If we express the characteristic curve as

$$i_p = A_0 + A_1 \sin(2\pi\beta) + \ldots + A_n \sin(2n\pi\beta) \ldots \text{etc.}$$
$$B_1 \cos(2\pi\beta) + \ldots + B_n \cos(2n\pi\beta)$$

V = characteristic voltage, where $\beta = V/V_0$, V_0 being some fixed arbitrary value of V.

Then $$I = \frac{Lp}{R} f(\beta_1)$$

where $\beta_1 = \frac{V_g}{V_{g0}}$; and $V_{g0} = \left(1 - \frac{L}{M_m}\right) V_0$;

L = inductance of oscillatory circuit;
M = mutual inductance to grid circuit; and

$$f(\beta_1) = (A_1 + B_1) J_1 (2\pi\beta_1) + (A_2 + B_2) J_1(2\pi 2\beta_1) + \ldots + (A_n + B_n) J_1 (2n\pi\beta_1)$$

where J_1 is a bessel function of order 1.

The conditions for the production of oscillations may be shown as follows: If we draw a line at an angle θ with the vertical axis, where $\tan\theta = M_p$, then the condition that self oscillations may be produced is that the line OPQ shall cut the (V_g, I) curve. In the figure the lines cross at O, P and Q, showing that three modes of oscillation are possible. These correspond to the three roots of the equation obtained by Dr. Appleton: one is of zero amplitude and is stable; the next, PP′, is unstable; and the other, QQ′, is stable again. The figure shows that with a given value of the reaction, determined by the angle θ, no oscillations can be maintained until an initial grid amplitude greater than OP′ is produced. This is the threshold value of grid voltage; once this voltage is produced the plate current automatically builds up to the value QQ′. These oscillations can be stopped by reducing the reaction M to the value $\tan\theta_1/p$, where the line θ_1 is tangential to the V_g, I curve. The method given here is more suitable for expressing the dependence of the oscillations on reaction rather than on the initial grid voltage, but it is possible by drawing the representative curves for various initial grid voltages to determine the effect of varying grid bias as well, but not so clearly. Obviously a large negative bias on the grid shifts the whole (V_g, I) curve to the right, and a bigger threshold value of V_g is necessary to start the oscillations, just as described in the paper. This method can be used to take account of the harmonics, but naturally becomes increasingly complex when more of these are included. The practical utility of the device which avowedly depends for its action on the non-linear characteristics of the triode, is, in my opinion, marred for this reason. The majority of wireless engineers try to avoid as much as possible anything which savours of "non-linearity." The reason for this is that the problem of interference is generally made more difficult by the introduction of non-linear characteristics, for the cross terms, due to the interaction of the signal and the disturbance, make impossible any method for the separation of the two. The fact that the characteristic note of the signal is lost, making telephony impossible by this method, is also traceable to the non-linear relation, which is therefore to be treated with great care.

Mr. R. C. Clinker: I am reminded of an experiment that I carried out some years ago with a single-valve receiver. I am not quite sure whether the effect was the same as described in the paper, but it was actually this. I was using a coil aerial, about 12 in. × 10 in. with about 200 turns on it, and a single valve with the anode circuit reacting direct on to the coil, for receiving Nauen, that is, the spark station. If I increased the coupling of the circuit so as to cause the valve to howl, that is, to make a certain unmusical note, I could easily read the signals from Nauen anywhere in the room with this single valve and small coil, because the signal changed the pitch of the howl just enough to enable the Morse to be read. I am not quite clear what the action was, but I imagine it was something like that described in the circuit shown in the paper, except, of course, that the howl was acting as the low frequency. It was simply a change in pitch—a very slight one—when the dots and dashes came in from Nauen, but it enabled the signals to be read anywhere in the room.

Major H. P. T. Lefroy: In reply to the authors, who ask for the experience of those who have used this method of reception, my results obtained in March 1922, when experimenting on high-frequency line telegraphy, may be of interest. I used a "trigger" arrangement which gave excellent results for high-speed work. I was transmitting, with the permission of the G.P.O., from Fenny Stratford on a subterranean cable, and receiving in London, the distance being 52 miles. The high-frequency energy input was rather less than 1 watt, and the received E.M.F. was about 1/1 000th of the input E.M.F., owing to attenuation along the cable. I received at the rate of 200 and 240 words per minute quite comfortably, on frequencies of 10 000 and 6 000 p.p.s. respectively. In the arrangement which I used, the incoming signals "triggered" a three-valve amplifier, controlled so as to be on the verge of self-oscillating when awaiting signals. Using a standard G.P.O. relay, I got, with strong incoming signals, a change from zero current in the relay circuit to 50 mA, and this enabled me to record 240 words per minute on tape. Using a specially wound relay of 8 000 ohms resistance, I got zero to 16 mA, which was still better for high-speed work. I then attempted reception at high speed on a subterranean cable on which the Post Office, about a mile distant, were working on Wheatstone automatic at 80 words per minute from London to Carlisle, this producing on my receiver the equivalent of severe atmospherics. After a little experimenting I was able to cut this disturbance out and receive at 100 words per minute from Fenny Stratford. I was struck with the freedom from jamming in this "trigger" method of reception, in view of the extraordinary strength of the Wheatstone interference, and I assumed then that this was due partly to the filtering arrangement that I was using, and partly to the fact that the only time when jamming could be effective was when the disturbance arrived during a spacing interval.

Major A. G. Lee: The authors lay stress upon the effects of the non-linear conductance of triodes in modern wireless circuits, and I should like to call attention to what I think is an equally fundamental principle governing the operation of some of those circuits. This, briefly, is that if we have a subsidiary E.M.F. acting in a resonant circuit, this E.M.F. may be regarded as contributing an impedance to the circuit. This impedance, depending upon the phase of the subsidiary E.M.F. in relation to the current in the circuit, may consist of either positive or negative resistance in

combination with positive or negative reactance. When dealing with forced oscillations this view-point gives exactly the same result as that arrived at by the normal process of adding the main E.M.F. and the subsidiary E.M.F. vectorially, and there is no advantage gained by looking at the process from this angle. With free oscillations, on the other hand, the phenomenon of the frequency being changed by the presence of the subsidiary E.M.F. is more readily understood when looked at from this point of view. For instance, in the normal operation of coupled circuits the effect of the reaction from one circuit to the other is to separate the frequencies of the self-oscillations. I have, however, found it possible to synchronize two damped, free oscillations of widely different natural frequencies by arranging suitable initial amplitudes and phases in the two circuits, and this was done without the intervention of a triode with its non-linear conductance. In the ordinary transformer case the current in the secondary is a function of the current in the primary, and its reaction on the primary is usually such as to change the natural frequency of that circuit. This is a particular case of the more general one outlined above in which it is indicated that the current in the second circuit can be a completely independent one and the effect of the current in the second circuit on the first may be regarded as the insertion of an impedance in the first circuit. Dr. Appleton's investigation into the "synchronization of triode oscillators" appears to me to be an example of this type of action. The theory is competent to explain the synchronization when the phase has arrived at the correct relation, though the quantitative explanation requires a knowledge of the triode currents, i.e. the non-linear conductance theory. It would also explain the pulling together of the frequencies outside the range of synchronization, which is another very important point to which Dr. Appleton has called attention, but it is to be expected in this case that there would be a cyclical change in the frequencies. Another interesting case is that of the ordinary triode oscillator such as that in Fig. 1 of the paper. In this case the effect of an oscillating current in the grid resonant circuit is to induce a current in the anode circuit through the coupling M_1, which, reacting back on the grid circuit by ordinary transformer action, increases R and decreases L of the circuit. The effect of the component of current in the anode circuit which is controlled by the grid potential is, however, to decrease R and increase L. As the latter effect is greater than the transformer effect, in general this type of oscillator oscillates at a lower frequency than that given by the L and C values of the circuit. There is a certain family of phenomena which are rather grouped together in my mind as being dependent upon this type of action, viz. the triode synchronization phenomena described by Dr. Appleton; the "Ziehen" effect investigated by German writers; the discontinuities in phase and frequency in coupled circuits in valve and arc transmission; the separation of frequencies in damped oscillations of coupled circuits; and various effects met with in ordinary triode retroacted circuits (not self-oscillating), such as the mistuning effect of retroaction when its phase is changed, etc. Some few years ago trigger systems of reception were somewhat popular, but their popularity quickly died. My own experience with them was disappointing. I found that their principal drawback was that they would not receive weak signals; and, after all, it is the weak signal which is the principal difficulty in wireless reception. It is quite easy to receive a strong signal by any other method. Some trigger systems, e.g. the Bolitho system, show a certain amount of advantage in reducing atmospheric interference, as the atmospheric is cut short by the quenching action.

Lieut. G. W. N. Cobbold: It seems to me of little value to consider, as Mr. Moullin has done, the ratio of a_3 to a_2, for the operation of this system, in which the character of the incoming signals is lost, involves essentially relay action rather than amplification. The device must accordingly be compared with a trigger system employing a mechanical relay; and in such a system the ratio of output to input may be increased indefinitely. I should therefore be glad if the authors could give us further information concerning the magnitude of the minimum signal required to operate their device, for one of the most important criteria by means of which it is customary to judge a trigger system is the value of the "backlash," i.e. the difference between the grid voltage at which the triode just bursts into violent oscillation, and the grid voltage at which the oscillations are killed. It was my privilege to assist Major Fuller at the Signals Experimental Establishment during some of the early developments of the Turner trigger relay for high-speed reception, and I have seen a good deal of the more recent improvements effected by Dr. Brydon. As a result of these developments at the Signals Experimental Establishment a very high standard of excellence has been reached; and, whilst wishing to thank the authors for their interesting mathematical analysis, I venture to doubt whether they have even approached in their practical apparatus the excellence of the instrument that was demonstrated before the Institution after the reading of Col. Cusins's paper on the 4th January, 1922.

Dr. E. V. Appleton and **Mr. F. S. Thompson** (*in reply*): We do not wish the method of reception which we have described to be regarded as being put forward by us as a rival to the Turner trigger relay system or to the methods of similar type described by Bolitho, Armstrong or Flewelling. In describing the periodic trigger method our chief aim has been to exhibit as transparently as possible the theoretical basis on which the method rests, since we have not as yet had time to examine all the practical aspects of it in detail. Since the paper was read we have been able to compute the oscillatory signal necessary for successful working with periodic trigger reception. As was stated in the paper, satisfactory signals were obtained on the coil of the receiver from GLA (Ongar), which station is about 30 miles from Cambridge. Through the courtesy of Mr. T. L. Eckersley of the Marconi Company, who has kindly supplied the necessary data, we have been able to calculate the field strength at Cambridge and thus estimate the oscillatory electromotive force impressed on the receiver coil. This computed electromotive force is found to be 5×10^{-5} volts. The actual value is, of

course, likely to be much less than this as no absorption has been allowed for.

In reply to Mr. Moullin's point regarding inefficient rectification, we can only say that for all practical purposes we have found the rectification sufficient, since when the receiver is "trigged" in any way the signal in the telephones is deafening. We also intended it to be understood that a signal of sufficient magnitude within a fairly wide range of frequencies would operate the receiver in the same way.

The graphical method of calculating the amplitude of a triode generator described by Mr. Eckersley is very similar to that described by one of the authors in the *Radio Review*, 1921, vol. 2, p. 424.

The phenomenon described by Mr. Clinker is, we think, quite different from that underlying periodic trigger reception. We have ourselves observed the same phenomenon as Mr. Clinker, using a condenser and grid leak in the receiver. In such a case with strong coupling the circuit may be made to oscillate in periodic trains, giving rise to an audible note in the telephone. A received signal, however, alters the mean grid potential slightly and the frequency of these periodic trains is altered—due to the alteration in the time of the discharge of the grid condenser. The telephone note is thus altered by the signal.

Major Lee's remarks on the problem of the synchronization of triode oscillators are particularly interesting to us, for it was by this linear treatment (which, as Major Lee admits, is necessarily incomplete in the case of triode circuits) that the problem of synchronization phenomena was first attacked before the more complete non-linear theory was worked out. As a result of this preliminary work it was found that for practical purposes it could be assumed that a circuit of natural frequency ω_0 is changed slightly to one of frequency ω by a periodic impressed E.M.F. such that

$$\omega_0 - \omega = \frac{E_0\omega}{2a}\cos\phi$$

where E_0 is the impressed E.M.F., ϕ is the phase difference between the impressed E.M.F. and the vibration, and a is the amplitude of the vibration. No doubt this formula would explain the phenomena mentioned by Major Lee. In the case where actual synchronization does not occur the same formula is approximately true, and we note that the free frequency varies with ϕ during a beat, giving rise to beats of an anomalous type previously described. A treatment of synchronization phenomena, which is more satisfactory mathematically than that previously mentioned, has recently been worked out. This deals with the attraction of frequencies observed experimentally. It is hoped that it will be published shortly.

Major Lee's experiments on the synchronization of damped linear vibrators are of very great theoretical importance and we hope that an account of them will soon be published.

THE RELATIONS BETWEEN DAMPING AND SPEED IN WIRELESS RECEPTION.

By L. B. TURNER, M.A., Member.

(*Paper first received 12th June, and in final form 9th November; read before the* WIRELESS SECTION *5th December*, 1923.)

SUMMARY.

Part I is devoted to an examination of the ordinary method of recorder working in wireless telegraph receivers, as affected by the damping of the receiver circuits. After a résumé of the significances of the decrement of any oscillatory system, its bearing on the possible speed of recording Morse signals is investigated. The quality (approach to correct Morse "shaping") is estimated from calculated curves of amplitude of oscillation set up in the receiver by the incoming dots and dashes constituting the letter "l." By comparing several such curves, a minimum practical value is found for the product of frequency and decrement and duration of Morse dot. The relation between speed of signalling and the requisite transmitter power is then investigated. Part I concludes (Section 5) with a summary and discussion of the results arrived at.

In Part II an improved method of reception, called "receiver curbing," is described and analysed. An estimate is made of the improvement obtainable, and practical circuits are given for putting the method into effect.

Part I.—ORDINARY RECEPTION.

(1) *Introduction.*—Ever since Lodge's enunciation of the importance of syntonization in wireless telegraphy—embodied in his famous patent 11575 of 1897—efforts have been made to produce electrical oscillatory systems, both transmitting and receiving, of low damping. Owing to the regrettable fact that we happen to have no materials for electrical conductors exhibiting much less resistance than do copper and silver, low damping was much more difficult to obtain in electrical than in mechanical systems (e.g. in the pendulum of an astronomical clock); but in recent years the thermionic triode has conferred upon us, amongst its other boons, the power of contriving negative resistance, thus enabling us to construct with ease electrical oscillatory circuits of extremely low damping. This advance in our technical abilities, combined with the general transition towards the use of longer waves and higher signalling speeds, has now greatly modified the situation, so that at the present time cases readily arise in which we have, so far from striving for the lowest attainable damping, to inquire rather how far it is in our interest to go.

In this paper one aspect is examined of the relation of damping to the reception of wireless signals, viz. its relation to the "shaping" of the received dots and dashes, using "shaping" in the sense in which it is used in cable telegraphy. It is surprising that the subject has not (as far as I am aware) attracted attention already, for its study is essential to an understanding of the relations existing between speed of working and transmitter power. The time has come when the problem of recorder speed in wireless calls for something of the effort which has been expended, with such beneficent results, on the like problem in submarine cable telegraphy; and it is hoped that this paper may help in preparing the way for the copious high-speed long-distance wireless traffic of to-morrow.

Let us first briefly review the significance of damping in oscillatory systems, and the terms in which it is measured. The disturbance in any oscillatory system where a quantity q varying with time t is described by the differential equation

$$L\frac{d^2q}{dt^2} + R\frac{dq}{dt} + \frac{1}{C}q = 0$$

dies down according to its solution

$$q = q_0\,\epsilon^{-mt}\cos pt \quad \text{(see Fig. 1)}$$

where $$m = \frac{R}{2L}$$

and $$p = 2\pi n = \sqrt{(CL - m^2)}$$

$$\approx (\sqrt{CL}) \text{ when } \frac{m^2}{p^2} \ll 1$$

The amplitude dies down according to the damping factor ϵ^{-mt} or $\epsilon^{-(m/n)N}$, where N is the number of periods

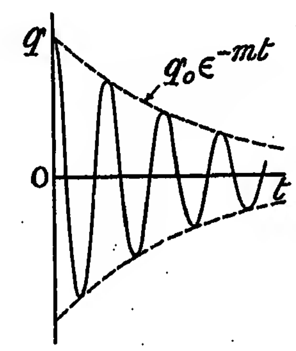

FIG. 1.

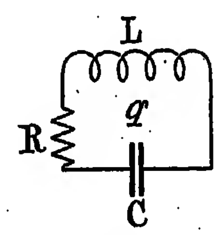

FIG. 2.

of the oscillation; the rate of fall is specified with reference to the number of seconds of time by the decay coefficient m, or with reference to the number of periods by the ratio $\epsilon^{m/n}$ of the successive maxima. The logarithm of this ratio, m/n, is called the logarithmic decrement—or briefly the decrement—δ of the oscillatory system, and we may write

$$q = q_0\epsilon^{-\delta N}\cos pt$$

The decrement $\delta = m/n = R/(2nL)$ specifies the period rate at which the oscillation dies away; thus the amplitude is divided by $\epsilon = 2\cdot 7$ during every increment of $1/\delta$ in the number of periods, N.

When the oscillatory system is an electric circuit as in Fig. 2, q is the quantity of electricity displaced, and the dimensions L, R and $1/C$ of the system are the inductance, resistance and reciprocal capacitance respectively of the circuit.

The root significance of the decrement is that just stated. But there are other properties of the circuit equally well specified by its decrement. When the circuit is excited by an impressed alternating E.M.F., say $e = E \sin p_1 t$, its final response depends upon the "tuning" (i.e. relation between p and p_1) in a degree determined by the decrement. The selective property of the circuit as regards frequency of impressed E.M.F. is well exhibited by the familiar "resonance curve" connecting final amplitude with the impressed periodicity, p_1. The lower the decrement the "sharper" this curve and the "sharper" the tuning; thus, in Fig. 3, $AB/OC = \delta/\pi$.

A third, quite different, significance of the decrement of the circuit is this: it specifies the period rate of growth of the oscillation engendered by the impressed E.M.F. when of the resonant frequency. Thus

$$L\frac{d^2q}{dt^2} + R\frac{dq}{dt} + \frac{1}{C}q = E \sin p_1 t$$

$$q = q_0\epsilon^{-mt}\cos(pt + \theta) - q_1 \cos(p_1 t + \phi)$$

where $$q_1 = \frac{E}{p_1\sqrt{[(1/p_1C) - p_1L]^2 + R^2}}$$

and $$\tan\phi = \frac{1/(p_1C) - p_1L}{R}$$

and q_0 and θ depend upon initial conditions. In the particular case of resonance ($p_1^2 = 1/CL$), low damping ($m^2/p^2 \ll 1$), and the circuit quiescent and discharged when the E.M.F. was first applied ($q = 0 = dq/dt$, when $t = 0$), this becomes

$$q = -\frac{E}{pR}(1 - \epsilon^{-mt})\cos pt$$

$$i = \frac{dq}{dt} \approx \frac{E}{R}(1 - \epsilon^{-mt})\sin pt$$

$$= \frac{E}{2L} \times \frac{1 - \epsilon^{-mt}}{m}\sin pt$$

$$= \frac{E}{2nL} \times \frac{1 - \epsilon^{-\delta N}}{\delta} \times \sin pt$$

The factor $(1 - \epsilon^{-\delta N})/\delta$ is plotted against N for several values of δ in Fig. 4. These curves show that after the lapse of (say) 500 periods from switching on the E.M.F., if $\delta = 0{\cdot}01$ the full amplitude has sensibly been reached; if $\delta = 0{\cdot}001$ the amplitude is still rapidly rising, having reached only about 40 per cent of its final value; and if $\delta = 0{\cdot}0001$ the amplitude is only 5 per cent of its final value. Let us now suppose that the E.M.F., $E \sin pt$, switched into our oscillatory circuit constitutes an incoming wireless signal which, when making a Morse dot, lasts for (say) 500 periods, and, when making a dash, for 1 500 periods. If $\delta = 0{\cdot}01$ the amplitude reached during dot and dash are sensibly equal and of magnitude $100 \times E/(2nL)$; if $\delta = 0{\cdot}001$ the dash amplitude is nearly twice the dot amplitude, which is $400 \times E/(2nL)$; and if $\delta = 0{\cdot}0001$ the dash amplitude is nearly three times the dot amplitude, which is about $500 \times L/(2nL)$.

An actual receiving circuit must respond to both dots and dashes, separated moreover by only a dot-length of spacing interval. It is obvious, therefore, that if conditions resembling those of the last two cases should prevail, the indicator, whether telephone or relay and recorder, would be asked to perform an impossible task; it could not reproduce anything like an accurate copy of the Morse signals transmitted. The difficulty with respect to the receiving instruments is precisely that met in the reception of submarine cable signals, although originating in the terminal apparatus instead of the medium connecting them.

The curves of Fig. 4 show not only the relative importance of the transient stages in the building up of the oscillation (in that respect obviously $\delta = 0{\cdot}01$ is much

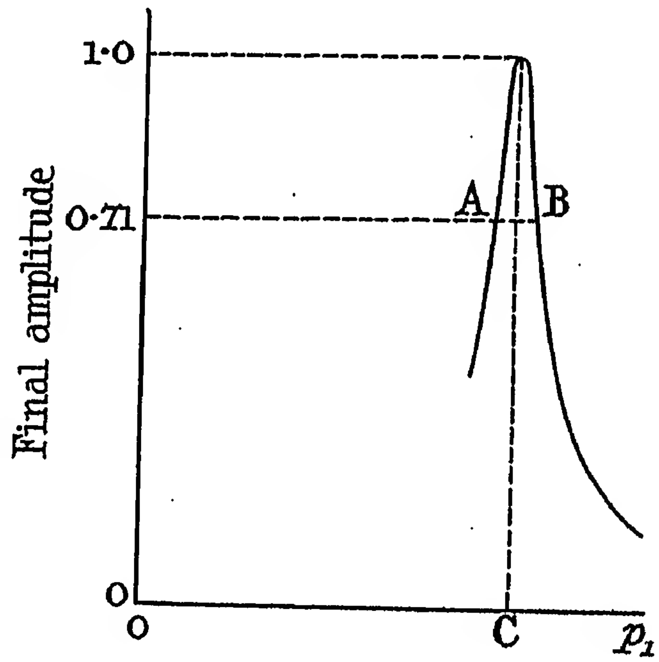

FIG. 3.

more desirable than $\delta = 0{\cdot}001$) but they show also the relative sensitivities of the receiver (assuming that the change of decrement is due to change of resistance). In this respect the sensitivity of $\delta = 0{\cdot}001$ is 10 times that of $\delta = 0{\cdot}01$ for indefinitely slow signals, and is 4 times for dots lasting 500 periods. It is, moreover, easy to see that gain in respect of selectivity between one frequency and another accompanies the gain in sensitivity; so that in these respects $\delta = 0{\cdot}001$ is much more desirable than $\delta = 0{\cdot}01$.

Now it is practicable to build receiving circuits whose decrement, due to inherent resistance, is as low as $0{\cdot}01$ or less, and by familiar retroactive triode arrangements the decrement can be reduced with adequate stability far below this figure, certainly below $0{\cdot}001$. It is therefore within our powers to provide very low decrements, and we have a task of practical interest in seeking for an optimum compromise amongst the above-mentioned conflicting claims in favour of high and low decrements. To utilize very low decrements it is, of course, necessary to provide very close resonance; and at present it is probably often the case in practice that the precision of tuning is quite inadequate,

e.g. owing to inconstancy of transmitter frequency. This is, however, an unnecessary imperfection, and with the modern type of thermionic transmitter in which a feeble unbroken master oscillator energizes the aerial through a key-controlled chain of amplifiers, it may be assumed that sensibly perfect syntony is obtainable.

(2) *Some calculated arrival curves.*—We begin our investigation by calculating the arrival curves—to borrow an appropriate cable term—for a representative sequence of Morse dots and dashes, viz. the letter "1" (· — · ·). Including the letter space ($3T$) following at the end, this signal in the Morse code has a total duration $12T$, where T is the duration of a dot and $3T$ the duration of a dash. We will suppose that the E.M.F. impressed in our oscillatory circuit is sensibly

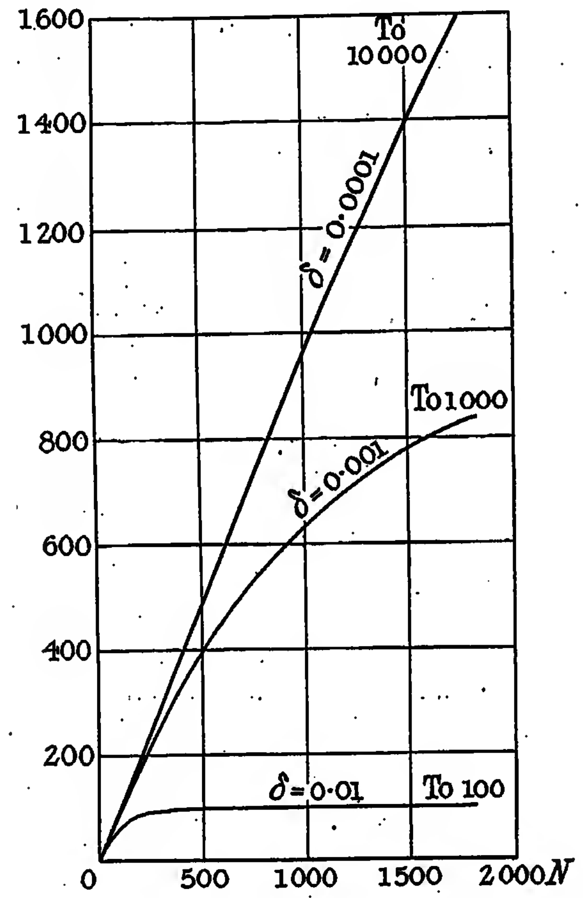

FIG. 4.

"square-shaped," i.e. rising suddenly from 0 to $E \sin pt$ at the beginning of a mark and falling suddenly to 0 at the end.

During a signal, the amplitude A of the oscillatory current in the receiving circuit is

$$A = \frac{E}{2nL} \times \frac{1 - \epsilon^{-n\delta t}}{\delta}$$

Its value $\dot{A}$* at the end of a dot lasting T secs. is

$$= \dot{A}\ \frac{E}{2nL} \times \frac{1 - \epsilon^{-n\delta T}}{\delta}$$

Its value $\bar{A}$ at the end of a dash is

$$\bar{A} = \frac{E}{2nL} \times \frac{1 - \epsilon^{-3n\delta T}}{\delta}$$

* Note that $\dot{A}$ does not mean $\frac{d}{dt}(A)$.

During a space it falls from its value at the end of the preceding mark according to the damping factor $\epsilon^{-n\delta t}$. Hence at the end of a short space following a single dot its value is

$$\dot{A}_s = \dot{A}\epsilon^{-n\delta t}$$

$$= \frac{E}{2nL} \times \frac{\epsilon^{-n\delta T} - \epsilon^{-2n\delta T}}{\delta}$$

and following a single dash it is

$$\bar{A}_s = \bar{A}\epsilon^{-n\delta T}$$

$$= \frac{E}{2nL} \times \frac{\epsilon^{-n\delta T} - \epsilon^{-4n\delta T}}{\delta}$$

The curves of amplitude of "received current" given by these formulæ are plotted, on a time base with T as the unit, for a single dot and space (dotted line) and a single dash and space (full line) in Fig. 5, in the case where $n\delta T = 2$.*

When the E.M.F. reappears at the end of a space the amplitude has not fallen to zero; hence the behaviour at the beginning of the next mark must depend on the phase relation between the residual oscillation and the new impressed E.M.F. If perfect synchronism between transmitter and receiver still obtains at the end of the space, the dying residuum is added to the growing new oscillation; but if they have got into anti-phase, the

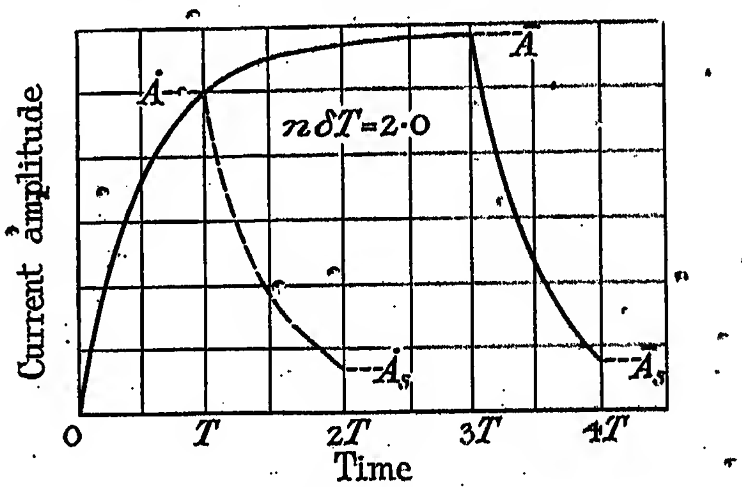

FIG. 5.

new E.M.F. (and the lapse of time) must reduce the residuum to zero before building up the new oscillation. With a keyed oscillator at the transmitter this phase relation is probably usually a matter of chance; but with the master-oscillator type of transmitter referred to at the end of the last section, already in fairly common use, the new E.M.F. may be assumed to be in phase with the residual oscillation, i.e. no phase displacement is introduced during the spacing epoch. For the arrival curves calculated in Fig. 6 and subsequent diagrams, an exact in-phase relation is assumed, but at the beginning of the last dot the effect of the anti-phase relation is also portrayed (in chain-dotted line), so that the significance of the phase relation may be seen in the several examples shown.

To ascertain the response of a relay actuated by this

* To make these curves more concrete, they may be applied to any interesting numerical case satisfying the specified condition $n\delta T = 2$, for example:— $\lambda = 10\,000$ m; $n = 30\,000$ p.p.s.; $\delta = 0{\cdot}0067$; $T = 0{\cdot}010$ sec. (i.e. signalling speed 125 words/min.).

received oscillatory current; we must know the operative amplitude A_0 above which the relay marks and below which it spaces.* If we were concerned only to operate the relay—without regard to the shaping of the signals recorded—the ratio between A_0 and the greatest amplitude attained would be made as near unity as practicable, in order to favour as much as possible the tuned signal E.M.F. in the contest with distuned E.M.F.'s, particularly atmospherics. In this connection it is important to distinguish between the sensitiveness of the relay *per se*, and the sensitiveness of the receiving circuit as a whole. The former is irrelevant, because the relay does not select between desired signals and "jamming"; the latter is very important, for while the tuned signal E.M.F. is competent to make the amplitude climb to the operative value A_0, an equally strong E.M.F. of other frequency is not competent. If our friend is provided with a good ladder and our enemies have poor ladders, it is well to build our wall nearly to the height of our friend's ladder.

The choice of A_0 is, however, dependent on questions of shaping. Referring to Fig. 6, if the relay is biased or otherwise adjusted to make A_0 too high, it will register dots too short, and there is danger of missing them altogether in the event of a slight departure from the ideal conditions. Again, if A_0 is too low, the relay will register the spaces too short and there is danger of running successive marks together. The best compromise can only be found by trial, and must depend to some extent on the quality of the recording apparatus. In Fig. 6, fairly accurate Morse shaping would be given by $A_0 = 0 \cdot 60$, but since easy legibility of the record depends much more on uniformity as between dot and dot, space and space, etc., than on the closeness of reproduction of their relative lengths in the Morse code, it is thought that $A_0 = 0 \cdot 70$ would be a preferable value.* The signals which would be recorded with $A_0 = 0 \cdot 70$ are shown in Fig. 6 by the thick lines drawn across the arrival curves at that height, and for comparison with them the true Morse-shaped transmitted signals are shown just above.

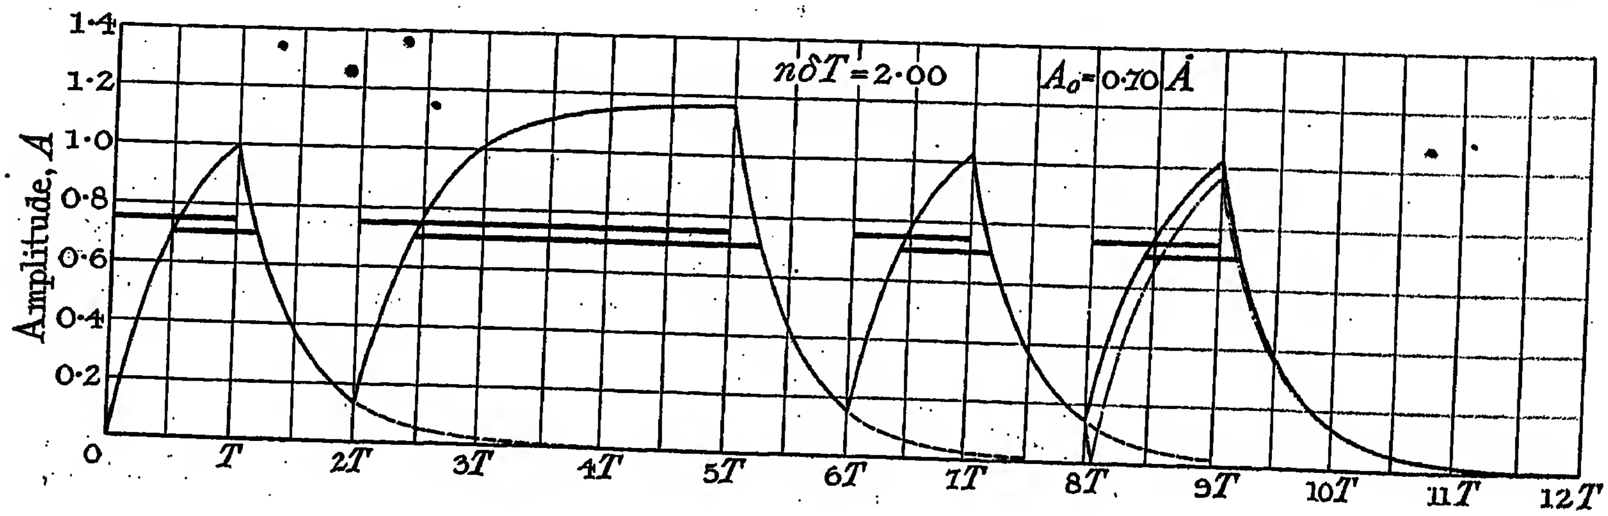

FIG. 6.

In Fig. 7 the corresponding curves are drawn for $n\delta T = 1 \cdot 50$, and in Fig. 8 for $n\delta T = 1 \cdot 00$. In Fig. 7 it is seen that good uniformity cannot be obtained with any value of A_0, but fairly good signals are obtained with $A_0 = 0 \cdot 75$ as a compromise between seriously unequal first and second dots if $A_0 > 0 \cdot 75$, and seriously unequal first and second spaces if $A_0 < 0 \cdot 75$. The signals for $A_0 = 0 \cdot 75$ are shown on the curves. In Fig. 8 no approach to uniformity can be obtained, whatever value is given to A_0.

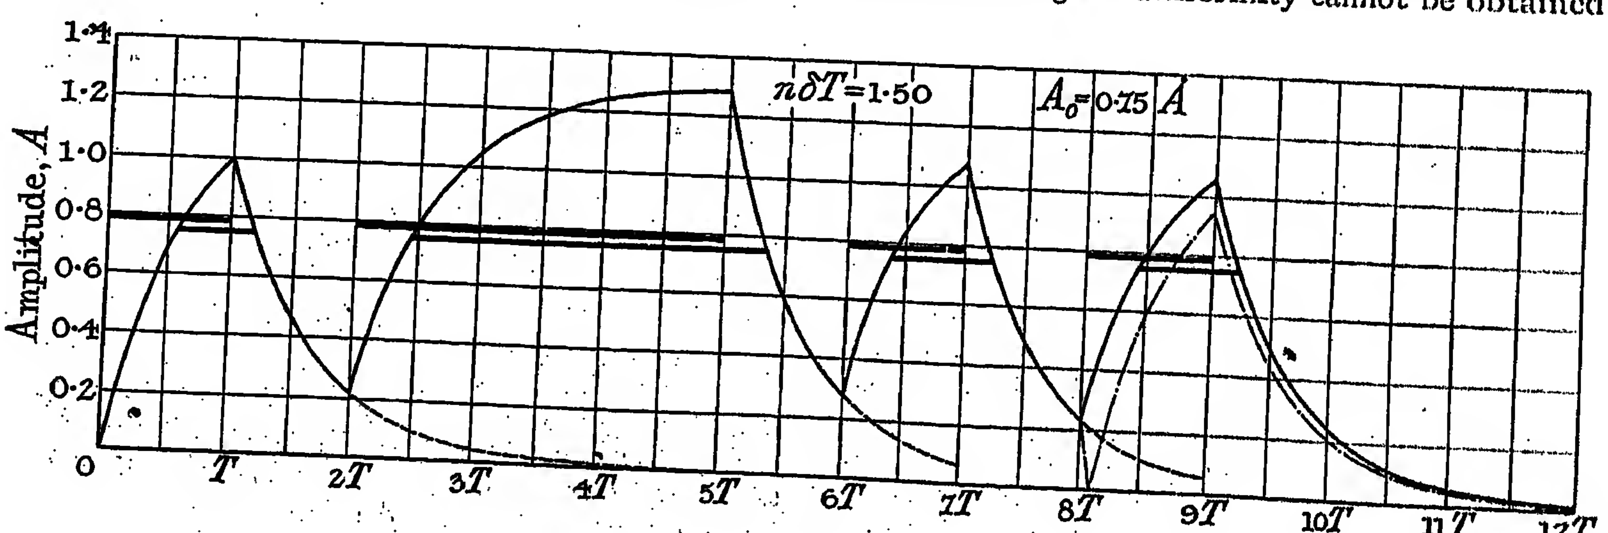

FIG. 7.

(3) *Minimum permissible value of $n\delta T$.*—It has been

* For simplicity we take no account of the necessary, though maybe very small, difference in the critical currents when rising to mark and falling to space, due to friction, etc., in the relay.

* Moreover, given uniformity, the clipped dots could always be restored by manipulation, mechanical and electrical, of the recording apparatus.

seen that the shape of the arrival curves is a function of $n\delta T$ alone, so that information as to shape gained

TABLE 1.

Wave-length	Words per minute	Decrement for $n\delta T = 2$	Decrements for lower sensitivities, S	
			$S = 0{\cdot}75\,S_0$	$S = 0{\cdot}50\,S_0$
m 1 000	200	0·0011	0·0016	0·0025

from a few trial curves such as Figs. 6, 7 and 8 is general for all wave-lengths, decrements and speeds of signalling.

low speeds of signalling), as has been seen already with reference to Fig. 4. It is therefore necessary to ascertain the relation between the decrement and the magnitude of signal E.M.F. requisite to operate the relay.

From Section (2) we have

$$A_0 = a\dot{A} = \frac{aE}{2nL} \times \frac{1 - \epsilon^{-n\delta T}}{\delta}$$

Therefore $$\frac{2nLA_0}{E} = a \times \frac{1 - \epsilon^{-n\delta T}}{\delta}$$

i.e. $$S = a\,\frac{1 - \epsilon^{-n\delta T}}{\delta}$$

where S (being proportional to A_0/E) measures the sensitivity of the receiver, when its decrement is δ, to tuned signals of wave-length given by n and speed by T. On account of the shaping of the signals we have

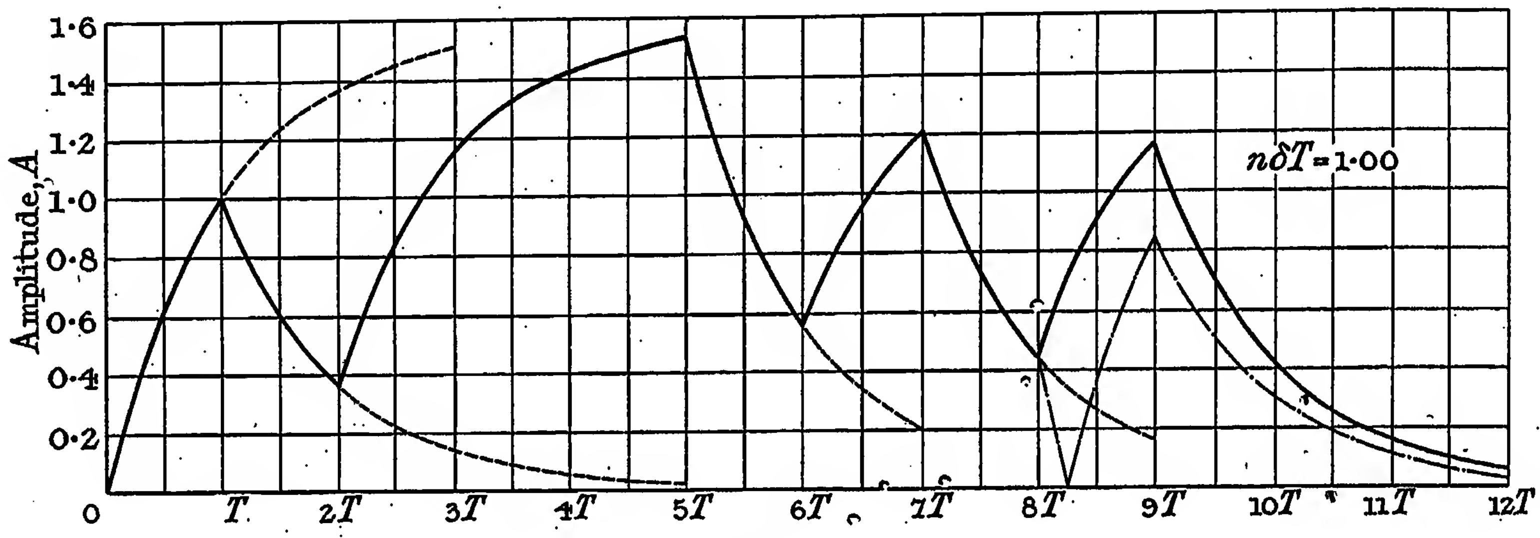

FIG. 8.

Where precisely to draw the line must be somewhat a matter of personal judgment. It is quite clear, however, that $n\delta T = 1{\cdot}0$ is too low, that $n\delta T = 1{\cdot}5$ is far from perfect, and that $n\delta T = 2{\cdot}0$ would give very readable signals. For the purpose of this paper, 2 is taken as the minimum permissible value of $n\delta T$ for any wireless recording, and this is done without reference to sensitiveness. On this basis, however strong the transmitter, $n\delta T$ must not be less than 2 if good signals are to be recorded. A few selected sets of values of wave-length, speed and decrement for which $n\delta T = 2$, are given in the first three columns of Table 1.

(4) *Power and speed of signalling.*—Table 1 illustrates how, for any specified wave-length and speed, we are limited in reducing the decrement of the receiving circuit by consideration of the shaping of the recorded signals. That as low a decrement as the shaping will allow is desirable, despite the modern facilities for almost unlimited amplification, is obvious when we reflect that the amplitude produced by an atmospheric or a distuned interfering signal is almost independent of the decrement, whereas the amplitude from the tuned signal E.M.F. increases as the decrement is reduced. The signal effect, however, is not linearly proportional to the reciprocal of the decrement (except at indefinitely

found that $n\delta T$ must not be less than 2, so that the optimum sensitivity is

$$S_0 = a\,\frac{1 - \epsilon^{-2}}{2/(nT)} = 0{\cdot}43\;anT$$

Therefore $$\frac{S}{S_0} = \frac{1 - \epsilon^{-n\delta T}}{0{\cdot}43\,n\delta T}$$

This ratio S/S_0 (viz. ratio between actual sensitiveness of receiver and sensitiveness when the decrement is reduced to its minimum permissible value at that wave-length and speed), is plotted as a function of $n\delta T$ in Fig. 9. At any given wave-length and speed, a decrement lower than $2/(nT)$ gives bad shaping, while any higher decrement reduces the sensitiveness to a fraction shown by the curve.

With the aid of Fig. 9, we can extend Table 1 to show, in the several numerical examples taken, the higher values of the decrements which reduce the sensitivities S from the optimum S_0 to (say) ·75 per cent and 50 per cent of S_0. This is done in the last two columns of Table 1.

To attach correct importance to the fall in S as the decrement is raised, it must be remembered that the

power required at the transmitter is proportional to the square of $1/S$. The minimum power, P_0, which at any given wave-length is competent to give a certain speed of working, is therefore proportional to the square of that speed, for

$$P_0 \propto (1/S_0)^2$$
$$\propto \left(\frac{1}{0\cdot 43\, anT}\right)^2$$

Some of the results at which we have arrived may be presented in numerical form by tabulating the relative transmitter powers for various speeds of signalling at

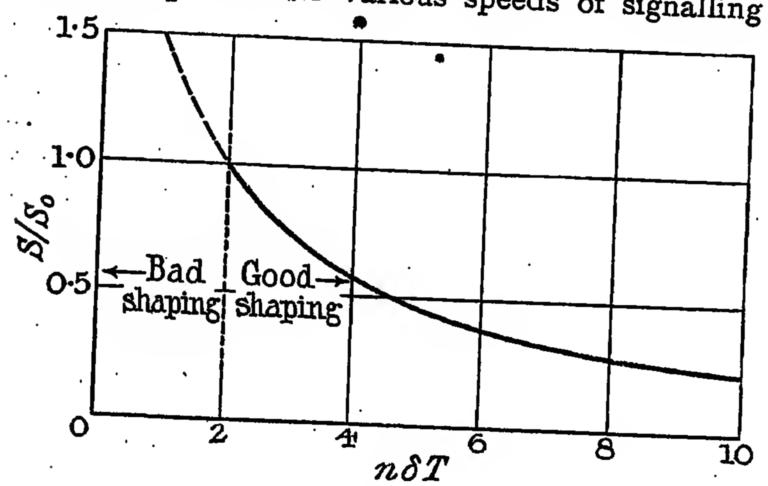

FIG. 9.

several specified *constant* decrements. This is done in Table 2 for the three wave-lengths already used in Table 1. The figures are arrived at as follows. At any one wave-length let P be the transmitter power producing in the receiver the E.M.F. E, which excites the oscillation actuating the relay when the amplitude A_0 is reached. Then

$$P \propto E^2$$
$$= KE^2 \text{ (say)}$$

where K is the transmitter power which produces unit E.M.F. in the receiving circuit at the particular wave-length. K is a factor depending upon the transmitter, the propagation between the stations, and the receiving aerial; it varies (in general) with the wave-length, but is independent of the speed of signalling and decrement of the receiver. Now we have seen that

$$E = A_0 \times \frac{2nL}{a} \times \frac{\delta}{1-\epsilon^{-n\delta T}}$$

Therefore

$$P = KE^2 = K\left(A_0 \times \frac{2nL}{a}\right)^2 \times \frac{\delta^2}{(1-\epsilon^{-n\delta T})^2}$$
$$= \frac{P_1}{(0\cdot 01)^2} \times \frac{\delta^2}{(1-\epsilon^{-n\delta T})^2} \quad \text{(say)}.$$

where P_1, the power required for low speed at $\delta = 0\cdot 01$, is used as a convenient arbitrary standard of reference.

Then
$$\frac{P}{P_1} = \frac{10^4\delta^2}{\left(1-\epsilon^{-\frac{1\cdot 25 n\delta}{w}}\right)^2}$$

where w = speed in words per minute = $1\cdot 25/T$.* From this expression the values of P/P_1 given in Table 2 have been calculated for speeds between 5 and 200 words per minute at the three decrements 0·01, 0·003 and 0·001.

(5) *Summary and discussion of results.*—We have seen that with long waves and fairly high speeds of signalling on the Morse code it may readily happen that the received current amplitude is far from the sensibly "square-topped" shape met with in land-line telegraphy and in early wireless practice; that the shaping depends on the product $n\delta T$ only, and that $n\delta T = 2$ is about the border line between bad and good shaping. At any wave-length, therefore, the higher the speed of signalling the higher is the smallest permissible decrement. The sensitivity, S, of the receiver (to the tuned

P = transmitter power at speed and decrement stated.
P_1 = transmitter power at low speed with $\delta = 0\cdot 01$ at wave-length stated.
Figures in brackets are for speeds higher than the maximum for good shaping ($n\delta T = 2$).

continuous-wave signal E.M.F.), instead of being sensibly inversely proportional to the decrement δ is found to be a function again of $n\delta T$, viz.

$$S \propto \frac{1 - \epsilon^{-n\delta T}}{\delta}$$

and similarly the transmitter power, P, required, instead of being sensibly proportional to δ^2, is

$$P \propto \frac{\delta^2}{(1 - \epsilon^{-n\delta T})^2}$$

Since, however, $n\delta T$ may not be less than about 2 (and then $1/(1 - \epsilon^{-n\delta T})^2 = 1 \cdot 34$), it follows that, with any specified wave-length and decrement, the power required to give the maximum speed is only some 34 per cent higher than the power for indefinitely low speed. It is, however, already a common experience in wireless operation that higher speeds sometimes require much higher power, and this is explained in the terms of our analysis by its implication that at a given wave-length the same decrement should not be used for low and high speeds. A rise in speed calls for a rise in decrement, to preserve the shaping; and it is this accompaniment of the augmented speed which is mainly responsible for the increase of power required.

It has been assumed that the signal E.M.F. impressed in the low-decrement receiving circuit is of sensibly square-topped shape. This cannot in fact be the case, because the inertia phenomena we have been studying at the receiver must also occur at the transmitter, though probably in less pronounced degree. The effect of the neglected transmitter inertia could probably be allowed for fairly accurately by applying a suitable fractional multiplier to the actual receiver decrement; thus if we find, with square-topped incoming E.M.F., that $n\delta T$ may be reduced as far as 2, with the actual E.M.F. the corresponding minimum permissible value would certainly be greater than 2 (though probably less than 4).

Most receivers comprise more than one circuit tuned to the signal, e.g. the antenna followed by one or a succession of circuits associated in series. Usually one circuit has its decrement maintained much lower than the rest, in which case our analysis may be applied with substantial accuracy to that circuit. Where, however, a succession of two (or more) lowly damped circuits is used, even a square-topped E.M.F. in the antenna may produce in the second (and subsequent) lowly damped circuits an E.M.F. far from square topped. The present single-circuit analysis is then not accurately applicable.

The bad effect on the shaping of the recorded signals of the too large residuum of amplitude at the end of a space suggests two ways of improving the signalling conditions. One is to transmit a curbing signal during the whole or part of a space, the transmitted dot or dash being ended, not by mere cessation, but by a change of phase of 180° in the aerial oscillation. This would be somewhat analogous to curbed-signal working in submarine cables. The idea might be carried further in making the latter part (or the whole) of the transmitted dash weaker than the dot, so as to reduce or remove the inequality between $\dot{A}$ and $\bar{A}$ (Fig. 5). Another form of curbing, easier to accomplish though perhaps less effective in theoretical possibilities, may be applied at the receiver. This method is examined in Part II of the paper.

Thus far only the recording of Morse signals by some form of relay has been mentioned. The receiver transients at the beginning and end of a signal are in some circumstances of vital importance, also in the low-speed reception of Morse signals, and obviously in telephony. When a receiver is so fitted up that very fine control of tuning and retroaction is obtained, the decrement can be pushed to and held at so low a value that marked "ringing" of the signals heard in the telephone is observed, even at wave-lengths of only a few thousand metres. However low the signalling speed may be, the bad definition at the beginning and end of the dot or dash so distresses the ear of the operator that further reduction of decrement, despite some increase in signal strength, does not help him to distinguish the signals. Measurements of these very low decrements—which are not easy to determine experimentally—are now in progress at Cambridge, and will, I hope, be published shortly.

Part II.—Receiver Curbing.

(6) *The process of curbing.*—When once the amplitude during a dash has reached the operative value A_0,

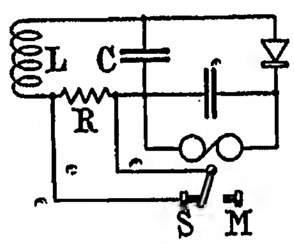

Fig. 10.

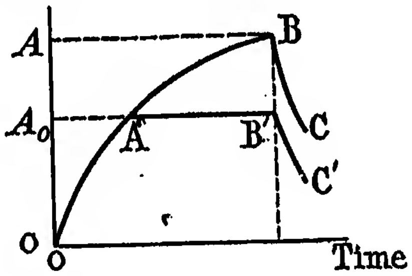

Fig. 11.

nothing is gained by allowing it to rise further; while in so far as it does rise further the residuum at the end of the subsequent space becomes more troublesome. Since the relay closes or opens a contact as soon as the operative amplitude is reached, it is feasible to make it introduce automatically at this instant additional impedance—preferably resistance—into the circuit, so curbing further growth of amplitude. Thus in Fig. 10, LC is the low-decrement receiving circuit, and contains a resistance, R, which is short-circuited when the relay spaces but is not short-circuited when the relay marks. As soon, therefore, as the operative amplitude has been reached, further growth is checked by the increase of decrement introduced by R; and if R is of suitable value the amplitude can be thereafter maintained at or just above the operative amplitude, and this whether the mark constitutes a dot or a dash of any length. The amplitude then follows the curve OAB'C' (Fig. 11) instead of OABC, and the conditions during the space following a dash are no different from those during the space following a dot. The advantage as regards uniformity is obvious.

If the curbing action is suitably prolonged, so that the resistance R (Fig. 10) remains in circuit during a considerable part of the space following the mark,

there is the further advantage that the amplitude falls more rapidly during the space than it otherwise would. It would be possible to arrange for this in Fig. 10 by utilizing well-known devices to make the relay dwell on its marking contact, and providing a separate relay for actuating the recorder; but other methods, of the type described with reference to Fig. 15, are also feasible.

(7) *The improvement obtainable.*—The improvement in terms of speed and power conferred by curbing will be greatest when the amplitude is curbed precisely to the operative value A_0; when the decrement of the circuit apart from curbing is negligible; and when the added decrement is retained throughout sensibly the whole of the space. Retaining, as in Section (2), the symbol $\dot{A}$ for the uncurbed amplitude at the end of during the curbed part of the mark

$$A = A_0;$$

and during the space

$$A = A_0\epsilon^{-n\delta_c t}$$

where t is measured from the beginning of the space and $\delta_c = 1/(\alpha nT)$.

When $\alpha = 0 \cdot 60$, our test letter "1" is shown in Fig. 12; and when $\alpha = 0 \cdot 75$, in Fig. 13. The signals are clipped as regards the marks; for with this curbed working the ends of the marks synchronize precisely with the rise of the key at the transmitter, whereas the beginnings are necessarily delayed. But, as already pointed out in reference to the uncurbed working, this

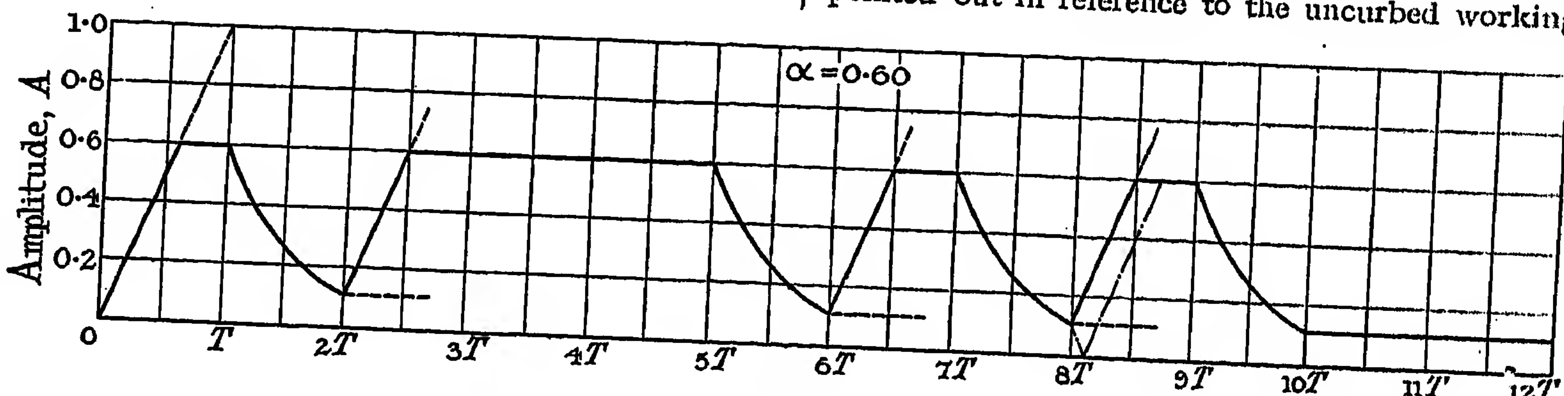

Fig. 12.

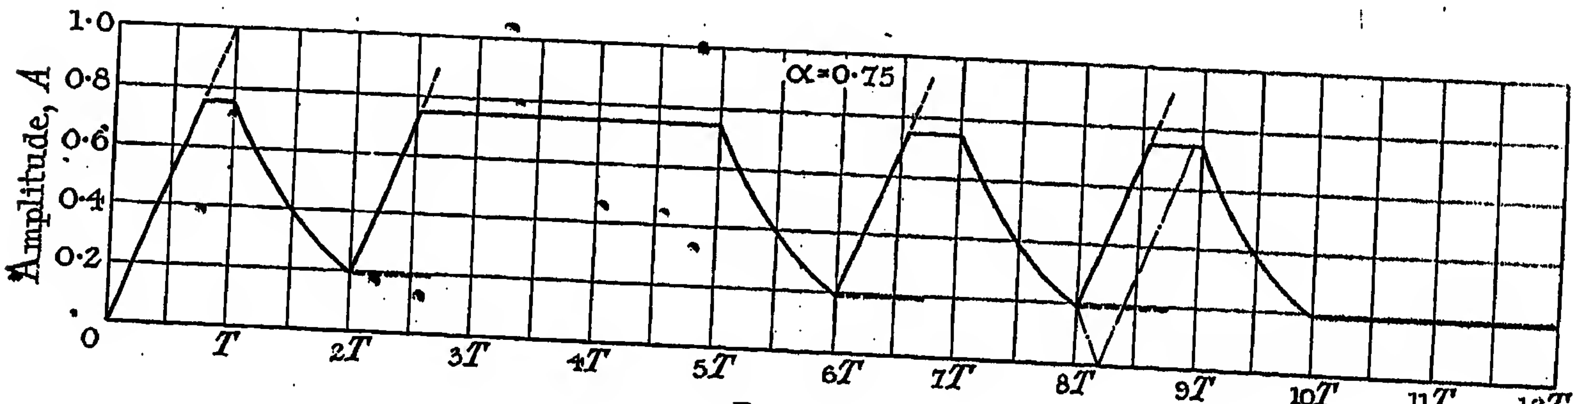

Fig. 13.

a dot, $A_0 = \alpha\dot{A}$, and writing δ_c for the decrement introduced by the curbing action, we have

$$\dot{A} = \lim_{\delta=0}\frac{E}{2nL} \times \frac{1-\epsilon^{-n\delta T}}{\delta} = \frac{E}{2L}T$$

$$\dot{A}_s = \bar{A}_{s_0} = A_0\epsilon^{-n\delta_c T} = \alpha\dot{A}\epsilon^{-n\delta_c T} = \frac{\alpha E}{2L}T\epsilon^{-n\delta_c T}$$

Now to keep amplitude constant at A_0 after curbing begins, δ_c must be given the value making

$$A_0 = \frac{E}{2nL} \times \frac{1-\epsilon^{-n\delta_c t}}{\delta_c} \quad \text{when } t = \infty$$

$$= \frac{E}{2nL\delta_c}$$

Therefore

$$\delta_c = \frac{E}{2nLA_0} = \frac{1}{\alpha nT}$$

During growth, therefore, $A = \dfrac{E}{2L}t$

where t is measured from the beginning of the mark; does not impede the reading of the tape; the shortening is the same in absolute amount for dot and dash; and moreover, the dot as recorded could be lengthened artificially if desired.*

The higher α is made, the greater is the sensitivity of the receiver, but the more pronounced becomes the discrepancy between a first and a subsequent dot. For the purpose of comparison with uncurbed working, some examples of uncurbed and curbed records, judged of equally good quality, must be compared. For this purpose Fig. 6 and Fig. 12 are taken as equally good and of high quality, and Fig. 7 and Fig. 13 as equally good though of poor quality.

For Fig. 6 we found [Section (4)]

$$\frac{E}{A_0} = 2nL \times \frac{\delta}{\alpha(1-\epsilon^{-n\delta T})} = 2L \times \frac{1}{0 \cdot 303\, T}$$

(because $n\delta T = 2$ and $\alpha = 0 \cdot 70$)

* It is interesting to reflect that Morse signals would theoretically be very nearly wholly determinate even if nothing were known of them except the instant of termination of each mark; the only ambiguity being that 4 units of interval might signify either a short space (1) followed by a dash (3), or a letter space (3) followed by a dot (1). The instant of termination is recorded accurately in our curbed régime.

For Fig. 12 we have found

$$\frac{E}{A_0} = 2nL \times \frac{1}{\alpha nT} = 2L \times \frac{1}{0 \cdot 60\, T}$$

(because $\alpha = 0 \cdot 60$)

Hence for equal speeds

$$\frac{\text{power, uncurbed}}{\text{power, curbed}} = \left(\frac{0 \cdot 60}{0 \cdot 303}\right)^2 = 4 \cdot 0$$

or for equal powers

$$\frac{\text{speed, curbed}}{\text{speed, uncurbed}} = \frac{0 \cdot 60}{0 \cdot 303} = 2 \cdot 0$$

Taking good signals in each case, therefore, the curbed régime shows a marked superiority over the uncurbed.

The comparison between Fig. 7 and Fig. 13, calculated in precisely similar fashion, is as follows. For equal speeds

$$\frac{\text{power, uncurbed}}{\text{power, curbed}} = \left(\frac{0 \cdot 75}{0 \cdot 39}\right)^2 = 3 \cdot 7$$

and for equal powers

$$\frac{\text{speed, curbed}}{\text{speed, uncurbed}} = \frac{0 \cdot 75}{0 \cdot 39} = 1 \cdot 9$$

Hence, comparing equally good signals of inferior quality, nearly the same superiority is shown by the curbed over the uncurbed régimes.

(8) *Application to working conditions.*—In actual working it is not possible wholly to satisfy either of the ideal conditions assumed in the last section; viz. zero decrement until the curbing is applied, and curbing retained during just the whole of the space between marks. The importance of these practical departures from the ideal régime is now examined.

During a mark before curbing the amplitude grows with time as

$$A = \frac{E}{2\,L} \times \frac{1 - \epsilon^{-n\delta t}}{n\delta}$$

whereas if $\delta = 0$ it grows as

$$A = \frac{E}{2\,L}\, t$$

These two growths are plotted in Fig. 14. The amplitudes diverge considerably—say by more than 5 per cent—only when $n\delta t$ exceeds (say) $0 \cdot 155$. If the operative amplitude is reached at $t = 0 \cdot 60\, T$ as in Fig. 12, the divergence is thus unimportant if

$$n\delta \times 0 \cdot 60T < 0 \cdot 155$$

i.e. $$\text{if } \delta < \frac{0 \cdot 26}{nT}$$

Hence at (say) 100 words per minute ($T = 0 \cdot 0125$ sec.) there is no important distinction to be made between decrements of zero and

$0 \cdot 00007$ when $\lambda = 1\,000$ m
$0 \cdot 00035$ when $\lambda = 5\,000$ m
$0 \cdot 0014$ when $\lambda = 20\,000$ m

If it is not practicable in any particular case to obtain such a low decrement as is sensibly equivalent to zero according to the above relation, a correction for the divergence of the two lines in Fig. 14 should be applied. Thus at 100 words per min. when $\lambda = 5\,000$ m if, for example, $\delta = 0 \cdot 001$ instead of zero (or $< 0 \cdot 00035$), the E.M.F. would have to be increased

$$\frac{0 \cdot 60\, n\delta T}{1 - \epsilon^{-0 \cdot 60\, n\delta T}} = \frac{0 \cdot 45}{1 - \epsilon^{-0 \cdot 45}} = 1 \cdot 24 \text{ times}$$

that is, the transmitter power would have to be increased $(1 \cdot 24)^2 = 1 \cdot 54$ times, so reducing the ratio (power, uncurbed)/(power, curbed) from $4 \cdot 0$ or $3 \cdot 7$ to about $2 \cdot 5$. It may well be that with wave-lengths such as 5 000 m and under, it is not feasible to use the indefinitely low decrements, and some such allowance is necessary. But with long waves, such as 10 000 m and upwards, the indefinitely low decrements of the ideal régime seem to be realizable.

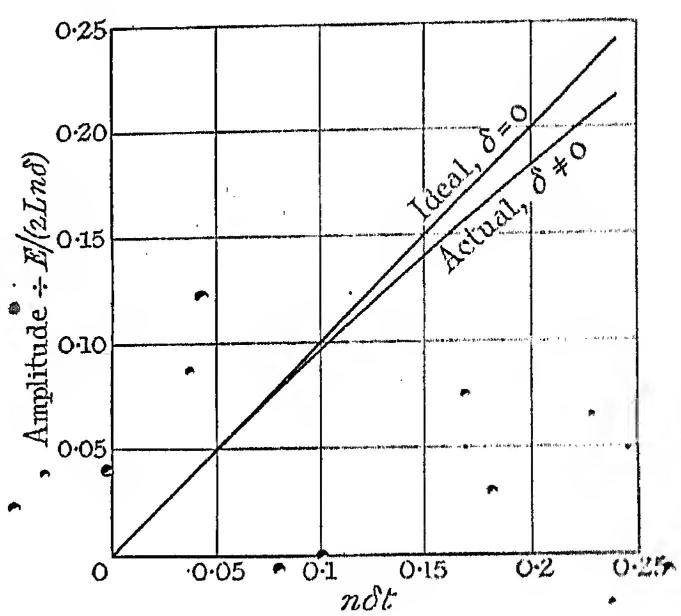

FIG. 14.

The retention of full curbing throughout sensibly the whole of the spacing epoch between marks does not present much practical difficulty, and one way of effecting it electrically is shown in Fig. 15. When the amplitude in the oscillatory circuit LC has grown to the operative value, the relay tongue moves from S to M. While it was at S the grid potential of the curbing triode was $-b_1$ (where b_1 is the E.M.F. of battery B_1), which is sufficient to prevent the coupling M_1 from introducing any damping into LC. On contact being made between tongue and M, the grid potential immediately rises to $-(b_1 - b_2)$, thereby allowing anode current to flow in the curbing triode and damping LC to an extent controllable by M_1. When the incoming signal ceases, the tongue returns to S, and the potential of the grid falls towards $-b_1$ according to the expression

$$-(b_1 - b_2)\,\epsilon^{-\frac{t}{C_1R_1}}$$

These changes are portrayed in Fig. 16. A transmitted mark starts at O and ends at B. At A the relay moves to mark, and at B returns to space. During the space, full damping obtains from B to C, because the triode is operating on the straight, steep, part of its charac-

teristic curve. From C until the end of the space D there is a short transition epoch corresponding to the change, FG, of grid potential. When the grid potential is lower than OG, the damping is sensibly nil. At D the transmitter comes on again, actuating the relay anew at E. By making both b_1 and b_2 large enough, we cause the transition range FG to be swept through as quickly as desired.

With any chosen voltages b_1, b_2 and b_3, the grid is made to pass through the transition range of potential FG at the right time by adjustment of the time-constant C_1R_1. This, therefore, is an adjustment which must be altered when the speed of signalling is altered, but it depends on that alone. There is one other adjustment dependent on the speed of signalling, viz. the mutual

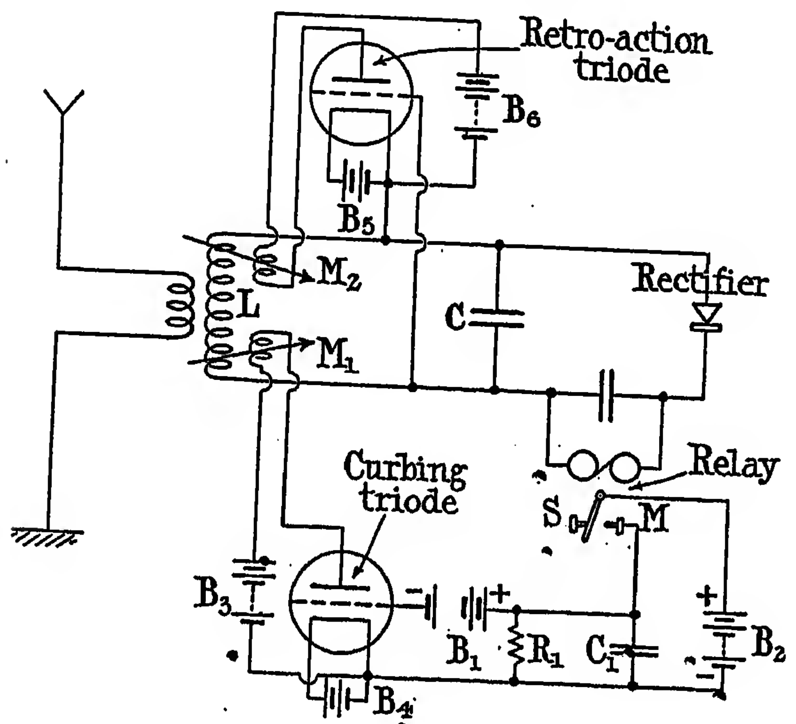

FIG. 15.

inductance M_1, which must be set to give the correct damping

$$\delta_o = \frac{1}{anT}$$

In Fig. 15 is shown for the sake of completeness a retroaction triode with variable mutual inductance M_2 for reducing the uncurbed decrement of LC to a suitably low value. The rectifier shown without detail would, of course, ordinarily be a thermionic triode rectifier, with some form of amplifier between it and the relay. The six batteries B_1 . . . B_6 are all shown separate for the sake of simplicity of diagram. In practice only three batteries would be wanted, viz. ($B_2 = B_3 = B_6$) in common, ($B_4 = B_5$) in common, and B_1. If the well-known "R" pattern of triode were used, suitable voltages might be about

$$b_2 = b_3 = b_6 = 120\text{ V}$$
$$b_4 = b_5 = 3\cdot 6\text{ V}$$
$$b_1 = 120\text{ V}$$

With these values, the transitional grid-potential range FG would be about -10 to -15 V, so that the time-constant C_1R_1 would be adjusted to make the grid potential fall from 0 to -15 V in time T (from B to D in Fig. 16). At 100 words per minute, therefore,

$$-[120 - 120\,\epsilon^{-0\cdot 0125/(C_1R_1)}] = -15$$

i.e.
$$0\cdot 0125/(C_1R_1) = 13$$

or $C_1R_1 = 0\cdot 1$ (say $C_1 = 1\mu$F and $R_1 = 0\cdot 1$ megohm).

The time CD covering the range FG = 5 V is then about 0·004 sec., which is probably sufficiently brief.*

It is not suggested that the particular arrangement of Fig. 15 is the best means of realizing the curbed régime we have studied; it illustrates one of various

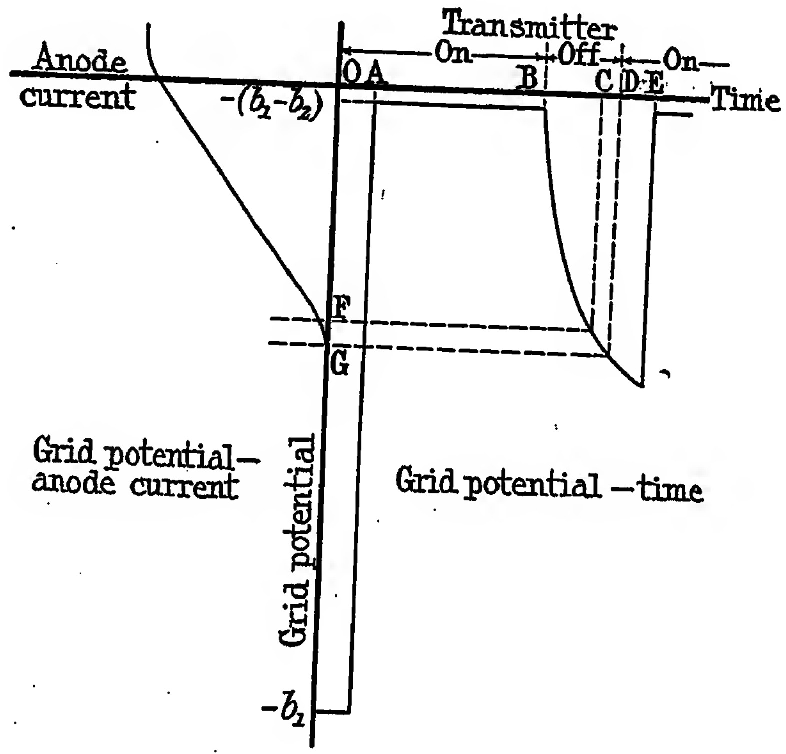

FIG. 16

possible means to that end. The various relaying and recording devices already applied to cable telegraphy would provide alternative schemes. The author's primary concern in Part II of the paper is to point out that the curbed régime offers important advantages over the uncurbed, and appears to be a practicable system. Despite the difficulties introduced by atmospheric disturbances and opacity—in some degree, because of them—the wireless art is now reaching a maturer stage in which the working speed is becoming as direct a measure of the worth of a wireless route as it is of the worth of a cable route. The time is ripe, technically and economically, for higher speeds. It may well be, as Dr. Eccles has recently suggested,† that this advance will ultimately involve a radical change in the type of signal transmitted; meanwhile, leaving the costly transmitter as it is, we shall do well to procure from the humble receiver the best service that an understanding of the latter's functions can command.

* The presence of full damping during the final stages of the space is, of course, of less consequence than during the initial stages. Thus in Fig. 12 the fall in amplitude during the first fifth of the space is 0·170, and during the last fifth is 0·044.

† "Studies from a Wireless Laboratory": discourse delivered at the Royal Institution, 18th April, 1923.

Discussion before the Wireless Section, 5 December, 1923.

Major A. G. Lee: The paper comes at a very opportune time, seeing that the problems of high-speed wireless telegraphy are very closely associated with the successful commercial operation of high-power stations. The practice has grown up, following the lead set by the American group of telephone engineers, of referring to a receiver in terms of the width of its resonance curve or band. This bears a definite relation to the operation it has to perform, viz. the reception of a carrier wave, modulated telegraphically at a certain speed. It may, therefore, be of interest to compare this view-point with that outlined in the paper. It is well known that a square-topped telegraph signal can be resolved into a Fourier series consisting of a fundamental sinusoid together with a number of harmonics. If, now, we neglect the harmonics as being relatively unimportant and suppose a carrier wave to be completely modulated by the fundamental of the telegraph signal, we obtain as the product the carrier wave together with two side frequencies, each differing from the carrier frequency by the amount of the fundamental of the telegraph signal. In order to receive this signal without appreciable distortion, the receiver must have a resonance curve wide enough to admit a band equal to twice that of each side band. If the dot frequency of the telegraph signal is $1/(2T)$, the side frequencies will be $n + [1/(2T)]$ and $n - [1/(2T)]$, and the width of band necessary for approximate distortionless reception will be $1/T$. Now $n\delta$ is twice the width of the resonance curve at the point where $I = 0\cdot 54 I_r = 2(1/T)$, i.e. $n\delta T = 2$. So that, neglecting harmonics of the fundamental, which will to some extent contribute to the shape of the received signals, this criterion that the receiver should have a band width of $1/T$ is the same as the author's condition of $n\delta T = 2$, for the case where the width of the resonance curve is taken at $I = 0\cdot 54 I_r$. Modern receiver practice tends towards a vertical-sided resonance curve, so as merely to include the side-band frequencies required and nothing else, and in practice there is considerable departure in shape from the theoretical resonance curve given in Fig. 3, which has a narrow top and wide feet. There may be some advantage in having a receiver with two peaks with a hollow in the middle, as this would compensate to some extent for the distortion produced by the antenna resonance curve at the transmitting end. It is well known that if one has a multi-stage tuned high-frequency amplifier, or a multi-stage tuned note amplifier the more stages one adds the narrower becomes the resonance curve of the whole apparatus. If one could start off with a square-topped wave in the transmitting antenna, the receiver may reduce its band to $1/T$, but in practice the low-decrement transmitting antenna comes in as part of the chain, starting from the square-topped telegraph signal at the transmitting key and finishing at the receiving telephone. With the low-decrement transmitting stations in use at the present time it is probable that the transmitting end is equivalent to 2 or 3 stages in this chain, so that for a given $1/T$ the receiver band has to be widened considerably to allow for the fact that part of the low-decrement effect has been used up at the transmitting end. In other words, the narrower we make the band received the more distortion there is. Therefore, if we have distortion at the transmitting end, the receiver must have relatively less distortion, so that the overall distortion comes within the allowable amount corresponding to the author's criterion of $n\delta T = 2$. The disadvantage of widening the receiver band is that atmospherics are let into the chain at an intermediate point, viz. between the transmitter and receiver, and hence do not have the whole battery of low decrements available against them. It is not, perhaps, sufficiently widely recognized that by the use of different marking and spacing waves the transmitting antenna can be made to change instantaneously at full amplitude from one frequency to another, giving the much-desired square-topped wave in the antenna. The use of this system would permit of a narrower band being employed at the receiver, with consequent greater selectivity against atmospherics. The suggestion to employ curbing at the sending end, or to signal by change of phase of 180 degrees, is of interest. I considered this proposition some time ago, but came to the conclusion that there were many difficulties, and that the current in the antenna would not present the square-topped outline that it does with the marking and spacing wave system. In any valve transmitting system in which the aerial is allowed to have any coupling whatever with the master oscillator, it will control the frequency of oscillation to some degree. If, now, the phase of this control is altered by 180° suddenly, violent frequency and amplitude fluctuations are liable to be produced. With regard to the suggestion to employ curbing at the receiving end, I am rather doubtful as to its effect, because the wireless problem differs from the cable problem in that atmospherics are present as well as signals. In the curbing system proposed, the decrement is increased over a considerable portion of the telegraphic cycle, a process which inherently renders the system more liable to attack from atmospherics. An alternative form of curbing would be to put the whole system out of action momentarily at the conclusion of a mark, by short-circuiting all the condensers of the set, after which the receiver would resume its normal low-decrement operation. On one point mentioned by the author, viz. the constancy of transmitter frequency, I should like to add some details: For a speed of 100 words per minute a band width of 80 periods for the whole chain (transmitter to receiver) is necessary. Now if the transmitter varies in mean frequency the receiver has to be tuned with a wider band to allow for these variations. I have had measurements made of the variation of frequency of existing stations, and find that the variations are approximately as follows, depending to some extent upon wind and weather conditions at the transmitting station:—

	Variation in frequency, p.p.s.
Most-constant alternators	10
Less-constant alternators	30
Separately-excited valve sets ..	30
Plain aerial valve sets	50
Plain aerial arc sets	160

The handicap due to this cause in receiving 100 words per minute is fairly obvious. There is no reason why the separately-excited valve set should not improve upon the figure given, but it demands perfect screening of the master oscillator from the effects of the aerial swinging, as well as good design in the oscillator itself and the voltages supplied to it. Another cause of variation in width of band in the case where note tuning is employed, lies in the local heterodyne at the receiving end. It is equally important that this shall be free from variation of frequency, and the causes of variation are the same as those affecting a transmitting oscillator.

Mr. E. B. Moullin: The paper is very interesting to me because it imposes a lower limit on the decrement of circuits for which n and T are fixed. Early next year I shall be reading a paper before the Wireless Section on "Atmospherics and Their Effect on Wireless Receivers," in which it will be shown that for slow signalling the best way to reduce the effect of atmospherics is to reduce the decrement indefinitely. If the speed of signalling is taken into account, but no regard paid to the shaping, it can be shown that a circuit for which $n\delta T = 1$ is about 40 per cent more immune from disturbance than one for which $n\delta T = 2$, and that there is little to be gained by reducing $n\delta T$ below, say, $\frac{1}{2}$. If $n\delta T$ must be greater than 2, I think that the transmitter power will have to be increased by more than is calculated in the paper, in order that the signals may still hold their own against atmospherics. If, as the author suggests, the transient effect of the transmitter may force us to keep $n\delta T$ greater than 4, it will therefore necessitate a very great increase of power. It seems important to examine whether $n\delta T$ is limited to 2 or 4, and I have attempted to calculate how much the transmitter will affect the shaping. As I have had no time to work out the problem in terms of the constants of the transmitter, I have supposed that the received E.M.F. is given by $e = E(1-\epsilon^{-bt}) \sin pt$ while the transmitting key is depressed, and by $e = E'\epsilon^{-bt} \sin pt$ after the key has been raised. Both the rise and the fall of current will then be delayed more than is considered in the paper. For instance, if $n\delta T$ equals 2 and 4 for receiver and transmitter respectively, I find that the first dot leaves a residue which is 50 per cent greater than if the received E.M.F. had been square-topped: the dot is also more displaced and slightly more clipped. Transmitting antennas of recent construction have very small decrements; $n\delta T$ may be approximately equal to 4 and then the shaping would not be good in a receiver for which $n\delta T = 2$. A small transmitter decrement will necessitate an increase of power in addition to the 34 per cent which has to be added because of the receiver decrement, for we must make the transmitter power sufficient to force the transmitter current up to a specified amount in a given time. If $n\delta T = 2$ both for transmitter and receiver, we should have to increase the power by 75 per cent in order to get operating signals, and we must then provide a further margin of power so as to obtain satisfactory shaping. The transmitter decrement must still be considered when we are using a "curbed receiver," for even if its decrement is zero when uncurbed the current will not rise uniformly and, after curbing, it will fall at a rate that depends mainly on the transmitter. A great improvement would be effected if we could curb the transmitter. To obtain good shaping with the curbed system presented in the paper it may be necessary that the transmitter should have $n\delta T > 2$. Much of the bad shaping is caused by the dash lasting longer than the dot; since the current rises to a higher value during a dash than during a dot it leaves a much bigger residue on which to build the ensuing sign. If we shorten the transmitted dot I think that we shall get a received record which is a much closer approximation to standard Morse. I have shortened a dash from three units of time to two and have drawn out the letter "l" as received in a circuit for which $n\delta T = 1 \cdot 5$ (see Fig. A). For ease of comparison the record of Fig. 6 of the paper is reproduced in the upper part of my figure (the dash of Fig. 6 has been reduced so as to bear the same ratio to the first dot as that obtaining in my record). The quality of the shaping appears to me to be equal to that of Fig. 6, and I think that the ratio of dot to dash makes it a better approximation to correct Morse. The clipped dash provides a simple method of lowering the limit of $n\delta T$ from 2 to $1 \cdot 5$, and it is also equivalent to a certain increase of signalling speed. Many of the difficulties caused by transmitter and receiver decrement

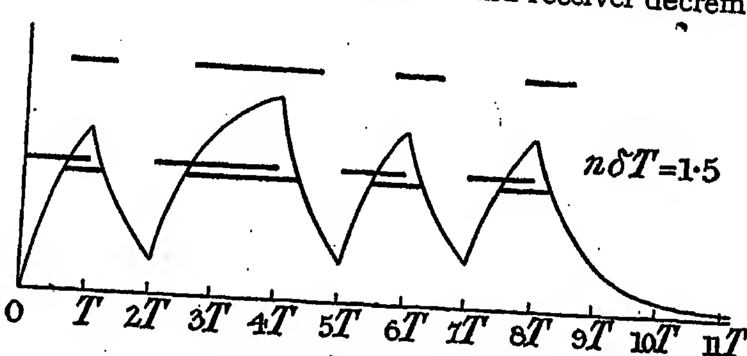

FIG. A.

might, I feel, be overcome by transmitting dots and dashes of equal duration but on slightly different wave-lengths. Two receivers would be used, one for dashes and one for dots, and the two recorders would be arranged to mark in parallel lines on the same tape. If the change of wave-length from dash to dot or space is made small the transient effect at the transmitter will be very small, especially if the change can be made at the instant of zero current. The average space between the marks on either receiver will be greater than with the present system and neither receiver is called upon to register marks of varying duration. The space between a dot and a dash is not required, and that combined with a short dash is equivalent to a great increase of speed. The letter "l" as recorded with the suggested system would appear on the tape thus: —_— —. The letter "l" now occupies 8 instead of 12 units of time, and the word "Paris" will occupy 30 units instead of 41. I am of opinion that the system which I have outlined would permit of the use of very small decrements, and for a given decrement an increase of 25 per cent in the signalling speed. It may also be noticed that with low-speed signalling almost perfect secrecy could be obtained by widely separating the dot wave-length from the dash wave-length; even though the dots of the desired message

could be picked up it would be necessary to search through every other detectable message in order to pick up the missing dashes.

Professor G. W. O. Howe: It seems a great pity that, having escaped from the serious limitations of the submarine cable by being provided with a medium and method of signalling which obviate all the troubles due to the conductor resistance and the specific inductive capacity of the gutta-percha, we introduce very similar limitations by the design and operation of our receiving apparatus. On comparing a figure like Fig. 8 with the ordinary siphon records from which submarine cable operators have to read, one would be inclined to call it a very good signal. Nobody looking at that curve could mistake it for anything else but an "l." As I have sat here this evening the idea has been forced on me that we are adopting a fundamentally wrong method of reading these signals in having to use non-proportional apparatus which is only operated by currents exceeding a certain limiting value. If we could only get that zig-zag signal of Fig. 8 reproduced in some way by some siphon recorder, even badly, we should still get signals enormously better than those that the submarine cable operators consider good. Those familiar with an ordinary submarine cable tape will know that the dots and dashes vanish entirely from the signal as recorded. The operator reading the letter "h," for instance, sees no sign of the four dots. He merely knows that there were four dots there because there is a hump which looks about four dots long. It seems to me that research should be directed to the development of some recording apparatus which will work in a somewhat similar manner to the siphon recorder and give a record of the "humps" in Fig. 8.

Mr. J. E. Taylor: In Part II, in connection with curbing, the author proposes to introduce a resistance into the receiver circuit which is normally short-circuited by the tongue of a relay on the spacing stop. He says that it is necessary to bring the current up to the marking value, and for making a dash, for instance, to retain it at that value until the dash has terminated. In my view it is not necessary to retain the current at the same value as that which is required to detach the relay tongue from the spacing stop. In operating a relay a certain strength of current is required to throw the tongue over, but usually a very much smaller current will retain the tongue on the marking stop. I think, therefore, that the author might very well allow his decremental resistance to become operative at the beginning of his signal. The delay action introduced in the diagram shown in Fig. 15 is, in my opinion, not really necessary. These considerations also lead me to think that it would be advantageous, in spite of the difficulties at the transmitter, to try to do as much curbing as possible at the transmitter. This would result in less expenditure in power, and, in addition, the tendency to interfere with other stations would be reduced.

Mr. F. P. Best: Under the supervision of the author I have been engaged on the investigation of the so-called "optimum decrement of a receiver" under conditions which exist in ordinary low-speed telegraphy as received by an operator. In this investigation of the optimum decrement, experimental evidence alone must indicate the values to be expected, for it is not possible to apply mathematical analysis as in the case of automatic reception. The low decrements had to be produced in such a manner that they would remain constant for some considerable period of time—a thing not easy to accomplish. Not only had that to be done, but once having obtained these low decrements their measurement becomes a matter of considerable difficulty, because the decrement itself, where retroaction by means of a triode is used, varies considerably with the actual amplitude of the current in the low-decrement circuit. These two difficulties were, however, overcome and measurements of this optimum decrement were made on six wave-lengths. The actual optimum decrement chosen is that decrement which makes the signal most easy for an operator to distinguish, and is, of course, a compromise between the actual loudness of the signal and the amount of ringing that can be permitted. The wave-lengths considered varied from 4 350 m (Ongar) to 23 450 m (Bordeaux), and the optimum decrements ranged from about 0·0018 for Ongar to 0·0083 for Bordeaux. Thus if we select a rate of signalling of about 25 words per minute, which was approximately the rate at the moment these measurements were taken, we obtain a value for $n\delta T$ of about 5. That is to say, if an operator is to distinguish without much difficulty the signals which are being transmitted, a decrement cannot be allowed which will bring the value of $n\delta T$ lower than 5. Another thing that seemed worthy of notice in this investigation was the value of $n\delta$ itself. The precise value of T above (= 0·05 for a speed of signalling of about 25 words a minute) did not seem to make a great deal of difference to the value of $n\delta$ and probably if the speed of transmission dropped to more than half that rate the decrement could not be appreciably lowered, since it appeared that below a certain fixed decrement (dependent upon the wave-length) the amount of ringing made it quite impossible for the operator to distinguish the signal, however low the speed of transmission might be. This value of $n\delta T$ compares unfavourably with the figure of 2 suggested by the author; but when it is remembered that in the case of the relay we are dealing with an almost physically perfect instrument, and that in the case of the ear we are dealing with an instrument not by any means physically perfect, this discrepancy is not to be wondered at.

Mr. R. E. H. Carpenter: I entirely agree with Prof. Howe that the signals which the author regards as unrecordable are very excellent signals indeed. It does seem remarkable that with this striving after a low value for $n\delta T$ the expedient of using a proportional recorder not working between fixed stops has not been mentioned by the author. I have already emphasized here the importance, in my view, of using such a recorder from the point of view of discrimination between signal and atmospheric. If one uses a proportional amplifier and a recorder which is also approximately proportional, and gives some approximation to a time/current graph of what is being obtained from the receiver, one can do a very great amount of visual discrimination between signal and atmospheric on the tape. The present paper

seems to me to bring out clearly a further advantage of such a recorder.

Professor E. W. Marchant: I have had the opportunity of seeing Mr. Best's results, and I think that he has left out one most interesting thing in his contribution to the discussion. Not only has he managed to determine the optimum decrement, for the two stations that he mentioned, but he has also obtained them for three American stations.

Mr. C. F. Elwell: Before the days of the triode, I was using on some high-speed work a system known as the Pedersen system. That system was quite capable of transmitting and recording 200 words per minute, and it might be of interest if I gave a résumé of how receiving was done, in view of this figure of $n\delta T$. The receiver consisted of the ordinary oscillating circuit and a detector which consisted of a piece of graphite, usually lead pencil, and a piece of galena. The received current passed through an Einthoven string galvanometer consisting of very fine gold wire, part of which was smoked in order to give a larger shadow. The movements of the wire were recorded on photographic tape, and we carried out tests up to 200 words a minute, at wave-lengths of 2 000 to 8 000. The signals were quite square-topped when there were few atmospherics. The Pedersen system had to be entirely abandoned because we could not eliminate atmospherics. We later employed the three-electrode amplifier, which was developed about 1911, and did our recording on the telegraphone, another invention of Poulsen. The use of some of this old apparatus might be revived in view of the attempts to-day to get really well-shaped high-speed wireless signals.

Major H. P. T. Lefroy: It seems to me that the author is rather pessimistic in regard to possible speeds of signalling with circuits of normal damping. In 1919 the Signals Experimental Establishment worked from Aldershot to Woolwich at a speed of 700 words per minute, on a wave-length of about 1 000 m, and the signals were clear. For such a high speed the type of recorder used was one of those in which the receiving tape, impregnated with a compound of iodine, changes its colour when the received signals cause current to pass through it. With regard to very long wave-lengths, I have found no difficulty in working at a speed of 240 words per minute on a 50 km wave-length. That speed indicates a very high damping factor, if we use the author's formula $n\delta T = 2$, viz. $\delta = 0 \cdot 067$, which, since the inductance of the tuned circuit was about $0 \cdot 5$ henry, indicates an effective resistance of about 400 ohms; but such a resistance seems improbable, in view of the fact that, whilst desired signals were being recorded faultlessly on the tape, the receiving circuit was exposed to severe interference from Wheatstone automatic. The recorder that I was using then was of the trigger-amplifier type, which appeared to be a good type to use, because it was possible, by trial and error, to adjust the bias of the relay in such a way that the space (on the tape) for a "dot" and for a "space" was the same, and, when so adjusted, clear signals were recorded; by this method only the crests of the signals are recorded, and the curves of growth and of decay are not shown on the tape. I have been much impressed with the extraordinary parallels between the ideas in the present paper and those in Mr. Sutherland's contribution to the discussion on "Loud-Speakers" on the 29th November last at the Joint Meeting of this Institution and the Physical Society. Mr. Sutherland showed a graph of the sequence of syllables, in connection with reverberation and the absence of damping in a room. That graph was practically the graph shown on pages 195 and 196 of the present paper. He pointed out that, if a room is not sufficiently damped, the number of words per minute must be reduced to suit that room. He also pointed out how useless it was to increase the intensity of speech if a room was not sufficiently damped, to both of which ideas the author has been calling attention this evening in connection with high-speed signalling.

Professor C. L. Fortescue (*communicated*): To anyone who has given any consideration to the problems of high-speed reception the paper is full of interest. But I think that although little has been published on this subject, far more work has been done than the author's opening remarks seem to imply. I believe that experiments were carried out some years ago in which the resistance of a receiving circuit was so far reduced that hand-speed Morse was unintelligible with a wave-length of 15 000 m. Telephony practice has led to many people looking upon this problem from the "side-band" point of view, and this immediately suggests that one way in which it might be possible to use ultra-selective circuits would be to work with only one "side band" and to supply the "carrier wave" at the receiving station. The author has assumed an incoming signal of sinusoidal form, whereas actually it must be one of gradually increasing amplitude. This does not appreciably alter the numerical results with the low-decrement circuits. There is one aspect that the author has not considered, viz. signalling by very small frequency-changes. It would appear that the difficulties in the way of using very low decrements would be still more serious than in the case assumed in the paper. Finally, I should like to ask what is the object of using circuits of decrement $0 \cdot 0001$. The adjustment of the reaction is infinitely difficult, the gain in signal strength is unimportant and the immunity from shock interference is not large. In fact, the incoming signal is already a "shock" to such a system.

Mr. L. B. Turner (*in reply*): Several points have been raised in more or less similar form by more than one speaker, and I shall deal with these first. It is suggested that I have overstated the difficulties of high-speed wireless recording in that I have investigated the case of relay rather than siphon recorder working, and that my assessment of 2 for the border value of $n\delta T$ between good and bad recording is too high. Now the paper makes no pretence to determine actual values of power required or speed obtainable in any particular case, but it investigates how power and speed depend upon damping and upon each other. Just as the practical performance of a submarine cable must be worked out by calculating arrival curves,* so, I point

* As done in Dr. W. H. Malcolm's admirable "Theory of the Submarine Telegraph and Telephone Cable" [Benn Bros., 1917].

out, must we endeavour to determine what corresponds to these arrival curves in the wireless receiver. These curves are found to depend upon the product $n\delta T$, and the three examples given in Figs. 6, 7 and 8 may be used in estimating the performance in all cases where this product has the assigned values. This is so whether the recorder is of the proportional type often used in cable telegraphy, or whether of the relay type always used on land lines, often used on cables, and at least hoped for by wireless engineers who are (like myself) optimistic enough to look for high speeds and automatic re-transmission.

In common with Prof. Howe, I lament the appearance of inertia effects in modern wireless. I agree with him and with Mr. Carpenter that a proportional recorder would often give readable signals when the relay signals which I have specially investigated would not be readable (or automatically re-transmissible). Of Fig. 8 (for $n\delta T = 1$) I did not write, however, as Mr. Carpenter suggests, that it represents unrecordable signals, but that "no approach to uniformity can be obtained whatever value is given to A_0." I set my standard of "shaping" at $n\delta T \nless 2$; I think it would distress a land-line telegraphist (whom wireless engineers should try to please) if it were put much lower than 2. It is open to anyone, however, to adopt any other figure he may find appropriate to his particular recording instrument, and still utilize the analysis that I have given. Let him not forget, however, that he has to cope with atmospherics with which my too-excellent curves are not defiled.

Major Lee and Prof. Fortescue refer to the "sideband" view taken by wireless telephonists, and the former definitely applies this criterion of distortion to Morse signalling. Now while telephone theory has commonly contented itself with analysis of the steady state—admittedly often far from reality, but yielding tolerably good practical rules as regards volume and clarity of speech signals—it is not possible to regard Morse signals as periodic. The series of dots from a Wheatstone transmitter when the tape has run out can be so treated, but not the irregular succession of dots and dashes when the tape is there. A resonance curve, whether of a single circuit as in Fig. 3, or with the steeper sides of a complex filter circuit, is a curve showing what will happen when the signal has been sustained for a sufficient period to enable the steady state to be sensibly reached. Its sharpness determines the "distortion" produced in a sustained note containing periodic constituents of several frequencies, and it is so used in telephone theory; but it does not exhibit conditions during the transient stage with which we are here concerned. The fact educed by Major Lee that "band width" $= 1/T$ is the same condition as $n\delta T = 2$ depends on his apparently arbitrary choice of 54 per cent of peak height at which to measure the "width." In my view the "band" method of telephony is inappropriate for investigating Morse reception. It is equivalent to disregarding the first term in the expression for q in the middle of page 193. As used by Major Lee, it leads to the conclusion that Fig. 6 is the Morse letter "1" "without appreciable distortion."

The use of two wave-lengths, either for mark and space, or for dot and dash, has been referred to by several speakers. I agree with Major Lee and Mr. Moullin in regarding it as an important method for reducing transients at the transmitter. Mr. Moullin proposes further to increase speed by utilizing the two wavelengths to permit the use of what would be practically siphon-recorder code with the space between dot and dash suppressed. The use of two marking wavelengths seems to me to be quite feasible, and the possible gain of speed without sacrifice of "shape" is considerable. A somewhat larger gain might, I think, be obtained from the analogue of a modified Gott form of Morse.* Marks would alternate in wave-length, the dash and dot would be of unequal length though of less than 3 : 1 ratio, and all spaces between marks would be suppressed.

Major Lee is, I think, mistaken in supposing that the receiver curbing which I propose renders the system more liable to attack from atmospherics. The use of curbing allows the receiver decrement for the reception of signals (and, of course, atmospherics) to be kept *lower* than it would otherwise be, and consequently confers some added protection. The higher the decrement at other times, e.g. after a mark has become effective and during spaces, the better.

Mr. Moullin's remarks as to the desirability, with regard to atmospherics, of keeping $n\delta T' < 2$, and his quantitative estimate of the effect of transmitter inertia (in the absence of two-wave signalling) are most interesting. The gain resulting from a reduced ratio between dash and dot, shown in his Fig. A, reopens the question of modification of the signalling code. I think that changes from the present ubiquitous transmitting practice are likely to come, but the significance which I have attached to $n\delta T$ will remain.

A relay having the properties named by Mr. Taylor might help in realizing good results from the curbed régime; but surely the feebleness of the holding-over force as compared with the moving-over force should be utilized by applying *larger* curbing damping, not applying it *earlier*. I think that Mr. Taylor is mistaken in supposing that curbing at the transmitter would reduce interference at other stations. It is a fact—paradoxical though it may seem at first sight—that the switching *off* of a transmitter can set up an interfering oscillation in a receiver which was not disturbed while the key was held down, and the greater the damping of the transmitter the stronger the interference would be.

I well remember trials of the Poulsen-Pedersen system of which Mr. Elwell speaks, and that, as he says, good tape was obtained at 200 words per minute. But the tape was photographic tape—which is much worse than siphon recorder slip, which is, again, worse than Wheatstone slip—and the value of $n\delta T$ was probably nearer 20 than 2. To attempt to cope with even English atmospherics and to moderate the transmitter power required, low decrements must be employed, and then the shaping considerations we have studied present themselves.

Like Major Lefroy, I was much struck by the close parallels between the ideas of acoustic damping pre-

* MALCOLM, *loc. cit.*, p. 350.

sented in Mr. Sutherland's remarks and those of the present paper. The problems of acoustic and wireless persistence are, of course, fundamentally alike.

I have no knowledge of the "ringing" observations mentioned by Prof. Fortescue, but I think that the phenomenon must now be well known to many experimenters, and at wave-lengths far below 15 000 m. Mr. Best has told us that he has taken actual decrement measurements in this condition at 4 350 m, and I have myself extensively observed and controlled the phenomenon while listening in Egypt to signals from Horsea at as low as 2 500 m. Smaller decrements than those making $n\delta T = 2$ for high-speed signalling could, I am sure, be obtained in practical work if wanted; but the answer given by the paper to Prof. Fortescue's question as to why a decrement of 0·0001 should be wanted, is that it never would be wanted except to bring $n\delta T$ down to a value such as 1 or 2.

PROCEEDINGS OF THE INSTITUITON.

703RD ORDINARY MEETING, 1 NOVEMBER, 1923.

(Held in the Institution Lecture Theatre.)

Dr. A. Russell, President, took the chair at 6 p.m.

The minutes of the Ordinary Meeting of the 18th October, 1923, were taken as read and were confirmed and signed.

Messrs. J. O. Girdlestone and H. M. Sayers were appointed scrutineers of the ballot for the election and transfer of members and, at the end of the meeting, the result of the ballot was declared as follows:—

Elections.

Member.

Corns, Samuel William.

Associate Members.

Angus, James.
Bird, George Webber, B.Sc.(Eng.).
Evenden, Edward Frederick.
Hutton, Leslie Bertram, B.Eng.
Radbone, Victor James.
Reed, Frederick Raymond.
Villa, Charles Croswaithe.

Graduates.

Allcock, Harold John B.Sc.(Eng.).
Axon, Albert Edwin, B.E.
Burnett, Robert Ernest S. F.
Glover, Arthur Reginald.
Moiselle, Thomas Henry.
Musto, Romeo Jose.
Pollard, Thomas Royle.
Rennie, William.
Singh, Inder.
Thornton, Charles James.
Waglé, Vasant Krishna, B.Sc.(Eng.).
Woods, Ronald Forster.

Students.

Ahmed, Shaikh Muzaffar.
Aldridge, Stanley Walter.
Allan, James.
Arnott, Frank Reginald.
Bacon, Charles Edward.
Banks, Raymond Ernest.
Bartley, William Coppen.
Bingham, Walter Ronald.
Bintley, Bryan Noel.
Birch, Sidney.
Blackburn, Ernest.
Bourne, Percival Edwardes.
Brown, Kenneth Ivon.
Cawson, William Fox.

Students—continued.

Clare, Bernard Scott.
Cope, William Francis.
Crowe, Henry Eyre.
Davies, Harry Beaumont.
Davis, Percival Sydney.
Dean, John Alfred A.
Dean, William Henry.
Faulks, John Ruskin.
Fenwick, Raymond.
Gill, Benjamin Gerald.
Gregory, Herbert Turberville.
Greig, James.
Grubb, Edward Joseph, B.Sc.
Grundy, Geoffrey Earnshaw.
Heaton, Peter St. John.
Hemsley, Sydney Henrick.
Hitt, Donald George.
Horne, Thomas George.
Horner, Francis Henry.
Jollie, Andrew.
Jolly, William Joseph.
Jones, Cyril.
Jones, Harold Hosgood.
Jones, Lionel Adrian.
Kelly, Bruce.
Kibblewhite, Curtis.
Kipping, Norman Victor.
Kirkwood, Ian Ward A.
Knox, Alfred Harold.
McCarter, Alan Lailey.
McWhirter, Harry Roy S., B.Sc.(Eng.).
Macwhirter, Robert.
Mathur, Roshan Lal.
Meadmore, Claude Clement C.
Metcalf, Bernard Leslie, B.Sc.(Eng.).
Metcalfe, Percival Ignatius H.
Moffat, Frank Allan.
Moore, Cuthbert Grafton, B.Eng.
Murrell, Alfred Capper.
Nash, William Aitken.
Oldham, Charles Frederick.
Parker, Thomas Wilfrid.
Paynter, Rene Philip T.
Pearce, Claude Rieder.
Pearce, Owen Avis, B.Sc. (Eng.).
Perry, Walter William.
Pizzey, James Herbert.
Purnell, Percival Lawrence.
Rayner, Guy Stillingfleet.
Richards, Alfred Stanley.
Scanes, Ralph Boyce.
Shearley, Lewis Clifford.
Smyth, Cyril Jack.
Spratt, Hector Gordon M., B.Sc.(Eng.).
Stubbs, William Ronald.
Sutcliffe, Ronald Arthur H.
Taylor, David Bruce.
Taylor, Victor Arthur.
Teesdale, Eric Stanley.
Templar, Reginald George.
Thimbleby, Arthur Wilfrid.

Students—continued.

Thompson, Sydney Whitehead.
Thomson, Robert Batchen.
Torond, Leonard Bernonville.
Turner, Albert Edward.
Turton, George Thomas.
Vause, Dennis.
Vowler, John Creed G.
Watts, Basil Kingsford.
Wheeler, Edmund Frank.
Whitley, Ernest.
Woffenden, Arthur.

TRANSFERS.

Associate Member to Member.

Binns, Herbert Sugden.
McLeod, Neil Gloster.
Robinson, Bernard Augustus.
Robson, Robert Edward.

Graduate to Associate Member.

Aylott, Henry Joseph.
Combes, Frank Roy, B.E.
Furness, William John.
Jenkin, Ralph Meredith.
Purday, Allen Charlton.

Student to Associate Member.

Dance, Herbert Ernest.
Dobeson, Richard Gray, B.Sc.
Jones, Harold William, M.Eng.

Associate to Associate Member.

Clifford, Edgar Alan T. W.

Student to Graduate.

Bullen, Eric Harold S.
Cassal, Charles Victor.
Corbin, Cecil.
Gandhi, Khan Chand.
Murray, George Edgar W.
Patel, Kashibhai Bhikhabhai.
Vembu, N., M.A.

Graduate to Associate.

Burnham, Walter Witt.

The following list of donations was taken as read and the thanks of the meeting were accorded to the donors :—

Library.—The Air Ministry (Director of Research, Meteorological Office, and Technical Committee on Radio Communication); A. H. Allen; The Association of British Chemical Manufacturers (Incorporated); The Astronomer Royal; A. H. Avery; Messrs. Ernest Benn, Ltd.; Messrs. Éd. Bennis & Co., Ltd.; L. Birks; Messrs. Blaikie & Son, Ltd.; A. Blondel; Messrs. Bowman and Gorman; The British Aluminium Co., Ltd.; The British Cast Iron Research Association; The British Engine, Boiler and General Insurance Co., Ltd.; The British Engineering Standards Association; The British Non-Ferrous Metals Research Association; The Carnegie Institute of Washington; Messrs. Chapman & Hall; The Chief Experimental Officer, Signals Experimental Establishment, Woolwich; The Chief Inspector of Factories, Home Office; F. E. Chilton; Messrs. Constable & Co., Ltd.; W. R. Cooper; Messrs. Crosby Lockwood & Son; H. T. Davidge; The Department of the Interior, Canada; The Department of Scientific and Industrial Research, Radio Research Board and Fuel Research Board; The Director-General of Posts and Telegraphs, India; The Electricity Commissioners; The Electrotechnical Laboratory, Ministry of Communications, Tokyo; The Engineering Association of Malay; Prof. J. A. Fleming, F.R.S.; Messrs. Frowde, Hodder and Stoughton; R. Grierson; Dr. H. S. Hallo; H. H. Harrison; C. C. Hawkins; The High Commissioner for Canada; The Imperial Mineral Resources Bureau; The Institution of Engineers, Australia; The Institution of Petroleum Technologists; The Institution of Royal Engineers, Chatham; The International Western Electric Company, Incorporated; Sir Alexander Kennedy, F.R.S.; Dr. A. E. Kennelly; Lloyd's Register of Shipping; W. T. Maccall; Messrs. Marconi's Wireless Telegraph Co., Ltd.; C. W. Marshall; Messrs. Methuen & Co., Ltd.; R. Mond; W. H. F. Murdoch; The National Illumination Committee of Great Britain; The Nela Research Laboratory, Ohio; Messrs. Sir Isaac Pitman & Sons, Ltd.; The Public Works Department, Wellington, N.Z.; Messrs. S. Rentell & Co., Ltd.; Prof. D. Robertson, D.Sc.; The Royal Board of Waterfalls, Sweden; Dr. C. P. Steinmetz; Messrs. E. & F. N. Spon, Ltd.; A. A. C. Swinton, F.R.S.; Tasmania Hydro-Electric Department; F. J. Teago; L'Union des Syndicats de L'Électricité; E. B. Wedmore; A. F. Williamson; The Wireless Press, Ltd.; E. W. Workman; and J. Paley Yorke.

The President: I have to report the death of one of our Honorary Members, Maurice Leblanc. He was well known to every electrical engineer, and was at one time President of the International Electrotechnical Commission. As to his work, one may say almost that he invented the induction generator and the dampers used for the parallel running of alternators. The Council suggests that this telegram be sent to the Société Française des Électriciens: "The Institution of Electrical Engineers, London, send their deepest sympathy to all French engineers on the death of Maurice Leblanc, one of the most esteemed of their honorary members. When President of the International Electrotechnical Commission he won golden opinions from everyone. His achievements in engineering science have been of the greatest help to his brother electricians all over the world." I have also to report the death of one of our most eminent Members, Professor C. P. Steinmetz. His work is well known to you all, and it is suggested that we send the following cablegram to the American Institute of Electrical Engineers: "The Institution of Electrical Engineers, London, send their sincere condolences to their American confrères on the death of Charles Proteus Steinmetz, one of the early pioneers and one of the greatest exponents of the science of electrical engineering. His fame is world-wide; his work lives and will continue to live."

The proposed telegrams were unanimously approved, the members present standing in honour of the two deceased Members.

The President: I have now to announce that the Council have unanimously elected Colonel Crompton an Honorary Member. It will be unnecessary for me to dwell on the man or his career at any length. Born in 1845, he entered the Army in 1863 and served with his regiment in India. He was associated with Dr. Kapp in inventing the compound winding of dynamo-electric machines. That discovery goes right back to the

beginning of our profession. He has contributed many papers to the engineering Institutions; many of the expressions in these papers, such as "load factor," which have now become household words to the electrical engineer, were used by him in them for the first time. In a paper at the World Congress at St. Louis he pointed out the beneficial results of standardization, and as a result the International Electrotechnical Commission was formed. The late Lord Kelvin was its first chairman, and Colonel Crompton has been its Honorary Secretary for many years. He was our President in 1895 and again in 1908, the year of Lord Kelvin's death.

A paper by Mr. W. Wilson, B.E., M.Sc., Member, entitled "Industrial Research, with Special Reference to Electrical Engineering Development" (see page 61), was read and discussed, and on the motion of the President a hearty vote of thanks was passed to the author.

The meeting terminated at 7.50 p.m.

INSTITUTION NOTES.

Kelvin Medal.

The second triennial award of the Kelvin Medal has been made by the Award Committee to Professor Elihu Thomson, who is an Honorary Member of the Institution.

Associate Membership Examination, October 1923.

SUPPLEMENTARY LIST.

Passed.

Payne, L. S. (Wellington, New Zealand).

Associate Membership Examination, April 1924.

The next Examination will be held on the 3rd, 4th and 5th April, 1924. Candidates must be either Students or Graduates of the Institution, or have lodged with the Secretary a duly completed form "E" for election as Associate Member. Entry forms for the Examination, which must be completed and returned by the 1st March, and particulars regarding election to membership of the Institution may be had on application to the Secretary, The Institution of Electrical Engineers, Savoy-place, Victoria-embankment, W.C. 2. The Examination is being held this year about a fortnight earlier than in past years in order that those successful candidates who have qualified in other respects for Associate Membership may be elected before the end of the session.

Informal Meetings.

The following Informal Meetings have been held:—

44TH INFORMAL MEETING (5TH NOVEMBER, 1923).

Chairman: Dr. A. Russell (President).
Subject of Discussion: "Engineering Training" (introduced by Dr. A. Russell).
Speakers: Lieut.-Col. W. A. J. O'Meara, C.M.G., Mr. P. M. Baker, Professor C. L. Fortescue, Dr. R. M. Walmsley, Dr. F. T. Chapman, Mr. W. Day, Mr. A. W. Berry, Major T. Rich, and Mr. L. W. Phillips.

45TH INFORMAL MEETING (19TH NOVEMBER, 1923).

Chairman: Mr. J. R. Bedford.
Subject of Discussion: "Power in Telephone Exchanges" (introduced by Mr. A. B. Eason).
Speakers: Mr. F. Gill, Mr. P. Dunsheath, O.B.E., Mr. W. E. Rogers, Mr. F. Pooley, Mr. A. F. Harmer, Mr. A. G. Hilling, Mr. W. L. Wreford, Mr. W. Day, and Mr. J. W. Wheeler.

46TH INFORMAL MEETING (3RD DECEMBER, 1923).

Chairman: Mr. J. Coxon.
Subject of Discussion: "Electrical Apparatus for the Deaf" (introduced by Mr. C. M. R. Balbi).
Speakers: Dr. J. A. Fleming, F.R.S., Dr. Wm. Hill (St. Mary's Hospital), Mr. J. E. Kingsbury, Dr. S. Scott, Mr. M. D. Hart, Dr. F. Thompson, Mr. W. Day, Mr. F. S. Robertson, Mr. P. G. Pettifor, Mr. A. A. Williams, Mr. J. W. Wheeler, and Mr. L. V. Rein.

47TH INFORMAL MEETING (17TH DECEMBER, 1923).

Chairman: Mr. P. Dunsheath, O.B.E.
Subject of Discussion: "Students in Electricity Undertakings" (introduced by Mr. G. R. A. Murray).
Speakers: Captain J. M. Donaldson, Mr. A. F. Harmer, Mr. J. W. Thomas, Mr. G. W. Preston, Mr. E. F. Hetherington, Mr. W. E. Rogers, Mr. P. Dunsheath, O.B.E., and Mr. F. Pooley.

National Certificates and Diplomas in Electrical Engineering.

The following is a further list of colleges, schools, etc., which have been approved under the scheme drawn up by the Board of Education and the Institution [see *Institution Notes*, No. 39, page (18), July 1923].

Approved for Ordinary Grade Certificates (Senior Part-time Courses).

Birmingham Municipal Technical School.
Bradford Technical College.
Brighton Municipal Technical College.

Bristol—Merchant Venturers' Technical College.
Burnley Municipal College.
Coventry Muncipal Technical Institute.
Derby Technical College.
East Ham Technical College.
Erith Technical School.
Gillingham and Rochester Technical Institute.
Halifax Technical College.
Horwich Railway Mechanics Institute.
Liverpool Central Technical School.
London—Borough Polytechnic.
Plymouth and Devonport Municipal Technical Schools.
Poplar School of Navigation.
Preston—Harris Institute.
Salford Royal Technical College.
Smethwick Municipal Technical School.
Wolverhampton Municipal Science and Technical School.
Woolwich Polytechnic Institute.

Approved for Higher Grade Certificates (Advanced Part-time Courses).

Birmingham Municipal Technical School.
Bradford Technical College.
Brighton Municipal Technical College.
Erith Technical School.
Huddersfield Technical College.
London—The Polytechnic, Regent Street.
Poplar School of Navigation.
Preston—Harris Institute.
St. Helens Municipal Technical School.
Salford Royal Technical College.

Approved for Ordinary Grade Diplomas (Senior Full-time Courses).

Manchester College of Technology.
Portsmouth Municipal College.
Salford Royal Technical College.

Approved for Higher Grade Diplomas (Advanced Full-time Courses).

Brighton Municipal Technical School.
London—The Polytechnic, Regent Street.

The Benevolent Fund.

The following Donations and Annual Subscriptions were received during the period 1–25 January, 1924 (excluding those paid direct to the Institution bankers which will be published later) :—

ELECTRIFICATION OF THE FRENCH MIDI RAILWAY.

By A. BACHELLERY, Ingénieur-en-Chef, Chemins de Fer du Midi, France.

(*Paper received 2nd October*, 1923, *and read at Joint Meetings of* THE INSTITUTION *and the* SOCIÉTÉ DES INGÉNIEURS CIVILS DE FRANCE (BRITISH SECTION) *22nd November*, 1923, *and 10th January*, 1924, *also before the* NORTH-EASTERN CENTRE OF THE INSTITUTION *26th November*, 1923.)

SUMMARY.

After a brief description of the experiments made before the war on the Midi Railway in the way of electric traction, the author gives an account of the extensive electrification work now pursued by that Company in accordance with the new standard regulations of the French Government, and of the first results already obtained on the electrified lines.

The Midi Railway of France extends in the southernmost part of that country from the Atlantic Ocean to the Mediterranean—from Biarritz to Perpignan—along the snow-covered Pyrenees, sending off branch lines up most of the valleys of that chain of mountains. It also runs up north of Beziers across the Cévennes district, a very wild, picturesque and mountainous country.

On account of these features, several of its lines have very steep gradients; grades over 3 per cent are not infrequent. The difficulties encountered in the working of such lines with steam locomotives, as well as the fact that water power is close at hand, were bound to place the problem of electric traction very early before the Midi Company.

It began effectively in 1902, when the company undertook the construction of a narrow-gauge line, 35 miles long, from Villefranche-de-Conflent to Bourg-Madame in the eastern Pyrenees, a single-track line climbing to an altitude of 5 000 feet, with long 6 per cent grades and curves of 200 ft. radius. Electric traction was decided upon, and the chosen system was direct current, third rail, at 850 volts. That was at the time the highest d.c. voltage used in Europe for traction.

The motor-cars (either freight or passenger), with a certain number of trailers composing the trains, were fitted with the Sprague multiple-unit control.

The line was opened in 1910 and has since worked to the entire satisfaction of the company, carrying a relatively heavy traffic to which the construction of the great mountain resort of Font-Romeu has substantially contributed.

When the line was built, it was considered an optimistic view to expect an annual return of 5 000 francs per mile. It is actually 40 000 francs, although the fares have been increased only from 100 to 150 per cent.

In the meantime, the company had been led to consider electrification of lines of normal gauge in connection with proposals for new railways in the Pyrenees; among these, two lines, crossing directly through the chain into Spain, involved, besides tunnels several miles long, gradients of over 4 per cent.

At this time—namely, between 1908 and 1910—the single-phase system had made sufficient progress to be considered as practically reliable, and the use of overhead construction and a high voltage seemed to secure the most economical installations.

In order to verify this through extensive tests, the company equipped 15 miles of line between Ille and Villefranche-de-Conflent. Six different systems of overhead construction—all based on the catenary principle—were effectively applied on this section.

The type of current was single-phase, 16 cycles, 12 000 volts on the contact wire.

Six locomotives, built by different constructors according to the company's requirements, were submitted to a series of tests, and three of them, having successfully passed such tests, were accepted.

It was accordingly decided to equip with the single-phase system 70 miles of double track between Pau and Montréjeau, and the single-track branch lines of Pierrefitte, Bagnères-de-Bigorre, Arreau and Luchon, measuring 63 miles. For this purpose a power house equipped with six 2 500-kW generators was built at Soulom. Orders were also placed for 30 motor-cars, each of 500 horse-power, and for 24 new locomotives.

The tests revealed serious trouble in the telegraph and telephone lines along the track, due to inductive interference by the single-phase traction current.

This question was closely investigated by the Midi Company, and a solution was found which consisted in running two extra wires beside the trolley wire, namely:

(1) A negative feeder along which the return current is forced by means of booster transformers, instead of going back through the track rails.

(2) A counter-voltage wire in which there is an alternating voltage directly opposed to that in the trolley wire.

By these means, compensation was obtained for both electromagnetic and static induction. The whole line between Perpignan and Villefranche, 30 miles long, only fed at one end, is actually worked with single-phase current without any trouble on the telegraphs and telephones.

The outbreak of war brought these experiments to a standstill. The whole of the energy available from the existing power houses, as well as from a new 25 000-kW plant equipped at Eget during the war, was given over to munition work, and it was only after the armistice that the company could resume work in the matter of electrification. In the meantime, however, things, from a technical point of view, had taken a new turn.

The French Government had decided to standardize for electric railways both the primary current and the traction current, in order that different power plants could work in parallel and that locomotives could be used indiscriminately on all the electrified lines.

A Commission was appointed at the end of 1918 by the Ministry of Transport, to decide on one system to be accepted by the French companies.

In 1920 this Commission, after close investigation of the different systems in use in France and abroad, produced its conclusions, which were adopted by the Government.

The primary current is to be three-phase, 50 cycles. The standard type of traction current is to be direct current at 1 500 volts, with the proviso that, in exceptional cases, 3 000 volts can be used.

Either overhead or third-rail equipments are permitted, and locomotives are to be fitted with current-collecting apparatus suited to both.

The reasons for this choice were the following:

Three-phase 50-cycle current is already standard in France for distribution systems, and it was deemed advisable to adopt the same type for the power plants built by railway companies, in order to facilitate interconnection and mutual help, the result being not only greater security, but also better utilization of both the power plants and transmission lines.

The type of primary current being thus fixed, the single-phase system loses one of its chief advantages, which is to do away with rotating machines in substations when low-periodicity current for traction can be directly produced at the power house. The necessity for substations fitted with motor-generator sets for the production of single-phase current would have involved high expense and low efficiency, whereas the use of rotary converters for producing direct current allowed much more favourable conditions.

On the other hand, the use of direct current was considered to be the best means of overcoming inductive interference on low-tension conductors.

Other advantages were also considered, such as lower weight and cost of direct-current locomotives, greater overload capacity, and cheaper maintenance of their motors.

As to the voltage for traction lines, 1 500 volts was chosen as being the maximum voltage allowing the use of a third rail, which certain companies wished to keep, notwithstanding the advantages which a somewhat higher voltage might have procured.

These decisions implied for the Midi Company the abandonment of the larger part of the work already done. Power plants, transmission lines, substations, overhead equipment and locomotives had to be fundamentally modified for use with the direct-current system.

The company set to work immediately on these alterations as well as on a new programme of electrification.

In two years' time, the first results have been attained by the appearance on the Pau–Tarbes division, in the last months of 1922, of the first French 1 500-volt direct-current locomotives.

The electrification work is actually carried out in the western part of the Midi system. The Toulouse–Dax line is to be entirely equipped this year, and is already partly run by electricity. Its branch lines are being changed over from single-phase to direct current.

The equipment of the main line from Bordeaux to Hendaye has been begun, as also of its branch lines to Arcachon and Biarritz. Other lines will follow both in the Pyrenees and the Cévennes districts, the whole length of road to be electrified in the next 10 years being nearly 2 000 miles.

Current is actually produced in the two hydro-electric stations at Soulom and Eget, the first equipped with 21 000 and the second with 35 000 horse-power, this last from a fall 2 300 feet high.

In addition to this, the Midi Company is building on the Gave d'Ossau three new power stations equipped for 130 000 horse-power with falls ranging from 600 to 2 500 feet. Other power plants are designed in the central and eastern Pyrenees for the time when electrification reaches those districts.

The current produced by all these plants is three-phase, 50 cycles, at 60 000 volts. It is transmitted by feeders following the railway, and in addition part of it is transformed to 150 000 volts for long-distance transmission. Lines for this purpose are already constructed as far as Bordeaux and Toulouse. Their total length is actually 420 miles, and the longest distance between step-up and step-down transformers is 175 miles.

These lines have been given a larger capacity than required by the needs of the railway. They are, in fact, meant to transmit, not only for traction, but also for distribution purposes, energy produced by numerous power plants all working in parallel. This transmission over lines belonging to the railway will be subject to taxes which will cover part of the expense.

Each line, designed to carry from 30 000 to 50 000 kW, consists of three copper cables each of 283 000 circular mils (0·222 square inch) section. A steel earth wire is provided for protection.

The cables are suspended by insulator chains of 9 plate-type elements from steel towers 66 feet high and normally 660 feet apart. Two of these lines, entirely independent of each other, join the Pyrenees to Bordeaux.

Transformation from 60 000 to 150 000 volts, and vice versa, is carried out in two step-up stations, equipped for 60 000 kW, and in three step-down stations equipped for 80 000 kW. The latter are provided with synchronous condensers of 60 000 kVA total capacity. All these stations are of the outdoor type.

Energy for traction is distributed along the railway by 60 000-volt feeders issuing either directly from the power plants or from the transformer stations. They are generally fixed to the same supports as the contact line. They consist of three 200 000 circular mil (0·157 square inch) copper cables or aluminium equivalents.

Substations for converting three-phase current into direct current are built at distances varying from 8 to 20 miles, the drop in the line voltage not exceeding 20 per cent under normal service.

Different types of converting apparatus have been used. Besides the classical groups of two 750-volt rotary converters connected in series, some substations have 1 500-volt 750-kW rotary converters as single

units. These are, the author believes, the first machines of this type wound for 50 cycles and they have been entirely successful. They can withstand 200 per cent overload during 5 minutes, without flashing over.

The newest feature, however, is the use, in some substations, of mercury rectifiers producing 1 500-volt direct current. Five substations have been equipped in this way, containing, in all, 16 groups each of 1 200 kW. Each group consists of a pair of cylinders connected in parallel, and fed with 12-phase current produced by special transformers.

The efficiency of these machines is very high, and practically independent of the load. Their overload capacity is equal to that of the rotary converters. Being static machines, they require very little attendance. We have so far experienced no difficulty in keeping the vacuum in the cylinders. The current they generate, although slightly undulating, is well withstood by the traction motors.

All substations possess high-speed circuit breakers on each group. In most of them, such high-tension apparatus as transformers and oil switches is placed out of doors.

The line equipment is of the double-catenary type. It consists of a steel messenger cable, an auxiliary messenger, and a contact wire, the last-mentioned being made of grooved copper of 0·155 square inch (100 mm^2) cross-section. The auxiliary messenger is suspended from the main messenger by flat steel hangers 30 feet apart on the straight and 15 feet apart on curves. The contact wire is fixed to the auxiliary messenger by clamps maintaining the two wires in a vertical plane.

On curves the catenary system is similar to that adopted on the Pennsylvania Railway. The line has no pull-offs, and follows the same curve as the track, the hangers taking an inclined position. This disposition gives a very smooth and uniform contact, and has the advantage of being self-compensating when the temperature varies.

On straight sections, pull-offs are generally used on the auxiliary messenger. Elastic pull-offs, consisting of two helical springs disposed V-wise, have been applied with success. On some sections, however, we have, as an experiment, suppressed the pull-offs. In this case the line is designed as a succession of curves staggered alternately 10 inches on either side of the middle of the track, and its tension is sufficient to prevent swinging. Up to now, this seems to give satisfaction.

The distance between supports varies from 300 feet on straight sections to 150 feet on curves under 2 600 ft. radius.

Different kinds of supports have been tried. On single track, the bracket type is generally used. We have also types of bracket construction for double track, with either steel or concrete poles. The last type adopted for double track is a cross-span construction consisting of two steel I beams assembled in the shape of a pointed arch. On these supports are fixed the 60 000-volt three-phase distribution line, the 1 500-volt direct-current feeders and catenary line, and in addition, in some cases, a 10 000-volt three-phase line for auxiliary and signal service.

Chain insulators are used for the high-tension line, as far as is allowed by clearance considerations. For the direct-current lines, double insulation is the rule, by means of either rigid or suspended insulators, the latter type being preferred.

Protection of transmission and contact lines against excess of current or voltage has been especially cared for. The high-tension lines are protected by selective relays and oil switches so disposed as to cut out automatically any section on which a breakdown occurs. The system is, moreover, earthed at one of the power houses at the neutral point of a transformer. It is protected against pressure-rises by earthed reactance coils with iron cores, and against steep-front surges by Capart apparatus consisting of mica condensers branched between two inductive coils, one of which is shunted by a resistance.

Direct-current machines in the substations are protected, in addition to the oil switches and quick-acting circuit breakers, by inductive coils and by an earthing device composed of a condenser shunted by a resistance.

Track bonding has been the object of a long discussion on the part of the Midi Company. We have experimented with a great many different types of bonds, and it must be said that up to now none have proved entirely satisfactory. The best, to our mind, consists of a pair of short copper bonds, made either of cable or packed strips, connecting each end of the fishplate with the corresponding rail. The fixing is obtained by through bolts or by split steel rings forced into the rail holes.

The different lines to be electrified present very diverse features, including level main lines carrying fast passenger and heavy goods trains, branch lines to watering places where traffic assumes a partly suburban character, and mountain lines with exceedingly steep grades requiring very powerful locomotives. Nevertheless, we have succeeded in limiting the number of different types of locomotives to four. These types have been studied jointly by the company's officials and by the makers, namely, the Société des Constructions Electriques de France, which is associated with the English Electric Company.

The first electrical equipments were made in this last-mentioned company's works at Preston, and the succeeding ones in the Lyons works of the Société des Constructions Electriques de France.

The locomotives are constructed in extensive shops especially built by the latter at Tarbes, in the middle of our electrified system.

The first two types of engines are a passenger and a freight locomotive similar to one another except for the gear ratio. They are mounted on two 4-wheel motor trucks. Each of the four axles is driven by a geared, nose-suspended motor.

These motors, of Dick-Kerr design, with 4 poles and commutating poles, are wound for 1 500 volts. Under forced ventilation, their one-hour rating is 350 and their continuous rating 250 horse-power. The total weight of the locomotive is 72 tons; and the speed limits are 55 miles per hour for the passenger engine and 40 for the freight engine. The motor control is the

Dick-Kerr cam-shaft multiple-unit system. Different speeds are obtained through series-parallel and field-shunting combinations.

Low-tension current for auxiliary service is produced by a 72-kW group. This includes, mounted on the same shaft, a 1 500-volt motor, two direct-current generators and two fans for ventilating the traction motors. One of the generators produces 120-volt current for the control circuits, for lighting the train and for feeding the air compressor. The second one is a variable-pressure dynamo used for exciting the motor fields when regenerative braking is in action.

Owing to this arrangement the locomotive has but one auxiliary 1 500-volt motor, which is an advantage, this being, as is well known, the delicate part of high-tension direct-current equipments.

The coupling devices and buffers are fixed to the truck frames, and these are themselves coupled together by a double drawbar and lateral buffers, so that the tractive effort is not in any way transmitted by the centre pins.

The cab suspension is so designed as to leave the highest degree of freedom to the trucks. The contact surface between centre plate and pivot has its concavity turned downwards and its centre near the axle plane; this eliminates reactions when the bogie pitches in any direction. To prevent the cab tilting, lateral springs suspended by swinging rods are interposed between the cab and the truck frames. This device is preferable to the ordinary support blocks, in that it allows perfectly free horizontal displacement. No equalization of the truck suspension has been found necessary.

Each motor drives its axle by two symmetrical gears. In order to avoid axle breaking, which has given a great deal of trouble on our first electrified lines, each gear-wheel, instead of being mounted on the axle, consists of a cogged rim bolted on to the truck wheel-centre.

The locomotive is equipped with both the Westinghouse automatic air brake and a straight air brake. Compressed air is provided by a Westinghouse gearless air compressor. In addition to these, an electric brake is provided. For the first machines, this is based on the regenerative principle, the current generated by the motors being sent into the trolley line. In this case the motors are separately excited by an auxiliary generator, and speed regulation is obtained by varying this generator's excitation.

Experience has shown that the saving of energy resulting from regenerative braking is comparatively small, and does not justify the complication it introduces into the locomotive's equipment. It has therefore been abandoned for the future, and rheostatic braking adopted in its place.

Whatever the system, electric braking is to be used for going down long grades, so as to save the wear of brake shoes. It is accordingly designed so as to hold the load which the engine is able to haul up the same gradient.

The current-collecting apparatus has been designed with special care, in order to obtain a smooth contact and to avoid sparking. It consists of a pantagraph fitted with ball bearings at each joint. The collector is made of two steel pans lined with copper strips and borne on helical springs. By these means, the greatest flexibility has been realized and good collection obtained at all speeds.

Passenger trains are lighted and heated by current obtained from the engine through special couplers. The lighting current at 120 volts is taken from the machine's auxiliary group.

Heating is provided by 1 500-volt current from the line. This current is sent into special radiators placed under the seats in the car compartments and protected by steel tubes and perforated steel plates. The heating couplers between cars are so designed as to prevent dangerous arcing while uncoupling. To secure this, an auxiliary wire fed with low-tension current runs throughout the whole length of the train. Its couplers are mechanically interlocked with the heating couplers, so that the latter cannot be uncoupled unless the former have been previously uncoupled, which automatically results in the opening of the main switch controlling the heating circuit on the locomotive.

A series of 90 of these machines is under construction, 13 of which are already running.

The freight locomotive is to haul trains up to 1 800 tons on the level. On mountain lines, this same engine can haul a 185-ton train on a 4 per cent grade. A helping engine at the rear will be normally used on these lines.

Another type of machine is a motor-car for suburban and branch-line services. It is carried on two 4-wheel bogies of the swinging bolster type. Each of the four axles is driven by a series nose-suspended geared motor. These motors are wound for 750 volts and connected two in series. They are self-cooling. The continuous rating of each is 125 h.p., and the one-hour rating 175 h.p. The maximum speed is 50 miles an hour.

Each axle has only one gear, similar in construction to those on the locomotives. The tractive effort is transmitted from the truck frame to the swinging bolster through articulated drawbars instead of the ordinary friction plates, which wear out quickly and impair the bolster's lateral displacement. The motor control is the same as on the locomotives. Air and hand brakes and electric rheostatic braking are provided.

The car is entirely of steel. It includes a third-class compartment with central aisle and reversible seats, a luggage compartment and two drivers' platforms. The total weight of the vehicle is about 52 tons and the number of seats is 48, besides which 32 standing passengers can be accommodated.

Those three types of machines are sufficient to haul any kind of train either on mountain or level lines, up to 50 miles per hour; but for higher speeds a special type of express locomotive had to be designed.

This problem is still under consideration in many countries, and could scarcely be said to have found an entirely satisfactory solution up to now.

The trouble, which is more of a mechanical than of an electrical character, consists mainly in the transmission between motor and driving axle. In the case of an express locomotive, the ordinary gear transmission requires a high peripheral speed for the pinions, at which their lubrication becomes very difficult. This difficulty disappears in the gearless type of locomotive

where the motor armature is fixed directly on the driving axle; but then the unsprung load increases to such a point as to tell severely on the track. To lighten this, the motors are often set in the cab and connected to the axles by means of driving rods. But this construction generally results at high speed in abnormal vibrations of the machine and in stresses leading to breakage of rods, cranks and even of the engine frame.

In order to avoid these various difficulties, the Midi Company has kept, for its high-speed locomotive, to the geared type, but with entirely suspended motors and quill drive. The particular feature is the use of a conical gear which allows smaller pinions and a lower peripheral speed and, moreover, is easier to lubricate than a straight gear.

Two locomotives previously built for use with single-phase traction were transformed according to this programme by the Société des Constructions Electriques de France. The general disposition of these machines is 4—6—4, that is, three driving axles independent of each other, and a 4-wheel bogie at each end.

The driving wheels are 69 inches in diameter. The adhesive weight is 54 tons, and the total weight 102 tons. The bogies are elastically centred and are practically identical with steam engine bogies.

The equipment of each driving axle is composed of a pair of vertical motors placed inside the cab and fixed to the main frame. The two pinions drive a double-cone gear-wheel fixed on the middle of the quill, and this in turn acts on the driving wheels through an elastic transmission.

The motor shafts are suspended on ball bearings at their upper extremity. At the lower end, the whole gear is immersed in oil. A pump raises the oil to a tank at the top of each motor, whence it flows down through ducts bored in the motor shaft.

The six motors are wound for 500 volts and are connected three in series. They are 4-pole motors (2 active and 2 consequent poles) with commutating poles. The one-hour rating of each is 375 h.p., that is, 2 250 h.p. for the whole machine. These motors, of very peculiar construction, have been designed and built at Liége, in the works of the Société des Constructions Electriques de Belgique, another firm associated with the Constructions Electriques de France.

The motor control is of the same type as in the former machines, and the maximum speed is 75 miles per hour. No electric braking has been provided for these machines, which are only for level lines. They are fitted with the Westinghouse automatic and straight air brakes.

The current-collecting apparatus consists of three pantagraphs similar to those previously described, each of which can collect, without sparking, 800 amperes at the maximum speed.

The machine has been tested up to a speed of 78 miles per hour, keeping perfectly steady on the track, without any nosing. This will perhaps be a surprise to those who believe that a locomotive with a symmetrical wheel-base cannot run smoothly at very high speeds. It may be of interest, therefore, to look into the matter more closely and to ascertain the origin of this somewhat legendary belief.

The above opinion was expressed by the Pennsylvania Railway officials, at the conclusion of tests carried out in 1907. These tests included the following machines :—

(1) Several steam locomotives, either American or Atlantic type.
(2) An electric locomotive with two driving axles rigidly connected to the frame and a 4-wheel leading truck (a disposition quite similar to that of an American type steam locomotive).
(3) Several electric locomotives with two 4-wheel trucks.

In fact, the symmetrical engines were limited to this last type, which behaved fairly badly at express speeds. Whilst, however, this inferiority was too hastily attributed to symmetrical construction, its real cause, to my mind, was quite different: first, the lack of a rigid wheel-base owing to which a 2-truck machine has a tendency to sway at high speeds; second, the rigid fixing of the pivots on the truck frames through which the side blows are transmitted from the track directly to the main frame; third, a centre of gravity decidedly lower than that of the steam engines.

The verdict thus delivered against symmetrical engines cannot, therefore, be considered to be final. Several engines—either electric or steam—which show perfectly symmetrical wheel arrangements, and ride nevertheless without difficulty at a fairly good speed, have before now brought it under suspicion; and the author will venture to say that the Midi Company's express locomotive has given it the final blow.

It will be noticed that this machine has been so designed as to avoid precisely the three defects which have just been pointed out. It has a rigid wheel-base 13 feet long, which keeps it steady on the track. The trucks are elastically centred through side springs; and, owing to the raised motors, which are set inside the cab, the height of the centre of gravity is similar to that on a steam engine.

This type has been adopted for a series of express machines to be built for level lines; but a new and more powerful machine of similar construction with four driving axles and a normal rating of 3 200 h.p. is already under consideration. It will pull on the level a 600-ton train at 60 miles an hour, or a 380-ton train at 70 miles.

It may now be asked what results, either economical or technical, the Midi Company has already obtained or expects to obtain through electrification of its lines.

Although electric traction is already in use on 140 miles of our lines, it is still too early for us to give figures as to its cost, as only 37 miles are established under standard conditions, whilst several hundreds of miles are under construction. Nevertheless, we may say that in many ways electrification has so far proved profitable.

Not only do drivers of electric locomotives get lower wages than steam locomotive engineers, but also their daily run is 30 per cent longer, on account of less time being spent for engine-shed operations.

As to the machines themselves, worked by several drivers they cover daily about 2·5 times the distance covered by a steam engine, which more than compensates for their higher price.

The cost of hydro-electric energy is naturally much less than that of the coal it saves.

Important economies are also realized on engine-shed and repair-shop expenses. Electric locomotives require much less labour for their maintenance than steam locomotives, a great many daily operations, such as coal and cinder handling, water pumping, tube blowing, boiler washing, etc., being entirely eliminated, whereas repairs are greatly simplified through the suppression of the boiler and much mechanism.

On the whole, and in spite of most of our electrification work having been done under very unfavourable price conditions, we have every reason to be confident that the operation will prove profitable.

A strong support to this belief is the rapid increase in traffic and revenue on our electrified lines, consequent on faster and more frequent trains. As a matter of fact, the technical advantages of electric traction are still more certain than the economical ones.

It allows, especially on mountain lines, a higher commercial speed. For instance, on our main line from Bayonne to Toulouse there is a grade of 1 in 30, $7\frac{1}{2}$ miles long, which takes an express hauled by a steam locomotive 34 minutes to climb. The same train hauled by an electric machine gets to the top in 13 minutes.

On the Transpyrenean lines long grades of 4 per cent will be ascended by passenger trains at a speed of 25 miles an hour, whereas it is doubtful whether steam engines could work any effective service on such a line.

Even on level lines train schedules can be made quicker, on account of a more regular and uniform speed being maintained by the electric locomotive, and of the suppression of those stops which are necessary only for taking in water. On the Bordeaux-Hendaye line, where the maximum grade is 1 in 200, our fastest train, the Southern Express, actually covers the 92 miles from Bordeaux to Dax in 1 hour and 49 minutes. With an electric locomotive it will run at an average speed of 65 miles, and gain about 25 minutes on the present schedule.

Trains can also be made more frequent without prohibitive cost. During the war, when the strictest economy prevailed and the daily number of trains was reduced, on a great many of our lines, to two in each direction, we could always maintain without extra expense four or five trains in each direction on the electrified lines. Our present programme is to establish around our mountain or seaside resorts a service of light and frequent trains very similar to a suburban service, and this can only be accomplished by electric traction.

It is perhaps needless to say that, from the traveller's point of view, the suppression of smoke and cinders is also a great improvement. This is particularly the case with lines such as the Transpyrenean running through tunnels several miles long.

Electric traction will also prevent the costly forest fires which are started too often by locomotive sparks in the forest properties along the railway.

One of the greatest advantages, however, to be found in railway electrification as carried out in France is the construction of a close network of electric transmission lines. In our country, extensive areas are mostly agricultural and only to a small extent industrial. In such districts the demand for electrical energy could scarcely be sufficient to justify the high expense involved in long transmission lines. On the other hand, a great many railway lines, on account of limited traffic, require only a small proportion of the current which the high-tension wires can carry, and this condition in general corresponds to cases where electrification could not be economical. In many cases the combination of these two unprofitable operations makes a profitable one, and the result will be not only to improve railway service considerably, but also to bring cheap electric current to every town and to a large number of small localities. While our 150 000-volt main transmission lines supply large centres such as Bordeaux and Toulouse, the 60 000-volt wires that follow the railway everywhere and feed step-down transformers in substations spaced some 15 miles apart will leave but little to do in order to build distribution systems covering the whole country.

When this is done on the 2 000 miles of road that the Midi Company intends to electrify, also when the Paris–Lyons–Mediterranean and Paris–Orleans companies have on their side electrified some 3 800 miles in accordance with a similar plan, and when the latter company has constructed the 300-mile 150 000-volt line from the Dordogne power plants to Paris, then not only railway electrification, but also public and industrial electrification, will have made a decided advance in France.

Discussion at the Joint Meetings of The Institution and the Société des Ingénieurs Civils de France (British Section), 22 November, 1923, and 10 January, 1924.

(22 *November*, 1923.)

Lieut.-Colonel H. E. O'Brien: I feel that what has been done in France in regard to standardization should be an example to us in this country: at the present moment, the standardization of the voltage and the various appliances in connection with electric traction in this country is little more than the pious expression of a wish on the part of a group of individuals who formed a Committee some time ago. On the other hand, both the French Government and the French electrical industry appear to have grasped the problem boldly and to have come to a very definite decision as to what they are going to do in the way of standardizing the voltage and the system generally for electric traction all over the country. It is particularly noteworthy that the Midi Railway, which had expended a very large sum on single-phase electrification, was, for the good of the country, ready to abandon the whole of that work and to fall in with the standardization which had been decided upon for the rest of the country. Although the electrification of main lines has a very definite though possibly limited scope in this country, yet that scope has as yet been but very dimly appreciated by railway managements here. The Englishman is intensely conservative; he is very slow to take up

anything new. When Mr. Garbe brought out superheating for locomotives and invited the locomotive engineers of this country to inspect what had been done in the way of coal and water economy by superheating, only two of our engineers responded to his invitation; the rest disregarded it, with the result that this country was one of the last to take up locomotive superheating. The varying apparatus which has been used in substations in the shape of direct 1 500-volt rotary converters and mercury-arc rectifiers will be of great interest when we can hear more about their actual performance, the mercury-arc rectifiers particularly. It is especially interesting, from a railway point of view, to learn that it has been possible to deal with such varying traffic on such widely different gradients with so few types of locomotives. Such a result can only have been attained by a great deal of work and co-operation between the manufacturers and the users. It is also rather striking, to railway people at any rate, to consider the features of these electric locomotives. The freight locomotive, which weighs 72 tons and has a one-hour rating of 1 400 h.p., may be compared with a steam locomotive which would weigh 120 tons and would only have a rated continuous drawbar horse-power of about 1 200 when in first-class condition and provided with picked fuel. Perhaps the most interesting part of the paper, apart from the wealth of technical detail in it, is the statement at the end to the effect that the technical advantages of electric traction are still more certain than the economical ones. I hope the author will, in the course of a very short time, be able to tell us that the economical advantages are even more certain than the technical ones, because there seems to be no uncertainty about the possibility of the solution of technical problems, whereas the economic problems are much more difficult. The people whom we engineers have to convince are the financiers. Therefore it is of great importance that actual figures should be brought forward showing what these economies are. The author, however, indicates very clearly that great economies will be effected in dealing with the locomotive as a machine. It is probable that in a very short time we shall have no difficulty in showing that the electric locomotive as a tractor on the railway is a very much more economical machine than any steam locomotive that can at present be built or is ever likely to be built. The whole problem will resolve itself into a question of the cost at which the current can be supplied to the locomotive. The author is in a slightly different position from engineers in this country in that he has water power at his disposal and the cost of energy will tend to become very much less the more he uses, whereas with us the cost of energy will not diminish in the same ratio.

Mr. E. M. Malek: The question resolves itself into one of economics. Technically I think that it is solved or is capable of solution. The French first of all determined to standardize and to scrap all lines hitherto in operation which did not lend themselves to modification. They looked upon the distribution of energy from every point of view and did not regard the electrification of railways as something apart and needing the supply of electricity for this particular purpose in isolated portions of their territory. I am certain that there is no other way of dealing with the problem than by looking upon it as a whole, the railways being the biggest potential users of energy and their systems the most convenient route for general power distribution. The Midi and other companies having laid down a programme which gives the French manufacturers a period of 10 years in which to look ahead, the latter have been able to organize production. This is very different from building special machines in small numbers, as development costs are wiped out and much money is saved in other ways. Colonel O'Brien has pointed out the difficulty—also mentioned by the author—of proving the direct financial benefit derived from electrification. We have to consider the capital expenditure. French engineers are noted for being able to design structural steelwork with less weight of material and at a lower cost of manufacture than almost anyone else. If the author's invitation is accepted, a tremendous impression will be created by the efficiency and cheapness of the overhead structures, whether for primary or for secondary distribution. I hope with Col. O'Brien that the author will give us, at a later date, some particulars of the economic results obtained.

Lieut.-Col. F. A. C. Leigh: On page 213 the method adopted to prevent inductive interference with the communication circuits in the case of the single-phase lines is very interesting, but I should like to know whether the present system costs less than that adopted on the Swiss railways. In view of the adoption of the overhead collector system by the Midi Company, why has the voltage of 1 500 still been retained? Presumably the pressure was decided upon because of the difficulties inherent to the third-rail system. The author mentions that 60 000-volt transmission wires are run on the same structures as the track overhead construction. It would be interesting to know whether there have been any difficulties with the communication circuits due to this, and what precautionary measures, if any, have been taken to avoid interference. On page 215 the author refers to the undulations in the voltage due to the use of the mercury-arc rectifiers. Have these undulations any effect on the telegraphic and telephonic communications? On the same page also the author rather indicates that he prefers a short bond for the third-rail system. On the old North-Western system our experience has been rather the reverse; we find that the long bond is more effective. On page 216 the author mentions that the auxiliary circuits on the locomotive are dependent upon one 1 500-volt motor only. If this is so, it would appear that, unless there are other special arrangements, the locomotive would be out of action if anything happened to this motor. The design referred to on page 217 is unique, and it will be interesting to learn whether satisfactory results are obtained from that system after it has been in use for some time. I should like to know whether the French engineers would have embarked upon the undertaking had not natural resources in the shape of water power been available. In North Wales there is

some water power, and certain inquiries have been made as to the power available there. Information has been obtained that under the proposed immediate development of this water power something like 350 million units a year could be produced. I should be glad if the author would state how many million units a year are available in France from water-power resources. I presume we may take it that all the power referred to in the paper will not be used at the moment for the railway only, but also for the encouragement of industrial enterprise. Has the Midi Railway been granted powers to distribute electricity for industrial purposes, like the power companies in this country, and if so is it controlled as regards the prices that it may charge?

Mr. T. Stevens: I have had four opportunities within the past six months of seeing parts of the work on the Midi Railway, and particularly of noticing the considerable progress made during that time. I greatly appreciate the action of French engineers in definitely limiting the voltage allowable on a third rail. In the "Final Report of the Electrification of Railways Advisory Committee of the Ministry of Transport" the pressure is given as 1 500 volts and multiples of that voltage. We have, however, to go to the technical Press to find what the limit is. In the *Tramway and Railway World* my statement was quoted: "It seems extraordinary that the Committee agreed to a multiple of 1 500 volts on third rail without even wisely limiting the multiple." An editorial comment on that read: "We consider where multiples of 1 500 volts were named in the Advisory Committee's report that no member of that Committee had any intention that it should be located near the ground." The present paper definitely states that 1 500 volts was chosen as being the maximum voltage for France allowing the use of a third rail. I consider that that pressure is satisfactory so far as the safety of the public and of the workmen on the lines is concerned. The author states that a steel earth wire is provided for protection. We all include steel earth wires in our estimates, but I should like to ask the author if he has made any

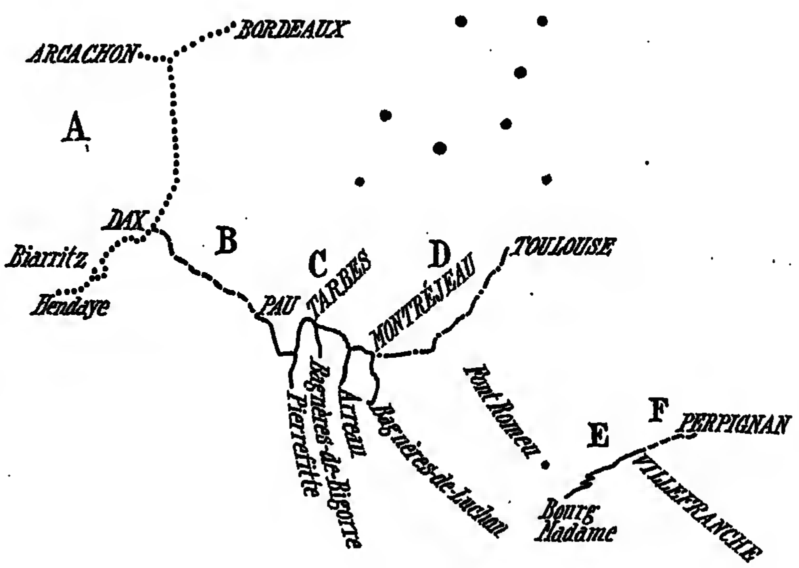

FIG. A.

definite experiments or has any definite experience to prove that it really does give protection. The voltage-drop on the line, with distances of between 8 and 20 miles between substations, is given as 20 per cent. Does that figure include the whole circuit? Calculations that I have made on published figures of the Chicago, Milwaukee and St. Paul Railway, show, with an annual saving of 20 per cent on the capital cost of electrification, that under normal conditions there is

an average loss of 12 per cent between substations and trains; while the Norfolk and Western Railway in America (single-phase at 11 000 volts) with three-phase motors shows similar economy but has an average loss of 1½ per cent in the circuit. The 650-mile Milwaukee line buys water power at under 0·3d. per unit, and energy is cheaper than interest, etc., on more copper to reduce the average loss. The Norfolk and Western hauls coal 29 miles and can sell at the top end of its gradient every ton saved from its transport. Therefore it pays the railway to put transformer substations 5 to 7 miles apart and enough copper to bring down the average loss to 1½ per cent. In a report widely circulated by its author the statement was made that if he were to use single-phase current in South Africa at 11 000 volts as is done on the Norfolk and Western Railway, his substations would be 50 miles apart. The Norfolk and Western Railway is 29 miles long, and the substations if put at 50 miles apart would be over 10 miles beyond each end, which would be absurd. It is stated that the train lighting on the Midi Railway is supplied by a generator on the locomotive at 120 volts. We have a good deal of 25-volt lighting for train service with generator and accumulators on each carriage, and I have seen as high a pressure as 60 volts used for lighting. If the author provides batteries to light the trains when the locomotive is not connected, it seems to me that he must have a 60-cell battery in each carriage. The curves for the Paulista Railway show no regeneration below 42 kilometres per hour for passenger trains, and none below 22 kilometres per hour for goods trains. The author banishes regeneration from the Midi Railway because the complication is greater than the advantage, but in my opinion it all depends on the nature of the line. Regeneration in actual regular service works splendidly, but in an emergency it has proved worse than useless. In one case a train in North America ran away and was wrecked. The time limit available for that driver to get his regenerative brake into action was 30 seconds, but this period had passed before he knew the emergency had arisen. The driver has to ascertain the field current and adjust it to the speed of the train before he throws in the armature to let it regenerate. It is an operation which throws a great strain upon the driver in an emergency, even if he realizes that the necessity for action has arisen. When studying the paper I found it necessary to prepare a map (see Fig. A) and I examined the frequency of train services and speeds (shown in Table A). These may prove useful to others.

(10 *January*, 1924.)

Mr. J. Sayers: The first matter to which I should like to refer is the question of induction on single-phase lines. When the directors of the Midland Railway entered into their experiment on the Lancaster, Morecambe and Heysham line, they did so in order to see what was necessary on a main-line electrification and what should be avoided. At that time there was no practicable direct-current system at a pressure higher than 600 volts, and it was therefore necessary to adopt single-phase traction at 6 600 volts. As a matter of fact that line, which was opened in 1907, was the first single-phase high-tension line in the British Empire. The matters which were to be chiefly investigated were, first, the trying-out of single-phase apparatus; secondly, the troubles which we expected to get from induction on communication circuits; and thirdly, the practicability of overhead collection at high speeds. The Midland Railway is pre-eminently a trunk telephone line; it carries what is called the "backbone line" of the Post Office to Scotland. It was very clear, therefore, that they had to make quite certain of their ground before they adopted any system of main-line electrification. The scheme for counteracting induction used on the Midi Railway was considered some years ago by the Midland Railway and patented by me in 1909, but it was not adopted because it seemed to me that to erect special wires carrying current to do nothing else but overcome the inductive interference from the contact wire, was not a practical solution. I should imagine that the line upon which it has been tried on the Midi Railway is a single line. This is, of course, a comparatively simple proposition; but if it were attempted to erect these counter-inductive wires overhead on, say, four tracks passing through junctions, cross-overs, and so on, I think it would become a very complicated problem indeed. The next method which I tried was quite successful, but, I am afraid, equally impracticable. The idea was to charge the telephone wires with an E.M.F. 180° out of phase with the contact wire to earth, and to charge the two wires through a condenser, the other end of the transformer winding being to earth. This was the only method with which we ever got silence in our very perfectly revolved telephone circuits. It is not very easy, however, to see how it could be applied to a large number of trunk lines. For that reason we gradually came to the conclusion that the inductive trouble with main-line working was a very serious matter indeed; and as higher pressures became practicable for direct-current work we formed the opinion that direct current had the advantage that the inductive trouble was very much less. The same reason has clearly influenced the Midi Railway, although we were quite unaware of it at the time. There is a very striking similarity between the best means we have been able to design for the contact system and that of the Midi system. An overhead system is far and away the simplest method for main-line working. The chief trouble here, however, lies in the design of "pull off" insulators, whose object is to hold the wire in the correct vertical plane for collection. These insulators are the only source of trouble which we have experienced and I have therefore tried gradually to eliminate pull-offs. On curves this is quite simple, because the messenger wire is kept on one side and the droppers keep the wire to the curve of the rails. On a tangent track we stagger the messenger wire across and this means that the droppers hold the wire alternately on the sides (see Fig. B). The rigidity of the contact wire in a horizontal plane against storms and wind is actually greater than where a pull-off is used at every gantry. Fig. C shows the results of tests with the old and new arrangements indicated in Fig. B. I should

like to know what the author has done in connection with avoiding joints in the contact wire. Joints are a weakness in every way, and generally they involve frequency surges. We put in an inductance leak to draw off static charges. It may surprise those who have had no experience with a line of this kind to

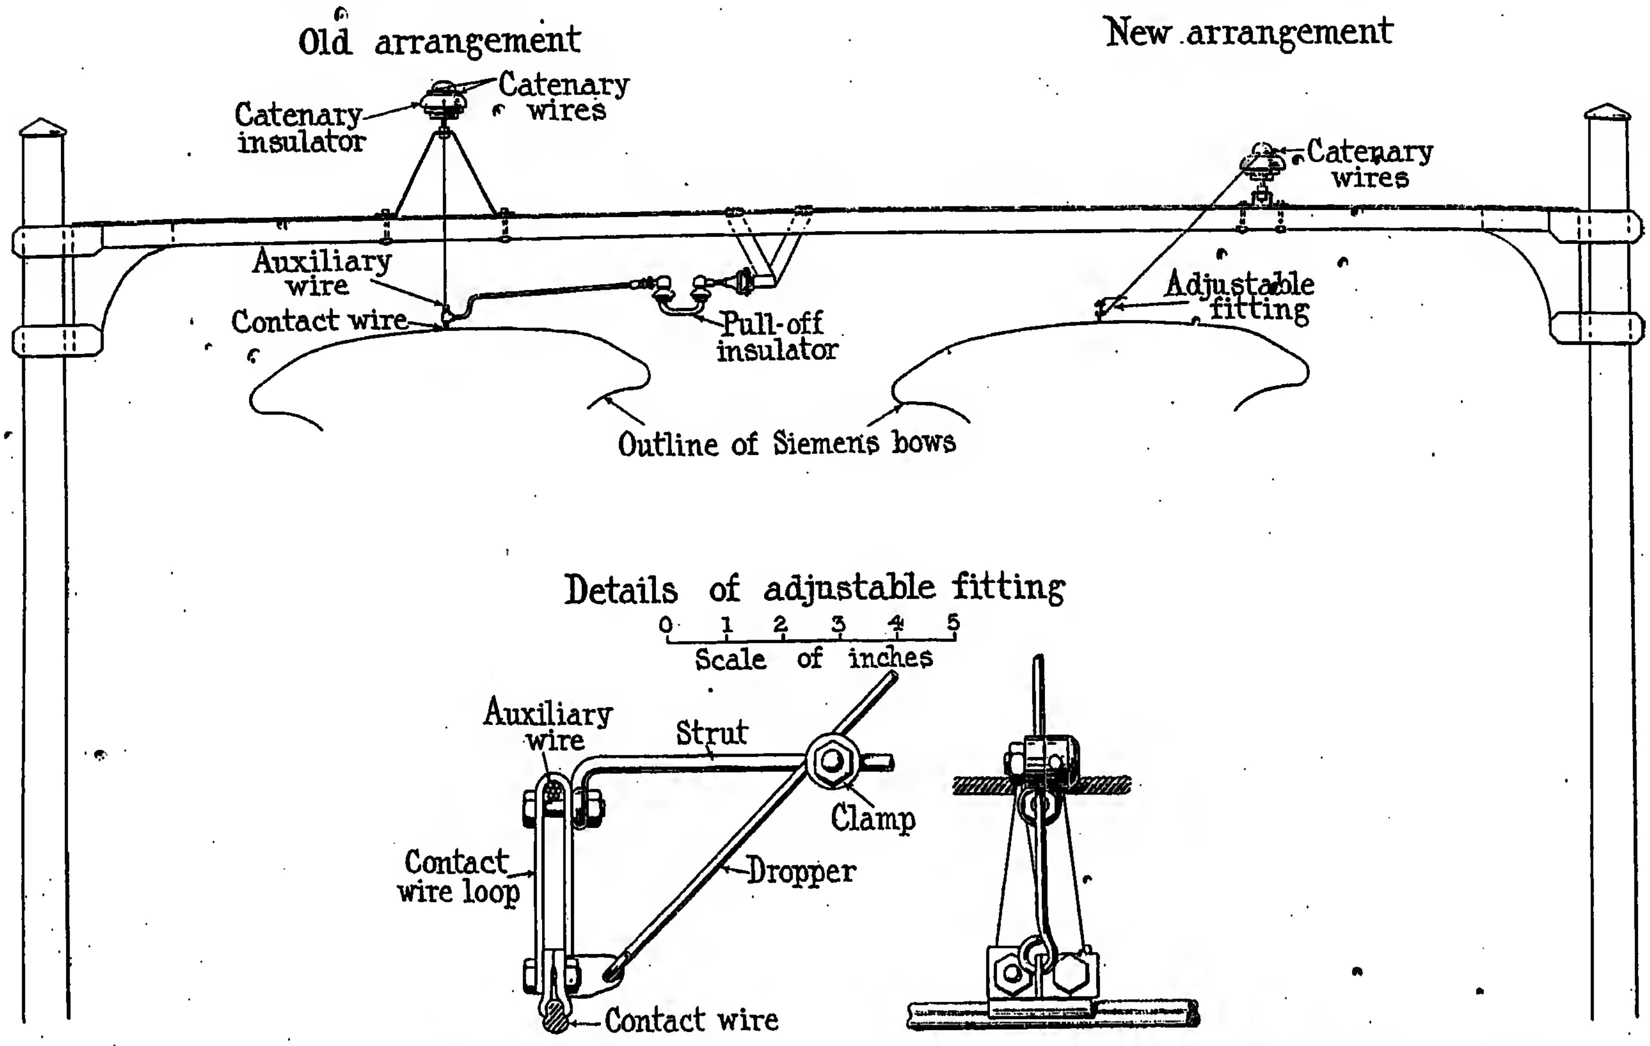

FIG. B.—Old and new arrangements of overhead wiring on a 30-chain curve between gantries on the Lancaster, Morecambe and Heysham line.

extra inertia in a vertical plane, which is the very worst thing possible in high-speed current collection. The author did not touch on the question of lightning

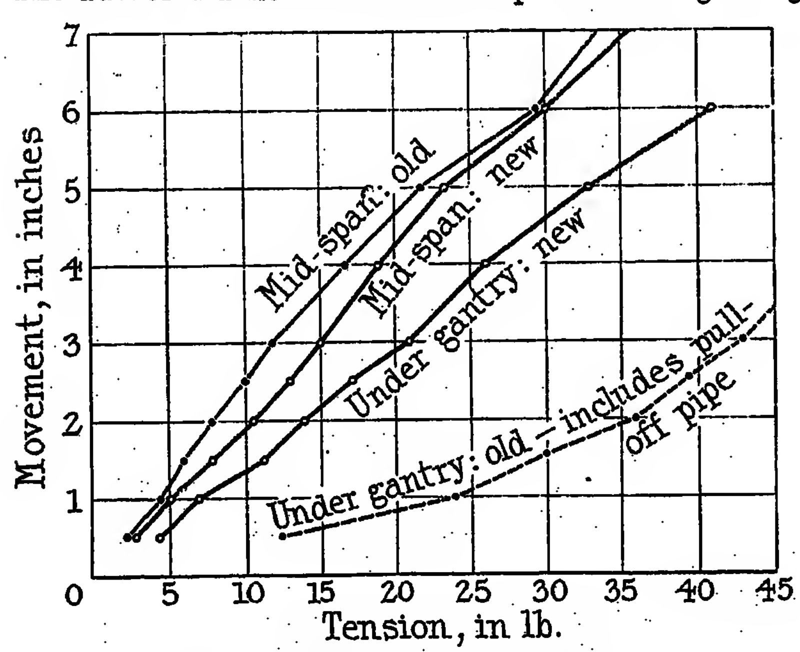

FIG. C.—Relation between upward movement of contact wire and tension on a 30-chain curve.

protection, but this is rather important. We have put in a set of Moscicki condensers to take charge of very high-frequency surges, and a Giles valve for moderate-

know that the static charge on a wire, say, 22 ft. above the ground is very high indeed in certain states of the weather. During the erection of the line we had numerous reports of men receiving shocks, although there was no connection with the power house. The last point to which I should like to refer is that of the power supply to a railway system. Evidently the Midi Railway is going to have the great advantage of a combined railway and industrial generating station and network supply, at 50 periods. In this country there is at present a strong prejudice against 50-period large rotary converters. But as the Midi Railway proposes to adopt mercury rectifiers I take it that these will replace the rotary converters. Whether 50 periods can be used for traction purposes and, therefore, whether the railway systems can be joined up to the general power supply—a very desirable thing in itself for economy's sake—has not been settled. Possibly it would be better to pay the extra cost of current and either run frequency-changers from the general supply or allocate certain stations and power supply systems to traction, than to run the extra risk of shut-downs on a big transport system.

Mr. F. Lydall: In this country we have seen the electrification of railways develop almost entirely along the lines of urban and suburban work, and that has necessarily been mainly confined to a direct-current

multiple-unit system operating at a low voltage. The Midi Railway, on the other hand, has had a much more diverse and wider experience. It commenced with low-voltage direct current, and developed along the lines of single-phase alternating current. For locomotive work the single-phase system was first employed, followed by high-tension direct current. The account of this period is of great value to us in foreshadowing the points which may have to be considered when we have to deal with main-line electrification. In one respect, however, the experience in France does not strictly apply to what may happen in this country. The Ministry of Transport has determined the system on which main-line electrification in this country is to develop, viz. direct current principally at 1 500 volts, with occasional exceptions. We have also to consider, however, as an exporting country what advantages there may be in utilizing other systems under other conditions in other countries, and therefore the experience gained on the Midi Railway is of value as influencing our consideration of the possibility of single-phase traction on railways abroad which may be equipped with machinery and apparatus manufactured in this country. The chief trouble with the single-phase system on the Midi Railway seems to have been inductive disturbance. A very full account of these troubles, of the tests made, and of the attempts to overcome them was published in the French technical Press (*La Technique Moderne*, March and April, 1919). The author gives general reasons why the French Government decided to standardize the direct-current system, and as our Ministry of Transport came to exactly the same decision we naturally uphold that decision. I think it should be recognized, however, that the single-phase system cannot be considered as having no place in railway electrification. As an example I may mention the electrification of the Virginia Railway in the United States. According to published accounts of this scheme the locomotives will have a maximum capacity of 20 000 h.p. For this output the electrical input will be about 17 000 kW, and if the d.c. system were employed with a distribution pressure of 3 000 volts the current taken by the locomotive would be about 6 000 amperes. No doubt it is possible to collect this current from an overhead line by using a sufficient number of collectors, but the cost of providing and supporting overhead conductors of sufficient section to carry such a large current would be very high if not altogether prohibitive. The single-phase system with a distribution pressure of, say, 15 000 volts would avoid this difficulty. A short time ago I was privileged to inspect various parts of the Midi Railway system. One of the substations which I visited contained three single-armature rotary converters, the other two mercury rectifiers. The rotary converters were, of course, 1 500-volt, 50-period machines, and the point which greatly impressed me was that practically no steps had been taken to guard against serious flash-overs on the rotary armatures themselves, except the provision of high-speed circuit breakers. The brush gear was as simple as on an industrial 250-volt motor. I understood that they relied entirely upon the high-speed breakers to prevent flash-overs. One or two flash-overs had occurred but these were due to short-circuits on the overhead line immediately outside the substation, so that the current must have been very considerable and the conditions very severe. When such flash-overs occurred the machines had to be shut down and the commutators cleaned up, and this probably took about 30 to 40 minutes. We should not, I think, be prepared to face this risk on lines in this country. Another thing that I noticed was that there was no guard of any kind round the rotary converters. In place of lightning arresters, flash suppressors of the Capart type were used. I should be glad if the author would say whether these are to protect the machine and apparatus in the substation from lightning troubles, or to prevent flashing-over due to surging caused by short-circuits. The rectifier substation contained two rectifier sets and a great deal of other apparatus. The rectifiers were the smallest pieces of apparatus in the substation and were remarkably compact. I should be glad if the author would give some additional information about them, as there is a general feeling in this country that they are liable to give trouble from backfiring. In a recent article the efficiencies of these rectifiers were stated to be as follows: On overload 95 per cent and at quarter load 93·2 per cent. I do not think that these figures show any substantial improvement on a really up-to-date 1 500-volt 50-period rotary converter. The general design of the locomotive as regards the method of mounting the motors on the axles is not very special. The interior of the locomotive struck me as being well arranged. There is a central aisle from end to end, on each side of which the control equipment is housed in compartments. The main motor-generator, which provides forced draught and auxiliary power for general purposes, is located in the centre of the aisle and is quite easy to get past. The arrangement seems to me to be satisfactory, except that the back of the switchgear is not very accessible, and this may rather tend to increase the maintenance costs of the equipment as it stands. It is interesting to note that regenerative braking has been abandoned in favour of rheostatic braking, but I should like to ask whether that does not involve a considerable increase in the weight and volume of the resistances into which the return energy has to be passed, and also whether any arrangement is made for forced draught on these resistances to prevent them from overheating. Can the author give any figures of the expected return of energy by regeneration? I do not think that we should take this decision of the Midi Railway as implying any doubt as to the value of regenerative braking under suitable circumstances. There is, I believe, no idea of abandoning the system on the Chicago–Milwaukee Line, where it has been in use ever since operations started; and in the latest locomotive being built by the General Electric Company of America for the 3 000-volt Mexican Railway system, provision is made for regenerative braking. In regard to the design of the experimental passenger locomotives, it is noteworthy that Sir Vincent Raven in his paper read last year before the Institution of Mechanical

Engineers, suggested for the locomotive oscillations which take place a cause quite different from those mentioned by the present author. Sir Vincent suggested that these oscillations took place in the United States and not elsewhere because the rail joints in that country are staggered alternately from side to side, and that this may at certain speeds of the locomotive set up sideways and vertical oscillations which will synchronize with the natural frequency of oscillation of the locomotive. It is difficult, of course, apart from actual experience and very elaborate experiments, to say whether one cause rather than another is definitely more likely to give rise to the trouble, but it is certainly worth while taking special note of the fact that both Sir Vincent Raven and the engineers of the Midi Railway took their courage in both hands and, in spite of the alarmist warnings of the engineers of the United States, built experimental locomotives which were symmetrical, and in both cases have found that their courage was fully justified and that no trouble was experienced. I should like to draw attention to a long account of the working of the six experimental single-phase locomotives built by the Midi Railway, in the 14 December, 1918, issue of the *Revue Générale d'Electricité*. The conclusions drawn in this article from the practical and theoretical discussion are very briefly as follows: There are five sorts of oscillations in connecting-rod locomotives, and such locomotives must have all these different kinds of oscillations to a varying extent as the speed increases. The concluding remark is, I think, illuminating: "Finally, geared locomotives are free from all these." On the general question of the height of the centre of gravity I am not satisfied that it is necessary to go to any elaborate and costly construction of the motors in order to secure a high centre of gravity of a locomotive. A high centre of gravity is undoubtedly of practical utility, but it must be admitted that this height is dependent on the general construction of the locomotive rather than on the position of the motors in relation to the axles. Certainly not much is gained by merely lifting the motors above the centres of the axles; in the passenger locomotive built by Sir Vincent Raven, the centres of the motors were 21 inches above the centres of the driving axles, but this had the effect only of raising the centre of gravity of the whole locomotive 3½ inches, compared with what it would have been if the motors had been mounted level with the axles.

Mr. H. N. Gresley: The author has rendered great service in bringing so prominently before us the far-sighted and wise policy of the French Government in allowing the railway companies to supplement their load by an industrial load, thereby improving their load factor. In England the position is, of course, quite different. The railway companies who wish to electrify will have to get their current from one of the power companies, or else have very great difficulty in making out a case—as we have seen on one of the lines which has recently started electrification. It would be interesting to know whether statutory areas of supply are allocated to various power supply companies in France. The electrification of railways is much more attractive in France than in England, because coal there is so much more expensive, and the Midi Railway uses water power. In this country a comparatively small zone is electrified—in most cases where there is a very dense suburban traffic and the load factor is, in consequence, very poor. There is a tremendous number of trains during the rush hours of the morning and the evening, and for the rest of the day there is a comparatively small traffic in cases where only the suburban passenger trains are worked electrically. On some of the railways which have been electrified in that way a procession of steam-drawn passenger and goods and mineral trains may be seen going over the electrified lines. If the cost of current were reduced and if the electric lines were extended to 40 or 50 miles, it would be practicable to take off the steam locomotives and use to much better advantage the capital which has been spent in a third-rail or overhead equipment. This would result in a very much steadier load and a much improved load factor. At present the power supply companies should be able to supply current more cheaply than a railway with only a suburban traffic at a poor load factor; but if the load factor were improved I suggest that a railway company should be able to have its own generating station and produce power more cheaply than a power company. A railway company with all its many and varied properties in the way of lands, lines, steamships and hotels, etc., would offer very much better security for debenture holders than a company which has only a power station. It could therefore raise money at a lower rate of interest than a power supply company could. Again, if a railway company had electrified the bulk of its main lines and obtained its power from a power company, it would practically be putting into the hands of that company for a period of 30 or 40 years—they require long agreements—the whole of the power for operating that railway. The railway would have no voice in the management, and would derive no benefits from the economies which might be produced, as its agreement would be at a fixed rate. I suggest that it might be possible for railways when electrified to make some co-operative arrangement with the power companies by which the railways themselves would have a direct interest in the power company. Possibly they might assist in financing the extra equipment required, in which case they would require to have a voice in the management and some representation on the directorate of the company.

Mr. A. T. Dover: In connection with the substations equipped with rectifiers and rotary converters, would the author give, if possible, the all-day efficiencies of these stations under similar loads, and also figures for the pressure regulation? Also, would he indicate what staff is required in the two classes of substations, and say whether periodic overhauls of the rectifiers are necessary? Do the ripples in the d.c. pressure cause any extra wear in the gears or in the motor bearings? The author's opinion would be appreciated on the question of the practicability of making fully automatic the rectifier substations supplying branch lines having light traffic. Has this been tried out in practice, and are the results as favourable

as those obtained with automatic rotary-converter substations? At the top of page 216 it is stated that the low-tension auxiliary service set on the passenger locomotive is rated at 72 kW. This is probably a misprint, as 72 kW is rather excessive for a locomotive equipped with four 350-h.p. motors. In dealing with track bonding, the author mentions that a number of experiments have been carried out with different types of bonds, the type finally adopted being one which bonds the fishplates to the rails, the bond being fixed by means of split pins and through bolts. Can the author give any further details of that system? The general practice in this country is to fix the bonds by hydraulic pressure. In describing the motor-car for suburban and branch-line services the author states: "The tractive effort is transmitted from the truck frame to the swinging bolster through articulated drawbars instead of the ordinary friction plates." That seems to be a new method, and I should be glad if the author would describe it more fully.

Mr. R. L. Morrison: At present in connection with the Midi Railway electrification scheme there are altogether five substations equipped with mercury-arc rectifiers, the total capacity amounting to about 19 000 kW, representing 16 sets each of 1 200 kW. These have been installed, I believe, where the loads are the severest, i.e. where the inclines are greatest. They are designed to deal with pressures up to 1 800 volts on the d.c. side. Rectifiers are specially suited to traction conditions, due to the fact that they are capable of handling extremely heavy momentary overloads and heavy short-circuit conditions. In fact, one is hardly conscious when near such plant that short-circuits have occurred, except for the tripping out of the circuit breakers. It will be noticed from the lantern slide which I shall now exhibit that for long periods the overload capacity is not great, but for short periods extremely heavy loads amounting to several hundred per cent overload can be handled, and under some circumstances for as much as $2\frac{1}{2}$ minutes at a time. It is the property of the rectifier in this respect that makes it so suitable for these particular conditions. The next slide shows a short-circuit curve taken on one of the Midi rectifiers. The normal current rating was 400 amperes and at the time the test was made the d.c. pressure was 1 800 volts. It will be noticed that before the circuit breaker cleared, the current rose to 8 700 amperes, or 22 times the normal value. Sixty similar short-circuits were applied for two days in succession, after which the cylinder was opened up and found to be in precisely the same condition as when sealed up prior to the test. Mr. Lydall has referred to the high-speed circuit breakers used in connection with some of the rotary converters. Similar circuit breakers are used in connection with the rectifiers. As seen from the next slide, this breaker is of novel design, the object being to cause the arc to spread out right round the circuit breaker. This is obtained by providing a heavy magnetic blow-out field round the switch, and from the next slide the effect of this field on the path of the arc is clearly seen. The switch is designed to open in about 1/100 second, and when the photograph was taken the short-circuit current amounted to 8 500 amperes. The next slide shows the same switch opening with 8 700 amperes—in this case the arc has travelled a good deal further round the switch. The total resistance in the circuit at the time was 0·025 ohm, while the switch opened in 1/60 second. The next slide is a photograph of one of the Midi sets. It consists of two cylinders each rated for 600 kW, with a vacuum-pump set common to both. The vacuum-pump set has recently been to some extent simplified, especially for automatically operated equipments, and the vacuum gauge in such cases would be of the direct-reading type, in appearance similar to an ordinary voltmeter. The next slide gives the test figures of the Midi sets to which Mr. Lydall has already referred. The efficiency curve includes all losses. The power factor at $\frac{1}{4}$ load is lower than what might be expected in the normal case and, in this instance, is due to the fact that a 12-phase connection is utilized instead of a 6-phase, which results in a rather complicated set of windings. The inherent regulation of these particular sets, taken on the basis of a constant primary pressure, amounts to a trifle under 3 per cent. The next slide shows efficiency figures obtained on another high-tension traction rectifier designed for 1 200 volts (d.c.) which has been running for some years at Ekeberg, near Christiania. The power factor is very high, dropping only to 90 per cent at $\frac{1}{4}$ load, while the efficiency is also very high. Automatic control of rectifiers has been highly developed and excellent results have been obtained with relatively few relays. The connections are simple and, in spite of what has been said by one speaker relative to the unsatisfactory operation of rectifiers, it can now be definitely stated that the earlier troubles have been so far eliminated, by improved design and other conditions, that the rectifier is now well on the road to being as reliable in operation as any other form of converter.

Mr. C. E. Fairburn: I do not think the author gives the impression that the regeneration system has been abandoned because it was in any way inefficient or because it did not work properly. Rheostatic braking is preferred to regeneration, because the mercury-arc rectifier substations have been placed on severe grades. It is impossible to regenerate into a mercury-arc rectifier, and when regeneration is started the return current flows to the nearest rotary-converter substation. In consequence the distance between the locomotive and the rotary substation is often very great, with the result that the consequent voltage on the line is very high, and this affects all the apparatus. The lantern slide shows a skeleton diagram giving the main connections. The main motor armatures are connected two in series with a small buffer resistance across the line. The fields of the motors are separately excited from a variable-voltage generator on the field of which there are some reverse turns in series with the regenerated current. This helps to regulate the current-rushes. The actual control of the regenerative braking is by varying the shunt field on the variable-voltage generator. The next slides show the relation between torque and armature current at a line pressure of 1 500 volts, and also at varying voltages. An auto-

matic relay is provided to prevent the armature current becoming more than 3·5 times the field current. The next slide shows the results of some tests taken last year. Actually the locomotives had been regenerating some months before that, and they have been regenerating satisfactorily up to the present date. These tests were carried out on a gradient at Capvern between Toulouse and Tarbes. This gradient has a constant slope of 3·3 per cent for 11 km, and it will be seen that a considerable amount of energy was regenerated. There is no trouble with this system of regeneration. The switch is thrown over to "regeneration" and an ammeter is provided showing the field and armature currents side by side. The only rule which the driver has to obey is that the needle for the field current must not pass that for the armature current. If it should do so, the automatic relay comes into operation. The driver operates the master controller exactly as if he were using it for driving the locomotive.

Mr. G. W. Partridge: The author states that the system "is protected against pressure-rises by earthed reactance coils with iron cores, and against steep-front surges by Capart apparatus consisting of mica condensers branched between two inductive coils, one of which is shunted by a resistance." I should be glad if he would describe this arrangement more fully. The paper states that the protection of d.c. machines is provided for by high-speed circuit breakers and an earthing device composed of a condenser shunted by a resistance, but I should like a little further information on this point. Does the term "high-speed" mean that the actual circuit is opened quickly at the moment the circuit breaker commences to start, or does it mean that a circuit is opened instantaneously when any disturbance occurs? I entirely agree with Mr. Lydall that in the supply to a railway, if these circuit breakers are set to open immediately there is any trouble on the system, various sections of the railway are liable to be shut down. Shock upon shock is thrown upon our station supplying suburban railway systems, and if the main circuit breakers opened every time there was a short-circuit, it is certain that the supply would be badly affected. I can conceive difficulties in the way of giving a commercial supply in certain districts where there might be rather heavy pulls on the railway, which would, I imagine, upset the regulation or cause drops in pressure on the commercial supply; whereas pressure-drops in moderation would have very little effect on the working of the railway. Has the author considered an apparatus for limiting the maximum demand in certain districts? If the charge made to the Midi Railway for current is on the principle of so much per kW of maximum demand with an additional charge per unit, the lower the maximum demand can be kept the better. I believe that this system has been tried in America with some success. Mr. Gresley seems to think that the supply company's tariffs are too high to-day. My experience is that most supply companies to-day are charging the public almost pre-war rates. In the case of railways, everybody will appreciate what it costs to travel and to send goods by rail at the present time compared with pre-war days. I can conceive that under certain conditions it might be to the advantage of a railway company to own the power station, but Mr. Gresley overlooks the fact that railway companies have no powers to sell electricity to the public, and so long as the supply companies have powers to sell electricity for its various uses, and so long as from year to year these various uses are multiplied, there may come a time (not far distant) when the supply companies will be selling electricity to certain users under special conditions at lower rates than those charged to the railway companies. I therefore fail to see how a railway company can generate electricity more cheaply than a large supply undertaking with various users of its supply. I can assure Mr. Gresley that in making a contract with any supply company there is very often a clause to the effect that the railway company should have the benefit of any improvement in the art so long as the company agrees to pay reasonable interest on the capital expended. Then, again, I think that it would be quite a reasonable condition in a contract if the charges were revised every 10 years, so that the railway company would not be left in the hands of any one supply company over a long period without power to modify the rates of charge if circumstances justified revision. The railway companies may, I think, safely leave the supply of electricity in the hands of those who have spent their lifetime in the industry.

Sir J. A. F. Aspinall (*communicated*): It is gratifying to find that the French Commission came to the conclusion that their traction system should be direct current at 1 500 volts, as this is the same as that recommended by the Electric Railway Advisory Committee in this country. It is also interesting to know that some of the French companies wish to keep to the use of the third rail although they will use 1 500 volts. The nearest present approach to this in this country is on the Manchester and Holcombe Brook line of the London, Midland and Scottish Railway, where 1 200 volts is carried on a side contact rail with great success and security. The author's praise of the mercury rectifier is very encouraging. The breaking of axles is being wisely overcome by bolting the gears to the driving wheels. Locomotive engineers have long been familiar with the fact that any stiffening of the axle at any one point due to anything being bolted round it may cause fractures, and more especially when a keyway is added. Uniformity of flexibility throughout the axle is a safeguard. Am I right in assuming that the author would accept regenerative braking on those railways where there are long inclines? I am in complete agreement with the author's remarks in regard to locomotive construction. The introduction of reciprocating movement by the use of outside rods is most undesirable. As in the first place we have the rotary motion of the motors, to convert this into the reciprocating motion of the rods, and then reconvert it into the rotary motion of the wheels, has always appeared to me to be a mechanical abomination. There are other and more attractive designs, and when this great French electrification of railways is more advanced we shall see these preliminary difficulties swept away very rapidly on account of the large field for experimental work. For instance, the locomotives

with twin vertical motors to which the author refers, have some very good points, and had this method of driving been applied to engines specially designed for it, the details would have worked out in a more advantageous way. The author also recognizes the advantage of a high centre of gravity. In conclusion, I quite agree with his view that the generally-held opinion that the symmetrical wheel-base makes for unsteady running is a fallacy.

Mr. J. Dalziel (*communicated*): It may be remembered that the late Midland Railway in its Heysham–Morecambe–Lancaster installation was the first to put single-phase traction into operation in this country. Various officers of the Midi Railway, in fact, visited that installation whilst their own scheme was under consideration. The adoption of a single-phase system by both railways was dictated by the same considerations, viz. that for main-line work the overhead collector system promised the best results and appeared to be the most feasible, and, as things were then, the single-phase system was the only practically applied system with which an overhead line could be used for heavy traction. As high-voltage direct-current systems working off an overhead wire are now available, and as the arguments against single-phase current, of intensified induction effects on weak-current lines and neutralization of the advantage of substation simplicity when 50-period supply is used, apply equally in this country as in France, one has to agree that there is no longer any substantial vogue for the single-phase system in this country, even though one must still contend that it has certain advantages in heavy traction which are of some importance, and that with modern development of its apparatus there is no reason why it should not attain a standard of reliability and of low cost of maintenance nearly equal to that of direct-current apparatus. It is stated in the paper that certain companies wish to adhere to the use of the third rail and use 1 500 volts thereon; there is a similar sentiment among some engineers in this country, and it would be of interest if the author would give the reasons which dictated his own disagreement from this policy and his adoption of overhead collection. In the meantime the third-rail system is practically standard in this country for urban and suburban work, chiefly due to the necessity for connecting up, and inter-running, with existing third-rail installations. It is still a matter of controversy whether it should be extended to main-line work or the overhead system preferred. The latter is the practice in nearly every country and railway that has instituted main-line electrification, and, speaking for myself, it would seem to be the obvious course, for while an overhead contact line can be applied without break of continuity throughout all lines and sidings, the third-rail system is subject to interruptions where it must be reinforced by lengths of overhead collection. Gaps must always occur in the third rail at points, crossings, etc. Multiple-unit passenger trains can bridge these or coast over them, but locomotives certainly can neither bridge them nor always coast over them, especially in freight service, where they occur, almost of necessity, at the very points where a shunting locomotive will have to do most of its starting and stopping. It would seem that the question resolves itself into this: If an overhead conductor can do all the work, and the third rail cannot and requires overhead assistance—with some complications—at intervals, why use the third rail at all? It may be that these considerations, with perhaps others, carried weight with the author. On page 214 the use of synchronous condensers of 60 000 kVA total capacity is mentioned. If the purpose of these is to correct power factor, as presumably it must be, it would be interesting to know whence comes the very low power factor which is implied by the use of these machines and their very high capacity. Presumably it is the industrial load which gives rise to their necessity, as one would hardly expect a purely traction load fed through rotary converters and mercury rectifiers (which are not comparably much lower in power factor) to need such correction. Another question that might be asked in this connection is why moving machines were used in preference to static condensers? The answer may be that the latter were not developed to the point of practical efficiency at the time the author had to make his decisions. The author's testimonial on pages 214 and 215 to the satisfactory operation of his 1 500-volt 50-period converters and of his 1 500-volt mercury rectifiers is particularly valuable if, as one believes to be the case, this voltage is so far the highest in practical use on both types of apparatus. One is given to understand that mercury-rectifier apparatus of still higher d.c. voltage is in course of installation. With regard to sectionalizing (referred to on page 215) it would be interesting to know what length of section is cut out automatically when a breakdown occurs. It is also not quite clear whether this cutting out is done on the high-tension line or the contact line. If the former, one would also like to know into what length of section the contact line is divided, and whether the sections are automatically isolated. On page 216, in the description of the first two types of engine, it is mentioned that the couplings and buffers are fixed to the truck frames and not to the locomotive body proper, as is more usual, the object being to avoid the transmission of tractive effort by the centre pins. It would appear that the author's method would exercise some restriction on the free radial play of the bogies in passing round curves. Has any such effect been observed? Regarding the author's remarks as to regenerative braking, I should like to ask to what extent the comparatively very small value of the regenerative current on the Midi Railway has influenced the decision arrived at. There is no question that unless the value of the regenerated current is substantial, the additional control gear and additional complication introduced will restrict its use to those cases where gradients are very heavy and the value of the current is unusually high. It is clear from the author's remarks that the saving in brake-shoe and track wear and tear claimed for regenerative braking is being obtained on his very heavily graded line by the simpler method of rheostatic braking. The author's express locomotive and his exposition of the characteristics governing the design of such locomotives are

of special interest. One is glad to note that he objects to rod locomotives, on the grounds that they give rise to "stresses leading to breakage of rods, cranks and even of the engine frame" and, the expressed opinions of certain of our leading technical journals notwithstanding, it will be agreed that in these remarks the author expresses the general consensus of opinion with regard to such locomotives. He does not, of course, suggest that there is no rod locomotive giving modified satisfaction, but only that it is a species which is dying of its own infirmities and had better never been invented. The author's vertical motor is a new departure which has the advantages, at least, of helping to raise the centre of gravity and of putting the commutators and brush gear into the cleanest and most accessible position available. I doubt whether the author's bevel gear can have any advantages over, or even be equal to, straight spur gear as regards either efficiency or maintenance, and it is generally accepted that bevel gear requires greater accuracy in alignment and setting than straight gear. The author's views as to the satisfactory operation of symmetrical wheel-base locomotives are rather opposed to those held by traction engineers generally with reference not only to electric but also to steam locomotives; it is generally considered that for trailing purposes a centrally mounted bogie is not so suitable as a single-axle or two-axle truck pivoted forward of its centre. Though the riding qualities may be sufficiently satisfactory both ways, it is certainly the case that some engines with a leading bogie and a trailing axle pivoted as mentioned above ride much better with the bogie leading than with the bogie trailing. Of course the inferiority may arise more from the fact that the single-axle truck is a bad leader than from the fact that the bogie is a bad trailer, but it is at the rear end that it shows the most. The author's locomotive will certainly be one of the most interesting so far put on rails, and if its riding proves his contentions it will not only mark a step forward in electric locomotive design but relieve a certain amount of anxiety on the part of electric locomotive designers on the subject of wheel-base symmetry.

[The author's reply to this discussion will be found on page 230.]

North-Eastern Centre, at Newcastle, 26 November, 1923.

Mr. H. W. Green: It is unnecessary to go outside our own country (or, in fact, outside our own locality) to learn of the reliability and successful results obtained with electric traction. The few lines on which this system has been adopted in this country have proved such a success that one is apt to wonder why further electrification is not taking place more rapidly. Every railwayman is proud of the steam locomotives now in service and of their performances, but they compare very unfavourably with electric locomotives. A number of economies which are effected by the adoption of electric traction are enumerated by the author, and these cannot be too often repeated. There are others not mentioned which are worth adding. Turntables would be unnecessary, due to the locomotives being arranged for driving from either end. The number of locomotives required would be reduced owing to the longer time they could be kept in service. Trains could be double-headed and still have a crew on only one engine. It would be interesting to know what savings the Midi Railway have effected in this respect and what they anticipate on the complete scheme. The limit to the size of locomotives has almost been reached and it would seem that if heavier trains and the existing or higher speeds are to be maintained, then the only solution is electric traction, in which the motive power is accommodated in considerably less space and is reduced in weight. This point was very clearly illustrated in a paper by Sir Vincent Raven a short while ago. The present tendency appears to be to consider electric traction for lines over which there is an assured traffic, but the fact that electrification invariably results in increased traffic should not be overlooked. This applies more to the suburban lines, and it would be well to bear this in mind in connection with lines over which there is not a large traffic. A better and more frequent service would undoubtedly lead to the opening up of many suburban areas and reduce the overcrowding in many of our towns.

Mr. F. H. Williams: In considering electric traction in a general way it has been fairly common to consider Continental practice as essentially based on the use of a.c. motors for transmitting the power to the driving wheels, and British practice as favouring the use of d.c. motors. This generalization has led to the impression that engineers in this country were not prepared to consider the possibilities of a.c. traction motors; but this is quite erroneous, and in considering any new schemes it is usual for both possibilities to be carefully explored and the decision to be arrived at purely on merit. On page 214 the author mentions that locomotives are to be fitted with gear for collecting current from a third rail as well as from an overhead conductor. It would be interesting to have some information on this matter, and also to learn what type of third rail has been standardized, and whether any special steps are being taken to prevent accidental contact, both with the third rail and with the collector shoes. It is by no means easy to design a third rail which will give reasonable safety when used with 1 500 volts. With regard to the cam-shaft control, how does this compare with the ordinary contactor control, and is any extra difficulty experienced in starting heavy trains on gradients when the rails are greasy, i.e. does the cam control return to the starting position as quickly as the ordinary contactor control? In regard to bonding, were the troubles referred to in the paper due to mechanical failure or to bad electrical contacts? I do not think the form of bond described is much used in this country, a ribbon type or stranded bond fitted under the fishplate being usually adopted.

I have seen a ribbon bond which had been submitted artificially to over a million vibrations and was still practically as good as when the test was started. If the troubles experienced were due to poor electrical conductivity, I should like to know what they were and how they were discovered. Has the author found any satisfactory method of measuring the conductivity of bonds, using the current flowing in the rails? So far as I am aware, there is no satisfactory method of doing this, and the only way of making a satisfactory bond test in situ is to use a special form of "Ducter." Measurements made with this equipment are very satisfactory and reliable but, unfortunately, require the rail to be made "dead." Badly bonded joints can readily be detected in frosty weather by an examination of the joints directly after a train has passed, as the frost or snow will have been melted round the joint.

Mr. R. J. H. Beaty: The greatest novelty mentioned in the paper is the rotary converter to work on a 50-cycle supply and give 1 500-volt direct current, but it is not described in detail, and the fact that it has a radial commutator is not even mentioned. What is the peripheral speed of this commutator? This is really a reversion to d.c. turbo-generator practice, which was thought to be extinct. Perhaps the day is not far distant when we shall completely enclose these machines, fill the case with compressed air, try to run at a higher voltage per commutator bar, and so reduce the peripheral speed. These abnormal types would not be necessary were it not that absurdly high frequencies have been standardized in most countries. We are told that a voltage of 1 500 has been chosen to allow the third-rail system to be used, but is this system necessary or desirable? It may be all right for tube or overhead railways where there are no level crossings and few junctions, so that the rail can be fairly continuous, but on most ordinary railways there are numerous private crossings leading to fields, each of which crossings necessitates a break in the third rail. Would not this be rather distressing at 90 miles an hour? A drop of 20 per cent in the line voltage under normal service is not a testimonial to the wisdom of standardizing that pressure at 1 500 volts, if the high-speed breaker can be relied upon. It is rather disappointing to hear that regenerative braking has been abandoned, as one would expect that a considerable amount of power would be regenerated on the 1 in 25 and 1 in 30 gradients mentioned in the paper. The first two types of locomotives are fitted with motors of the wheelbarrow type, a survival of the unfit. In these the driving force is vertical as in some of the pioneer steam locomotives, but this method was discarded by Stephenson over 90 years ago owing to the whole engine being rocked on its springs. In this type of motor, however, the rocking is reduced by having half the weight unsprung, a state of affairs which can hardly be accepted as the final solution. The 4–6–4 express locomotive is one of the most interesting machines mentioned in the paper, and its evolution is a step in a direction in which progress has been all too slow. The author's remarks on nosing will take a permanent place in the history of electric railways. The 4–8–4 locomotive is said to be capable of pulling a 600-ton train, presumably as a test load only. Far too many passenger trains have been broken in two in recent years, and, so far as this country is concerned, 300 tons should be the limit for any passenger train. I think that if we had an electric locomotive capable of taking a 300-ton train up a 1 in 100 gradient continuously at 50 miles an hour our booked speeds could be considerably improved. At the present time we have to compete only with the inefficient steam locomotive, the power of which, as is well known, is limited by the size of boiler that can be built within the loading gauge; but the future may bring forth an internal-combustion locomotive free from this limitation and capable of giving a constant pull over a fairly wide range of speed. I think it is desirable that British engineers should study the conditions which exist on their own lines and deal with them in their own way without being unduly influenced by foreign practice or limited by standards prematurely fixed.

Mr. H. R. J. Dunthorne (*communicated*): The outstanding feature of the paper is the magnitude of the undertaking described therein, and one would have liked to have asked the author for some information as to the estimated cost of the work divided over permanent way, rolling stock, power stations, substations and distribution. It would be interesting to know how the system adopted compares with straight single phase using e.h.t. distribution with step-down transformers on the locomotives, and series motors, in respect of first cost, running costs and overall efficiency; and also how the work is being financed, i.e. out of revenue, by increase in capital or by State aid. It is not without interest to note that France is at present in a position to carry out works of this magnitude. Attention has been drawn in the discussion to the type of overhead construction adopted and to the restrictions imposed in this country. There appear to be two methods which may be adopted in dealing with safety measures for a comparatively new and rapidly expanding industry: (1) To make the minimum or no regulations at the outset, and to make or add regulations as accidents or other causes point to their necessity. This, to some extent, was the way in which the Factory Acts were built up; and a heavy toll of life and limb was taken before the present, by no means perfect, rules and regulations were evolved. (2) The second method is to make stringent regulations at the outset, providing protection from every probable or, one might almost say, possible form of danger connected with the business, and to relax or modify these in the light of experience and, in the case of electric power distribution, improvement in the reliability of switching and other safety appliances. While it may be argued that this method imposes an unduly heavy burden on an infant industry, it certainly prevents the growth of vested interests in unsatisfactory and even dangerous methods, which are frequently most difficult and, generally, very costly to deal with. One finds an excellent object lesson in the lighting of passenger trains, where gas lighting is still retained. The decision as to whether the first or second method

shall be adopted appears largely to depend on the value placed on human life. Finally, it may be pertinent to remark that even in America it has been found necessary to adopt the slogan "Safety First."

Mr. W. D. Horsley (*communicated*): A very striking feature in connection with the paper is the great rapidity, extent and thoroughness of the recent developments of the Midi Railway. No comparison should be drawn with progress in this country. In France, and particularly on the Midi Railway, the conditions obtaining demand electrification. Coal costs probably four times as much as in England, and with the large amount of water power available an alternative to electric traction can hardly be considered. Other advantages such as higher average speeds, due to the overload capacity of the electric locomotive, and increased capacity of a given line for the same number of tracks, are common to all electrification schemes. It is of very great importance to hear of the adverse experience with regeneration on the Midi Railway. In view of the fact that this has always been claimed as one of the advantages of the electric locomotive, it would be of great value if the author would amplify his remarks concerning this point. What actual saving of energy has been obtained and what are the difficulties experienced? The author states that "the present programme is to establish around our mountain or seaside resorts a service of light and frequent trains." In the case of the former, at least, will not regeneration effect a large saving and compensate for any slight complication? With a regular and frequent service of trains in a hilly district it would perhaps be possible, with the line sections tied, to dispense with rotary machinery in the substations while still retaining regenerative braking. No interchange of energy would take place through the substations, but only through the line, the effect being simply to take less current from the supply. With regard to the mercury-arc rectifiers installed, it is not clear whether there are 12 phases or whether two 6-phase rectifiers are fed from a single transformer. The ripple in the d.c. voltage must be slight and, as stated in the paper, would not be likely to affect the operation of the motors; but it would be of interest to know whether any trouble has been experienced from this cause through interference with telephone lines. The Midi Railway has undoubtedly had a unique experience with electrification schemes and it would be of great value if the author would give some further comparisons of the single-phase and d.c. systems, particularly with regard to first cost, maintenance and overall efficiency.

Mr. A. Bachellery (*in reply*): There is no doubt that cheap electrical energy produced from water power is a very important factor in the development of railway electrification in France. Up to now, only suburban sections have been supplied with current generated by steam. The Paris–Orleans Company, however, proposes to use for its Paris–Vierzon line electrical energy obtained from the combustion of fuel and also from hydro-electric plants. All the power to be produced in the Midi Company's power stations will not be used for the railway, at any rate at first, and the company intends to sell its surplus electrical energy. This can be done only by permission of the Government. As I have mentioned, our experience both with 50-cycle rotary converters and with mercury-arc rectifiers has been quite successful. Practically no flashing-over occurs in our substations equipped with rotary converters. These machines include a cylindrical commutator but not, as Mr. Beaty believes, a radial commutator. We are to have, in a number of substations, English Electric rotary converters with radial commutators, but they are not yet in service.

Concerning the reasons why overhead collection has been chosen rather than third rail, there is not much to add to Mr. Dalziel's views on the subject. I may say, however, that we have a great many level crossings and, moreover, that on an existing railway it is often difficult—and would have been so in our case—to design a 1 500-volt third rail so as to leave the necessary clearance from permanent obstacles along the track and also from the rolling stock.

The synchronous condensers provided in the transformer substations not only are intended to improve the power factor, which is lowered by the industrial load, but are also necessary for the regulation of the voltage at the extremity of such long lines as ours. They can accordingly supply either leading or lagging wattless current.

The voltage-drop of 20 per cent is calculated from the substations. This is, however, not an average figure but a maximum one corresponding to a full-load train half-way between two substations. It is not, therefore, to be compared with the average loss of power calculated on other electrified systems.

Automatic switches to cut out a defective section are provided on the high-tension line as well as on the traction line. They are located in the substations. We have experienced no difficulties with the communication circuits due to interference from the 60 000-volt wires (which are fixed on the same supports as the contact line) except in the case of a short-circuit, which produces an inductive shock. The only precaution taken to prevent induction from our high-tension transport lines is the periodical transposition of the three-phase wires on their supports.

Voltage fluctuations in the direct-current wires, due to the use of mercury-arc rectifiers, give in the telephone a low musical note which does not prevent hearing. We prefer short track bonds to long ones because they are cheaper and less liable to be stolen. The difficulty was to find a type of short bond which would not be very quickly broken by the motion of the rail ends. The system which I have described seems to answer this purpose.

We have experienced no difficulty as regards restriction of free radial play of the bogies of our two-truck machines due to the couplings being fixed to the truck frames. On the contrary, in order to run such machines at a speed of 50 miles per hour, experience has led us to add to this restriction by putting in lateral buffers between the two trucks, where there was originally only a central coupling.

We have only one motor-generator set to feed the

auxiliary circuits on our locomotives. To have two such sets would certainly be safer, but also more expensive. My observation, however, did not allude to this, but to the fact that to drive the various auxiliary apparatus by special 1 500-volt motors instead of by low-tension motors would be a mistake, small 1 500-volt motors being very liable to get out of order. It is, in fact, because this motor-generator has to supply all the auxiliary motors on the locomotive, including the air-compressor, and also to excite the traction motors when regenerating and to provide the lighting of the train in some cases, that it has to be capable of an output of 72 kW. The 600-ton load on which we based the study of the 4–8–4 locomotive is not, as Mr. Beaty thinks, a test load, but a practical load which has already been attained quite frequently by our steam-driven express trains.

In reply to Sir James Aspinall's question concerning regenerative braking, we think that electric braking is necessary on lines where there are steep gradients; but we prefer rheostatic braking to regeneration because it is more easily managed by the driver on account of the voltage factor being eliminated.

Current supplied from the locomotive will only be used for carriage lighting on branch lines, and in such cases no batteries will be provided. On the main lines, the current for lighting the carriages is supplied at 25 volts from a dynamo on each coach, and the lighting couplings on the locomotive will not be used.

With reference to the table in Mr. Stevens's communication, only passenger trains are referred to, local and freight trains being omitted. The speeds tabulated are scheduled speeds and include intermediate stops, whilst the details regarding the number of stops do not refer to the fastest trains. For instance, on the Bordeaux–Hendaye line, the Southern Express and the Pyrenees–Cote d'Argent Express have only one intermediate stop on the 92-mile trip from Bordeaux to Dax, and only 5 in all. The scheduled speed of the former is 41 miles per hour on the down journey and 40 miles per hour up, and it is 51 miles per hour between Bordeaux and Dax. Similar remarks could be made as regards the express trains between Pau, Montréjeau and Toulouse. Accordingly, the figures in the table do not always give an accurate idea of the lines to which they refer.

PHONOFILMS, OR TALKING PICTURES.

By C. F. ELWELL, Member.

(ABSTRACT *of a paper read before the* LONDON STUDENTS' SECTION, 16*th November*, 1923.)

Attempts to record sound vibrations photographically are not new. The first successful attempts to record sound upon a cinematograph film were those of Ruhmer, who in 1906 and 1907 succeeded in obtaining a crude photographic record of telephonic currents which were superimposed upon the direct current flowing through what was known as the speaking arc. These telephonic currents produced sufficiently large fluctuations in the light from the arc to make it possible to record them photographically upon a film moving at several metres per second.

Properly-synchronized talking-motion-pictures involve light photography at 186 000 miles per second and sound photography at 1 090 feet per second. In addition, if results are to be good, it is necessary to record frequencies of from 600 to 2 000 for voices and good articulation, and from 27 to over 4 000 for music. If the talking-motion-picture is to be practical and commercial it is necessary to put the sound and picture records on the same film, which should be the standard film employed in thousands of cinemas. Dr. de Forest has solved the problem by recording the sound in the blank space, about 2 mm wide, usually left between the driving holes in the film and the picture. It is instructive to watch this band when the talking-motion-pictures are being shown, and to note the change in the number and thickness of the horizontal lines as the frequency of the sound varies. It will be noticed that the synchronization is absolute, and that the width or amplitude does not vary, the sounds being reproduced by the variations in the density of the photographic image on the film.

The photographs are taken by means of a standard motion-picture camera to which is fitted the necessary apparatus for recording the sound.

The ideal form of transmitter for distortionless work is one without a diaphragm. Various forms of transmitters without a diaphragm are now available, e.g. the flame transmitter, consisting of a gas flame in the form of a bat-wing, which is made more conductive by means of salts and in which two platinum electrodes are suitably inserted. Sound waves impinging upon the flame alter its conductivity and cause a current of varying intensity in a local circuit.

Another form of transmitter having no diaphragm and employing very fine and very short platinum wires has been tried. The wires are heated to a dull red by means of a local source of current, and when sound

waves impinge upon these wires their resistance increases or decreases. By means of a local battery and a telephone transformer a faithful representation of the sound waves is obtained with frequencies as high as 3 000. The sensitiveness of the device is greatly increased by means of a gentle stream of air. To be really useful, such a transmitter should be capable of faithfully transforming into electric currents sound waves emitted at distances of from 5 to 25 ft. The resulting currents are naturally exceedingly small.

The method successfully adopted by Dr. de Forest is to pass the amplified telephonic currents through a gas-filled two-electrode valve, which he calls the "photion." The photion glows at all times with a violet light of high actinic quality, and the intensity of this light increases or decreases in exact correspondence with the fluctuations of the amplified telephonic currents. The photion lamp is mounted in the motion-picture camera at a point where the film is moving continuously, that is some 10 inches away from the window of the camera, at which point the motion of the films is intermittent for the purpose of photographing the picture. The light from the end of the "photion" lamp is focused by means of a lens upon a very fine slit directly in front of the emulsion side of the film. This slit, in order that the highest harmonics may be recorded upon a film travelling at a speed of from 12 to 18 inches per second, must not be more than two-thousandths of an inch in width. The length of the slit is about $\frac{3}{32}$ inch.

In order to reproduce the sounds recorded upon the film, a tubular-shaped attachment is fastened just below the film magazine of a standard motion-picture projector. This attachment contains a small incandescent lamp, which shines through a lens and then through a slit two-thousandths of an inch in width and $\frac{3}{32}$ inch in length. This slit is so located that the sound record upon the film passes directly in front of it, and thus the intense light from the small incandescent lamp passes through this cloudy band.

The light which passes through the film falls upon a photo-electric cell. The cell which has been adopted by Dr. de Forest is that invented by Mr. T. W. Case, and known as the "thalofide" cell. The thalofide material is composed of thallium, oxygen and sulphur, which is fused on a $\frac{3}{4}$-inch diameter quartz disc. This disc is mounted in a glass bulb, which is then evacuated in order to prevent oxidation, and also to increase the sensitivity of the photo-active material. The resistance in the dark is high compared with the ordinary selenium cell, and may range from 5 megohms to 500 megohms. The average sensitivity is such that the direct resistance is lowered by 50 per cent when 0·25 ft.-candles from a tungsten-filament source falls upon the photo-active material. It is without appreciable lag. Probably the best-known material for photo-electric cells is selenium, but its lag in response, or fatigue, bars it from talking-motion-picture work. The variations in the amount of light caused by the presence of the dense and thin horizontal lines on the film between the incandescent lamp and the photo-electric cell, are thus transformed into electric currents, which are quite small, being of the order of a weak wireless signal. These small currents are next amplified by means of a four- or five-stage amplifier, which must also be distortionless, and the amplified current is then passed through one or more loud-speakers, completing the cycle by transforming electric currents into sound.

Although loud-speakers have been developed to a high state of perfection, they still leave much to be desired. I do not believe that perfection will come as long as a diaphragm is used. Some better method of transforming electricity into sound waves is required, and here is a field for the ingenuity of Students, as the experimental apparatus necessary may be quite inexpensive. The reverse action, for example, of the batwing type of flame transmitter is susceptible of development; also that well-known possibility of influencing a singing arc may yet be used. When one milliampere can be made to influence a 10-ampere direct-current arc, it is still possible that a workable method may be evolved in which an arc is employed.

THE CHARACTERISTICS OF A D.C. SERIES MACHINE SELF-EXCITED BY RECTIFIED CURRENT FOR PURPOSES OF REGENERATIVE CONTROL.*

By R. D. ARCHIBALD, D.Sc., Member.

(*Paper first received* 13*th July, and in final form* 16*th November,* 1923.)

SUMMARY.

The present position of regenerative control for tramcars is discussed, and a description is given of a method of self-exciting the field of a series motor with a low-voltage rectified current transformed from alternating-current tappings in the armature. Under these conditions the motor behaves like a shunt machine, and characteristics are shown when it is acting regeneratively and also when it is used as a generator and motor.

Calculations are given for finding the conditions of sparkless commutation of the rectifier, and tests are included which corroborate the calculations.

In conclusion, some points are discussed with regard to the practical application of the device.

The position of regenerative braking at the present time is that whilst it has been successfully applied to railway systems, and is almost essential for mountain railways, it has found small favour with those in charge of tramway systems, even in places where the hilly nature of the country would appear to justify the assumption that its use would lead to economy. Numerous systems have been proposed for tramway use, and some of these have been tried and proved workable, but the additional outlay and complication have been too great for the advantage gained; consequently the power used in accelerating and in ascending gradients is still very largely wasted. It has often been deplored that no simple device for recovering this energy in the case of tramcars has so far been produced. Yet there are many towns with gradients of sufficient length and steepness where the saving in energy and in wear and tear of brakes would be a real one, provided that the accessory apparatus required were not too costly, even if the power lost in starting and stopping had to be sacrificed.

Whilst working with a rectifier for improving the balance of a three-wire d.c. system (see *Journal I.E.E.*, 1922, vol. 60, p. 303) the author thought that some advantage might be gained by making a series motor self-exciting with a low-voltage rectified current transformed from alternating-current tappings in the armature. This method of excitation has been adopted for alternators in the past, though mainly for purposes of compounding, but it has been abandoned in favour of more effective controls such as the Tirrill regulator and others, and a common impression exists that the chief objection to it was due to sparking of the rectifier. Miles Walker, however, has shown in a paper on "Compensated Alternate Current Generators"* that a rectifier could be quite satisfactorily employed for this purpose without sparking.

In the case of the series motor a potential transformer is used to reduce the voltage at the armature tappings to the pressure required for exciting the field. Thus the problem of sparking differs slightly from that in the case of the alternator, but it will be seen from the tests which follow, and from the investigation into the question of commutation by the rectifier, that sparking is not likely to be a source of trouble in the case of the series motor—possibly less likely than in the case of the alternator. The advantages of exciting a series motor in this way, over excitation by a direct-current exciter, are:—

(1) For the same volt-ampere output the cost of a static transformer is considerably less than that of a rotating machine, provided that the frequency of the alternating current is not abnormally low. The extra cost of the rectifier is not a heavy item.

(2) The transformer can be more readily stowed than a rotating machine.

(3) The driving of the rectifier from the axle or spur wheel of the motor is easier to arrange than an exciter, as the rectifier is small. The rectifier could more easily be detached for inspection.

(4) The power used in driving the rectifier is small.

To set against these, there is the necessity of tapping the armature (of one or both motors) for the alternating current, and the provision of slip-rings and brushes. There is difficulty in doing this on account of the cramped space available, but the current is only a matter of a few amperes, so that not much space is required. The method employed for these tests is not suitable for a traction motor, but numerous other ways suggest themselves and the problem does not present insuperable difficulties. Any method adopted must be such that it can be applied to an existing traction motor without danger of breakdown and at a trifling cost.

The tests were made with the apparatus available in the electrical laboratories at the Technical College, Dundee. The series motor used was a 4-pole machine with a normal output of 8 h.p. at 770 r.p.m. on a 400-volt circuit. The armature was wave-wound with 4 brush spindles. The commutator had 153 segments, and tappings were taken from No. 1 and No. 39.

The motor was driven as a generator by a similar

* The Papers Committee invite written communications (with a view to publication in the *Journal* if approved by the Committee) on papers published in the *Journal* without being read at a meeting. Communications should reach the Secretary of the Institution not later than one month after publication of the paper to which they relate.

* *Journal I.E.E.*, 1905, vol. 34, p. 402.

motor mounted upon the same bedplate and separately excited from a battery. The field-magnet system of the driving motor was mounted on ball bearings and was arranged for measuring the torque by the reaction on the frame. The arrangement could be used for measuring the torque exerted on, or by, either machine.

The connections for the test are shown in Fig. 1. The armature of the motor (M_1) is tapped at the points 1, 1′ which are connected to the slip-rings (2, 2′). The slip-ring brushes (3, 3′) are connected to the primary of the transformer (T). The secondary of T is connected to the brushes (4, 4′) of the rectifier (R). These brushes

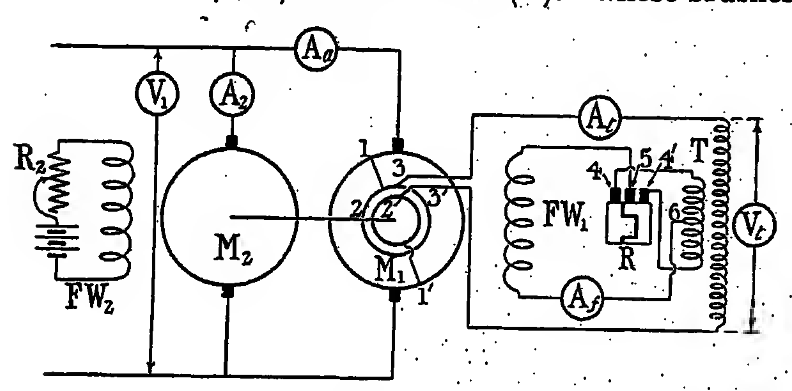

Fig. 1.

make continuous contact with the two parts of the commutator as shown. The centre brush (5) makes contact with 4 and 4′ alternately as the commutator revolves. The secondary winding of T is tapped at the centre point (6). Unidirectional current is then obtained between brush 5 and tapping 6, and these are connected to the field winding (FW_1). The driving motor (M_2) was run off the same supply and its field winding (FW_2) was excited from a battery through a variable resistance (R_2). Voltmeters were placed at V_1 to read the line volts, and at V_T to read the transformer primary voltage. Ammeters were placed at A_2,

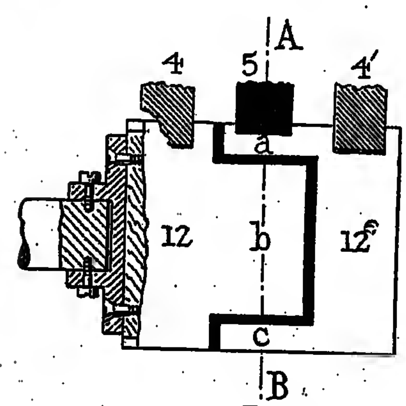

Fig. 2.

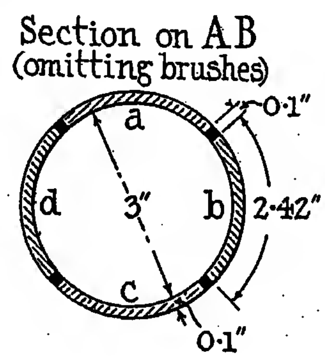

Fig. 3.

A_a, A_t and A_f, to read the armature current of M_2, the armature current of M_1, the primary current of T, and the field current of M_1, respectively.

The transformer (T) had a normal output of 6 kW at 50 cycles and a voltage ratio of 440/245.

The windings were tapped at points giving the following voltages:—

High tension: 192, 29, 162, 29, 29
Low tension: 106, 16·5, 89·5, 16·5, 16·5.

The rectifier was fixed on the commutator end of the shaft in the manner shown in Fig. 2. The commutator was made from a short length of 3-in. copper pipe, 0·1 in. thick, fixed on a hardwood core. A zigzag slot about 0·1 in. wide was cut round the pipe forming the 4 segments (a, b, c, d) and the two parts (12 and 12′). Brushes 4, 4′ were of copper gauze, and brush 5 of hard-quality carbon ("link C4") ½ in. wide by ⅜ in. broad. The current density in brush 5 at full load (17·5 amperes) was thus 47 amperes per sq. in.

Characteristics as a Regenerator.

The regenerative properties of the arrangement were tried by a series of tests with different ratios of transformation. At each ratio a number of readings were obtained of: (1) current regenerated, (2) torque, (3) speed.

The order of procedure was, in general, as follows:—

The field switch of the driving motor (M_2 in Fig. 1) was closed and the motor was run up to speed through a starting resistance. Usually the machine M_1 then built up its field like a shunt generator. When, at high ratios of transformation, it did not do so automatically, it was sufficient to pass a current through the armature from the mains with a resistance in series. This forced a current through the transformer primary and field. In this way the contact resistance of the rectifier brushes was sufficiently reduced to enable the field to build up. The motor could then be disconnected from the mains without losing its field (unless, of course, the ratio of transformation used was above a critical point). The speed was then adjusted by varying the field of the driving motor until the voltage of the regenerator was the same as that of the supply, when the main switch of the regenerator was closed. The set now acted like two shunt machines run back to back, and by weakening the field of M_2 the speed could be raised and M_1 caused to regenerate.

The brushes of the rectifier were set in such a position that the rectifier segments were just being short-circuited when the position of the armature tappings was half-way between the positive and negative brushes. In other words, brush 5 was in advance of the geometrical neutral axis of the rectifier by a distance $\frac{\text{One brush width} - \text{one mica width}}{2}$. This position gave sparkless running throughout.

In addition to the readings of voltage (V_1), torque, speed and regenerated current (A_a), readings were taken of the field current of the driving motor and of the regenerator (A_f), the slip-ring voltage (V_t), the primary current of the transformer (A_t), and the armature current (A_2) of the driving motor.

Tests were taken with the supply pressure equal to half the normal and also at full voltage, thus representing the case of the motor running respectively in series or in parallel with another. With the arrangement of the tappings in the transformer, however, it was possible to obtain a larger range of ratios of transformation at the lower voltage, and the tests taken at half voltage will therefore be studied in detail first.

The tests A, B, C and D were taken with the two

adjacent 29-volt portions of the high-tension winding used as the secondary of the transformer, the tapping between them forming the tapping 6 in Fig. 1. In the tests E, F and G, the portions used were the 16·5-volt sections of the low-tension winding.

The variations of torque and speed with current regenerated are plotted for all the tests in Fig. 4. A study of these curves will show that the characteristics are similar to those of a shunt machine. A given ratio of transformation corresponds to a given setting of the field resistance in a shunt machine. For a given ratio, the torque is practically proportional to the armature current, the slight bend in the torque curve being due to the weakening of the field by armature reaction. The field current remained practically constant with load, though the tests showed a slight rise of field current with load at the higher ratios, which gave a small compounding effect. (In test G the field current rose from 8·2 amperes at no load, to 9·3 amperes with a load of 15 amperes.) For all practical purposes, however, the arrangement behaves like a dynamo with constant field on a constant-voltage circuit, and greater loading is brought about by a rise in speed. With low ratios, the field is strong, the torque large, and the speed low, and the rise in speed from no load to full load is a matter of some 15 to 20 per cent. With high ratios, on the other hand, the percentage rise in speed is much greater, since armature reaction still further weakens the field. For example, in test G the rise in speed from zero to 17·5 amperes is from 710 to 990 r.p.m., or 40 per cent.

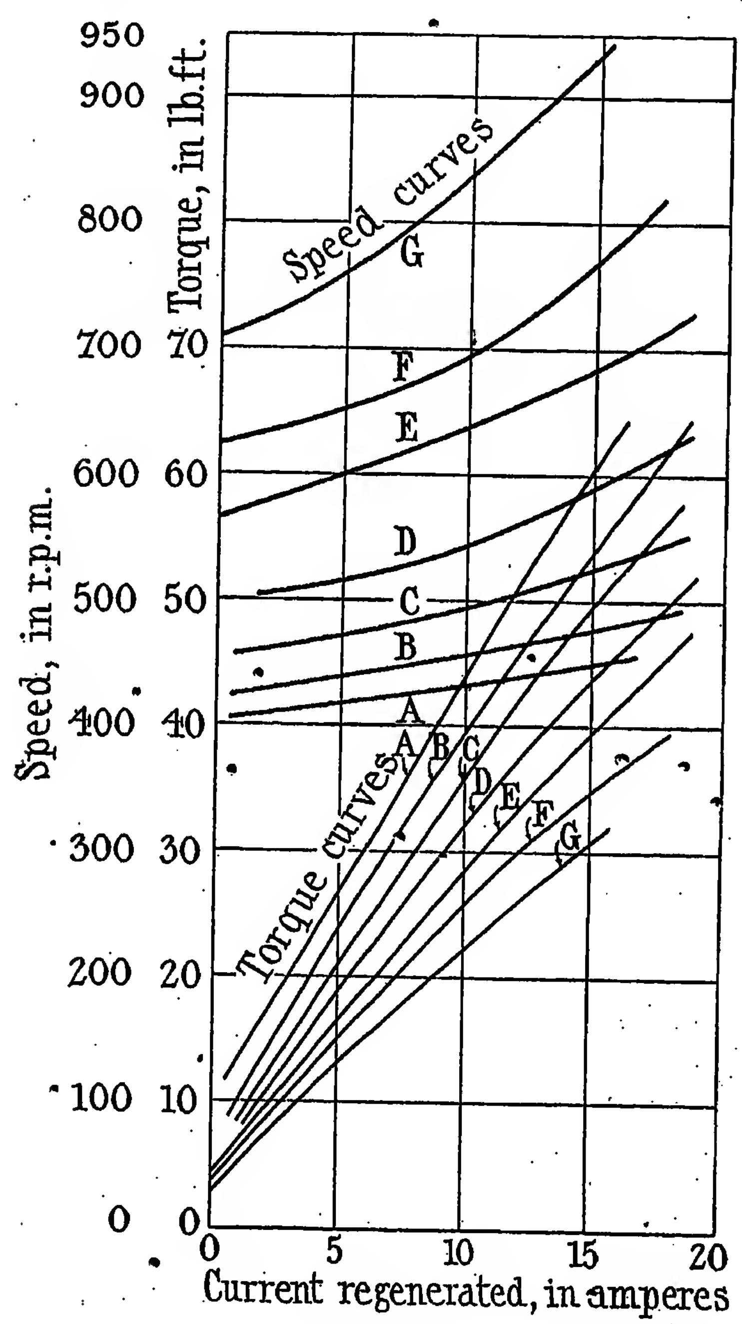

Fig. 4.

Speed/torque curves are plotted in Fig. 5, with speed as ordinates and torque as abscissæ. On each of these curves points can be found corresponding to some definite value of the load current, from the curves in Fig. 4. Such points are shown in each case for 2·5, 5, 7·5, 10, 12·5, 15 and 17·5 amperes. Constant-current curves can then be drawn as indicated by the dotted lines. In this form * a better idea of the relation between braking effect, speed and current regenerated is obtained. If the gear ratio and the diameter of the wheels on the track are known, the ordinates can be made to represent speed in miles per hour, and the abscissæ braking effort at the track.

The effect of a change of ratio can now be seen. For example, suppose that the gradient, and therefore the torque, are constant and that the machine is running at the point x (Fig. 5), so that the torque is 30·5 lb. ft., speed 730 r.p.m., and current regenerated 12·5 amperes, the ratio being 24·2/1. On suddenly changing the ratio to 26·7/1, the current and braking effort would alter along a horizontal line from x to the point y on the curve G, the speed being momentarily constant.

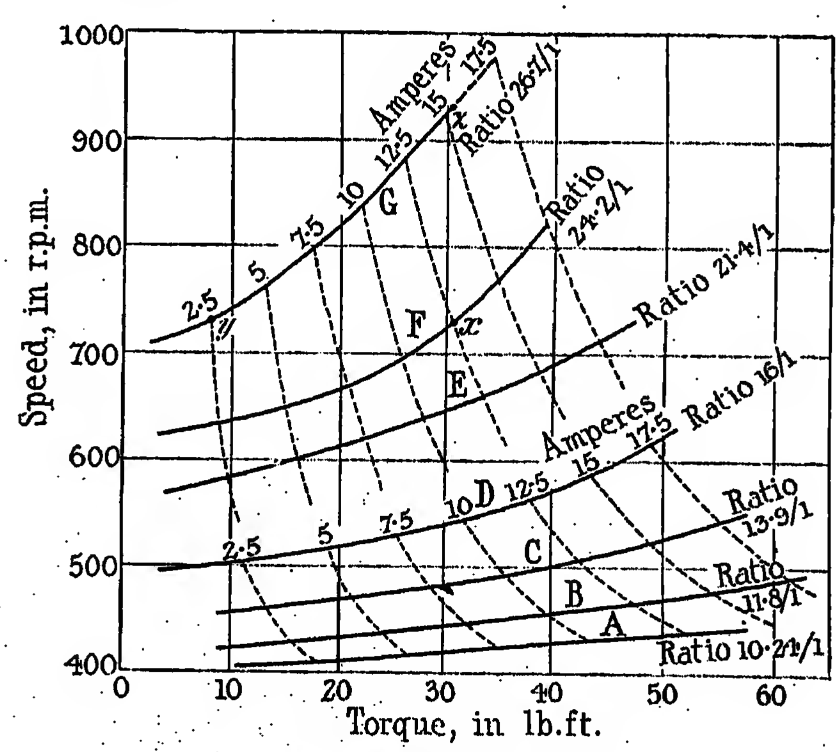

Fig. 5.—Speed/torque curves.

The current and torque (or braking effort) being now very much reduced, the speed rises along the curve G until the torque is the same as before at point z. The regenerated current is now 15·2 amperes, and the speed 930 r.p.m.

It might be mentioned here that the field current

* Fairburn and Harper: "Analysis of Regenerative Braking," *English Electric Journal*, vol. 2, no. 7.

could be varied equally well by the use of a variable resistance in the primary circuit of the transformer without involving much loss, since the current is small. This would be analogous to the use of the field-regulating resistance in a shunt machine. The transformer would then only require to be designed for the lowest ratio, and the higher speeds would be obtained by inserting resistance. Thus a smaller transformer could be used, at the expense of the losses in, and cost of, the resistance.

The compounding effect noticeable at the higher speeds is caused by the gradual increase in voltage at the slip-rings as the load on the d.c. side increases. This raises the secondary voltage of the transformer and rectifier, and hence the field current.

This rise in slip-ring voltage constitutes a change in the ratio of a.c. to d.c. voltage in the armature, and is attributable to the distortion of the field caused by the load current on the d.c. side.

In case any reflex action from the rectifier might be a disturbing factor in the wave-shape of the slip-

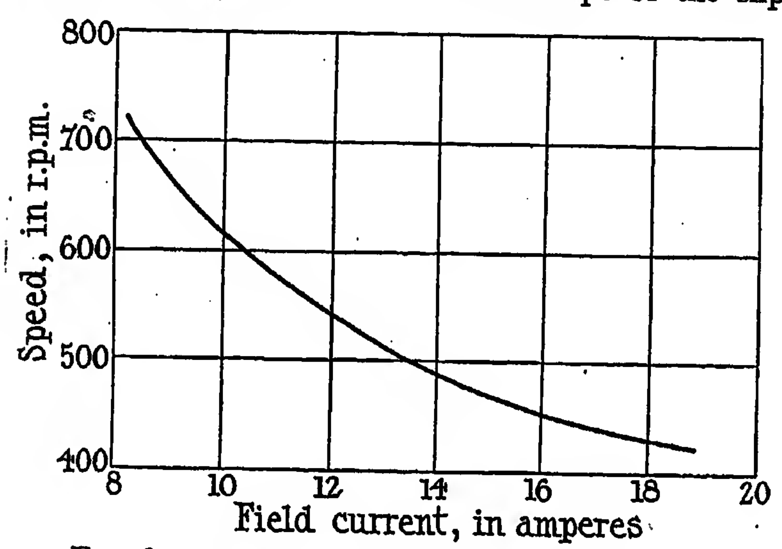

FIG. 6.—Speed at no load, with varying field.

ring voltage, tests were made with the rectifier connected to a separate inductive resistance, the field magnets being excited from a battery. The brush position of the rectifier was the same as that used in the previous tests, and no effect was produced on the slip-ring voltage by switching on and off the rectified current, nor did switching off the transformer primary make any difference.

Besides the increase in the slip-ring voltage with load, another factor which affects the compounding is the position of brush 5. This, however, will be discussed later.

FACTORS DETERMINING THE SPEED.

The speed is a function of the internal voltage, E, of the armature, and the flux per pole.

If V = terminal voltage,
I_a = armature current,
R_a = resistance of armature and brushes,
then $E = V + I_a R_a$.

The flux depends on the field current and on the effect of armature reaction. The brushes of the armature were set in the neutral position during the tests, so that the armature reaction consisted of cross-magnetizing ampere-turns only. With constant terminal voltage the cross ampere-turns combine to raise the speed in two ways: (1) by the demagnetizing effect due to distortion of the field; and (2) by shifting the magnetic neutral position ahead of the geometric position so that the brushes, which remain in the latter position, are not in the proper place for giving maximum voltage. This second effect is difficult to estimate and is small.

The first factor, however, has an appreciable effect, and can be approximately determined from the design particulars of the machine. From a knowledge of this and the resistance R_a, and also a curve representing speed plotted against field current at no load, it is possible to show roughly how far the speed might be

expected to rise with load, and to compare the results of the calculation with those found on test.

The variation of speed with field at no load was tested: (1) with the field excited by the rectifier, and (2) with the field separately excited, the rectifier and transformer being disconnected. Practically the same result was obtained in both cases, and the curve is plotted in Fig. 6. The speed/load characteristic calculated from this curve did not, however, agree with the tests in Fig. 4, and it was found that the characteristic was affected considerably by a small movement of brush 5 of the rectifier. Tests were therefore made of the alteration in speed from no load to full load with different brush positions. The ratio used was the same as in test E and the results are shown in Table 1. In fixing the position of the brush, in each case the tappings were set midway between the positive and negative brushes, which were

in the neutral axis. The brush was then set relatively to the mica, as shown in the table.

With the brush in advance of the mica by the distance of 2 mica widths, the machine would not excite properly and was apt to excite in the reverse direction, but only partially. Quite satisfactory running was obtained in positions 1, 2, 3, 4 and 5, but in position 6 there were again signs of instability. It will be noticed that the speed-range increases as the brush is moved back, or the compounding effect becomes greater as the brush is moved forwards. This is due to the forward movement of the main field under the pole with load. It will be clear that if brush 5 is set so that at no load the E.M.F. is rectified at zero point, then, as the load comes on, the centre of the field moves forward and rectification will take place before the E.M.F. has reached zero. The rectified E.M.F. will therefore be reduced. But if the brush is forward of this position, then at no load the E.M.F. will have reversed before rectification takes place, and the rectified E.M.F. will therefore be less than before; as load comes on and the point of zero E.M.F. moves forward, the rectified E.M.F. increases.

of tappings on the transformer. The position of brush 5 was the same as in the tests on half voltage (see page 234) and the machine self-excited without any aid in both

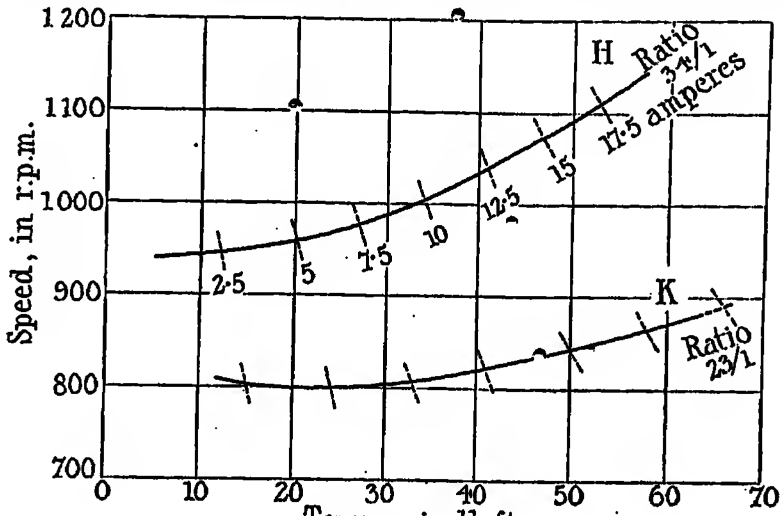

FIG. 7.

tests. Curves of speed are plotted against torque in Fig. 7, and constant-current lines are indicated similarly to those in Fig. 5.

Ratio = 23·15, viz. (191 + 29 + 162)/16·5.

On the other hand, if the brush is in a backward position the E.M.F. at no load will be less, but on load it will be still less.

CHARACTERISTICS AS A REGENERATOR ON FULL VOLTAGE.

Connections were made as in Fig. 1 and the supply was taken from the 400-volt mains. Two different ratios of transformation were used—the first, 23·15/1, which was the lowest possible, and the second, 34·1/1, which was the highest possible with the arrangement

VOLT-AMPERE CHARACTERISTIC AS A GENERATOR AT CONSTANT SPEED.

The volt-ampere characteristic as a generator is interesting, in showing the resemblance to that of a shunt machine. Connections were made as in Fig. 1, with the exception that M_1 was connected to a lamp load instead of to the line. The ratio used in the transformer was 23·15/1, the primary consisting of the portions 191, 29 and 162, and the secondary of the two portions 16·5 with a tapping between them.

This ratio gave with no load 400 volts at 790 r.p.m., or nearly normal full-load speed.

The armature brushes were set in the neutral position, and the rectifier brush (5) was given the same amount of lead as before. The speed was maintained constant at 790 r.p.m. and the machine was loaded to the limit of its output, which occurred at about 29 amperes. Readings were taken as shown in Table 2. From these the external and internal characteristics have been plotted in Fig. 8.

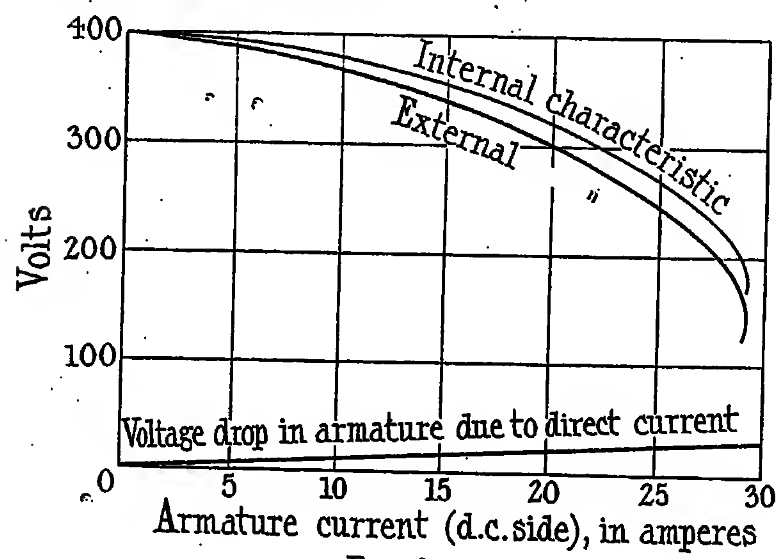

FIG. 8.

It will be seen that the characteristics are those of a shunt-wound generator in all respects. The voltage falls away due to the drop in resistance in the armature and also to armature reaction on the field, and a point of maximum current is reached. Near this point the readings were very uncertain, and a considerable difference could be made by varying the pressure on brush 5. By increasing the pressure a point at 38 amperes, 120 volts, was obtained.

A point of interest is the relation between the d.c. and a.c. voltages of the armature. At no load the ratio, d.c./a.c. voltage, was 1·4, or approximately $\sqrt{2}$. At 18·5 amperes it fell to 1·29, and at 27 amperes to 1·02. The last three readings are not reliable owing to unsteady conditions, so that the ratio 0·84, which makes the a.c. voltage greater than the d.c., may be wrong, though not necessarily impossible.

The characteristic is affected considerably by a small movement of the rectifier brush 5. Tests were taken of the drop of voltage from no load to full load when brush 5 was at the neutral position, behind the neutral position, and in front of the neutral position. The results are shown in Table 3. With the brush

lagging, the maximum current that could be obtained was only 8 amperes, the drop in voltage being nearly 40 per cent. With further forward setting the regulation improves within the zone of sparkless commutation.

Characteristics as a Motor on Constant Voltage.

Connections were made as in Fig. 1, the direction of rotation being reversed so that the torque transmitted from M_1 to M_2, which now acted as a generator, was in the same direction as before. This saved any alteration of the torque-measuring device.

Tests were made with the brush 5 in the same forward position as before. No sparking at the rectifier was observed up to full load, but there were signs of instability, and at an overload of about 15 or 20 per cent the rectifier developed violent sparking, the speed commenced to rise, and the cut-out operated. Brush 5 was then set at the neutral position and the tests in Table 4 were taken. The maximum load which the spring balance would read was equivalent to 9·73 b.h.p., but a much greater load could be applied without the machine being unstable.

For the purpose of comparison, light readings were taken of M_1 with rectified field current, and of M_2 with separate excitation of the same value. With no load current in the generator M_2 and no current in the field, the input to M_1 was 725 watts, as shown in the first set of readings in Table 4. The output was 122 watts. This is the loss due to friction and windage in M_2. The two machines being similar, we may take it as being the friction and windage loss in M_1 also. To this has to be added the friction loss in the rectifier. The total pressure on brush 5 was 3 lb. Making a small allowance for loss in the gauze brushes, we may assume the friction loss in the rectifier to be about 16 watts.

The resistance of the rectifier and field circuit was 0·59 ohm. The loss is therefore $(20 \cdot 2)^2 \times 0 \cdot 59$, i.e. 240 watts. We may now deduce the other losses from the total light-load losses on test as follows :—

etc. Output, torque, efficiency and speed curves are plotted with armature current as abscissæ in Fig. 9.

Tests of the effect of the position of brush 5 on the speed characteristic were made and are given in Table 5. As would be expected, the compounding effect gets greater as the brush is moved backwards, since the

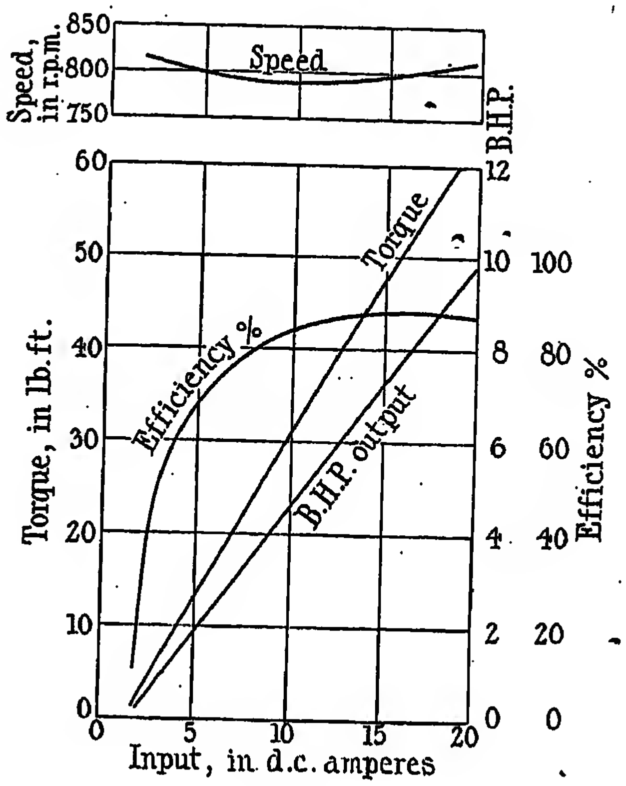

FIG. 9.

armature current and distortion are in the reverse direction from that in a generator. This is shown by the greater drop in speed from no load to full load as the brush is shifted backwards.

Conditions Necessary for Sparkless Commutation of the Rectifier.

The problem of the commutation of single-phase rectifiers has been investigated by Prof. Miles Walker in connection with compensated alternating-current

	M_2 watts	M_1 watts	Remarks
Friction and windage	122	122	Lost in M_2
	138	138	Lost in M_1 + rectifier
Copper loss in field circuit ..	—	240	
Iron loss (to balance)	210	Iron loss and loss in transformer (to balance) 225	
Total from test in Table 4 ..	470	725	

At 440 volts across the whole high-tension winding, and 50 cycles per second, the transformer loss was 107 watts at no load. In this case the frequency is nearly half normal and the voltage at least 20 per cent below normal. The losses will therefore be of the order of about 20 to 30 watts, including the small copper loss. We may presume from the above figures that the rectified current in the field does not introduce any appreciable extraneous losses due to eddy currents,

generators (*Journal I.E.E.*, vol. 34) where the method of compensation used was a rectified current, proportional to the main current, passed through a portion of the field winding. The results showed that sparkless commutation could be obtained at all loads with a fixed brush position, provided that the power factor did not alter.

The problem in the case of the series motor differs from that of a compensated alternator in several respects.

In the first place, a potential transformer is used and, as the primary is placed across the whole armature winding, the short-circuit must necessarily last a short period, at or near the point of no voltage. In the case of the alternator a small short-circuit period causes much greater fluctuation in the value of the current in the compensating winding. The compensating winding is, however, only a portion of the field winding,

* Inverse of position 3 (Table 1). † Same as position 3 (Table 1).

whereas in the series motor the whole field winding is used. Thus the variation of current is considerably reduced by the high inductance of the field.

In order to determine whether there was an appreciable variation of current in the field due to the pulsating nature of the voltage of the rectifier, an induction-type ammeter was placed in the field circuit. No movement of the pointer could be detected on switching on or off the field circuit. With the field separately excited and

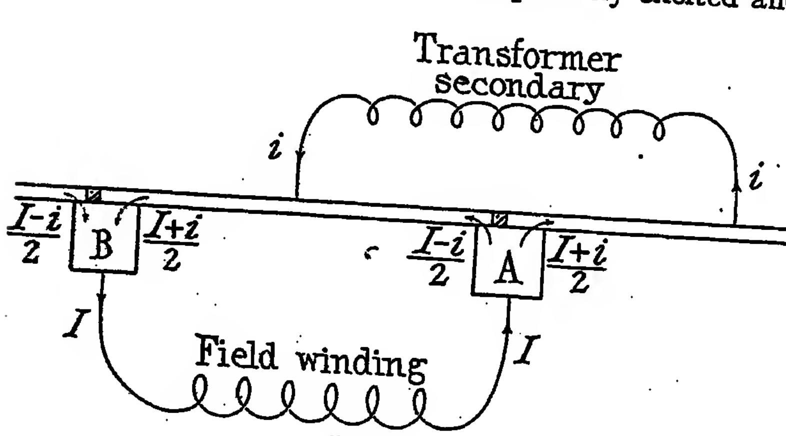

FIG. 10.

the rectifier connected to a non-inductive circuit consisting of a carbon-block resistance, a considerable deflection of the induction ammeter was shown with 15 amperes registered on a moving-coil instrument in series with it. It can be presumed from this that the inductance of the field winding was sufficient to keep the rectified current nearly steady. For practical purposes, therefore, the assumption that the rectified current remains constant is justifiable.

In the first place, a rectifier with two brushes on the commutator will be considered, as in Fig. 10, which shows a two-segment commutator developed out straight.

Let I = the current (assumed constant) in the field winding;
T = time of short-circuit in seconds;
t = time from commencement of short-circuit in seconds;
i = short-circuit current in secondary of transformer at time t;
R = resistance of a single total brush contact;
r_1 = contact resistance between brush and arriving segment;
r_2 = contact resistance between brush and leaving segment;
L = total equivalent inductance of transformer secondary.

Since i varies very rapidly, we may take it that r_1 and r_2 do not vary with the current density, so that

$$r_1 = R\frac{T}{t} \quad \text{and} \quad r_2 = \frac{RT}{T-t}$$

The currents I and i will be distributed as shown in Fig. 10. Consider the circuit commencing from brush A passing through the transformer secondary and back to A in an anti-clockwise direction.

By Kirchhoff's second law we have

$$\frac{I+i}{2}r_2 - \frac{I-i}{2}r_1 + L\frac{di}{dt} = 0 \,*$$

or

$$\frac{RT}{2}\left(\frac{I+i}{T-t} - \frac{I-i}{t}\right) + L\frac{di}{dt} = 0$$

$$\frac{di}{dt} = -\frac{RT}{2L}\left(\frac{I+i}{T-t} - \frac{I-i}{t}\right)$$

The conditions for sparkless commutation are that the constant $RT/(2L)$ is greater than unity, or

$$R > \frac{2L}{T} \quad \therefore IR > \frac{2IL}{T}$$

Now the average reactance voltage induced in the transformer secondary is $2IL/T$, and therefore

$\frac{2IL}{T}$ must be less than IR

The reactance voltage must therefore be less than the voltage-drop at one brush contact.

In the case of the single-brush rectifier (Fig. 11) it simplifies matters to choose $2I$ as the value of the current in the field winding, and, as before, the value of the short-circuit current in the transformer secondary † varying between the limits $+I$ and $-I$. The distribution of the currents during short-circuit is then as shown in the figure.

Using the same symbols as before and going round the path of short-circuit current in an anti-clockwise direction, we have

$$\frac{(I+i)RT}{T-t} - \frac{(I-i)RT}{t} + L\frac{di}{dt} = 0$$

$$\therefore \frac{di}{dt} = -\frac{RT}{L}\left(\frac{I+i}{T-t} - \frac{I-i}{t}\right)$$

* The resistance of the secondary of the transformer and the contact resistances of the brushes 4, 4′ (Fig. 4), which connect the secondary to the commutator are here neglected. The effect of these resistances is to assist commutation, so that the conditions chosen are worse than in practice.

† i flows through both portions of the secondary in series.

The condition for sparkless commutation is therefore

$$\frac{RT}{L} > 1, \quad \text{or} \quad R > \frac{L}{T}$$

or

$$2IR > \frac{2IL}{T}$$

The reactance voltage is $2IL/T$, and $2IR$ is the total voltage-drop at the brush A. Hence the reactance voltage must again be not greater than the voltage-drop at one brush contact.

The value of L depends on the inductances of the primary and secondary windings of the transformer, the mutual inductance between them, and the inductance of the armature winding between the slip-rings. It

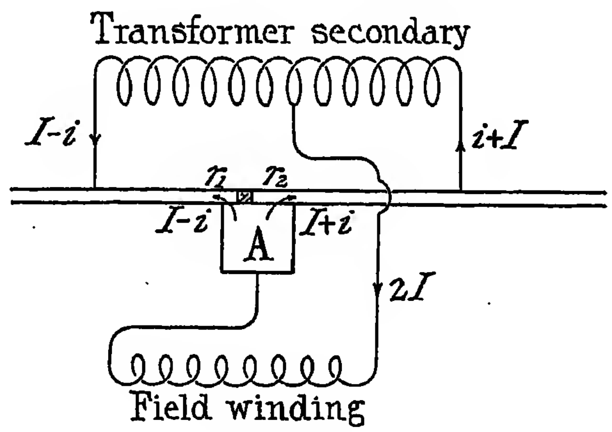

FIG. 11.

is also dependent on the resistance in the primary circuit if this is large.

Let L_1 = inductance of primary of transformer;
L_2 = inductance of secondary of transformer;
L_a = inductance of armature between slip-rings;
M = mutual inductance of primary and secondary;
R_1 = resistance of primary winding;
R_a = resistance of armature between slip-rings.

Then if an alternating current of frequency f be supplied to the secondary the equivalent inductance will be

$$L = L_2 - \frac{M^2(L_1 + L_a)4\pi^2f^2}{4\pi^2f^2(L_1 + L_a)^2 + (R_1 + R_a)^2}$$

$(R_1 + R_a)$ is small in comparison with $(L_1 + L_a)$ and may be neglected.

$$\therefore\ L = L_2 - \frac{M^2}{L_1 + L_a} = L_2 - \frac{\eta^2 L_1 L_2}{L_1 + L_a}$$

where η is the coupling coefficient.

In transformers η is very high (of the order of 0·98 to 0·99) and, since L_a is small in comparison with L_1, L is the difference between two quantities of very nearly the same value. Any inaccuracy in the determination of L_1, L_2 and η will therefore make a considerable error in the value of L.

When η is high, however, we can, without appreciable error, substitute for L in the following way:—

Let L_p = inductance due to leakage in the primary;
L_s = inductance due to leakage in the secondary;
n_1 = number of primary turns;
n_2 = number of secondary turns.

Then

$$L = L_s + (L_p + L_a)\left(\frac{n_2}{n_1}\right)^2$$

L_p and L_s can be measured by short-circuiting, say, the secondary winding and applying a low-voltage V at frequency f to the primary. A wattmeter and ammeter are placed in the primary circuit. Then if W is the reading on the wattmeter, and I the reading on the ammeter, the equivalent inductance in the primary is

$$\frac{V}{2\pi f\sqrt{[I^2 - (W/V)^2]}}$$

This is equal to $L_p + (n_1/n_2)^2L_s$. Usually, without much error, $(n_1/n_2)^2L_s$ can be taken as equal to L_p

$$\therefore\ L_p = \frac{V}{4\pi f\sqrt{[I^2 - (W/V)^2]}}$$

and $L_s = (n_2/n_1)^2L_p \quad \therefore\ L = (n_2/n_1)^2\{2L_p + L_a\}$

The average of a number of tests gave $L_p = 0{\cdot}0018$ henry. The armature inductance, L_a, was measured with a steady current of 20·7 amperes flowing in the field and was 0·0137 henry.

TEST OF THE LIMITING CURRENT FROM THE RECTIFIER WITH SPARKLESS COMMUTATION FOR A GIVEN RATIO.

The full primary of 440 turns and a secondary consisting of two adjacent secondaries of 16·5 turns were used, giving a ratio of 440/16·5 = 26·7/1. The field was separately excited from a battery with 20·7 amperes, i.e. the same as was used in the test of L_a. The speed was maintained constant at 850 r.p.m. The rectifier was loaded by means of a reactance consisting of the winding of a transformer in series with a variable carbon-block resistance. The number of turns of the transformer could be varied, but they were always sufficient to keep the rectified current steady, i.e. no indication was obtained on an induction ammeter.

The tests were taken in semi-darkness and the results are given in Table 6.

TABLE 6.

Transformer primary P.D.	Rectifier current	Field current	Speed	Remarks
volts	amps.	amps.	r.p.m.	
310	24·5	20·7	850	No sparking
310	40	20·7	850	Slight sparking under brush
310	50	20·7	850	Slight sparking under brush
310	60	20·7	850	Definite sparking
310	75	20·7	850	Bad sparking

NOTE.—Brush 5 in neutral position during test. Brush pressure = 14 lb. per sq. in.

Before tests were taken the machine was run for half an hour with 25 amperes from the rectifier, to warm the brushes and get a steady condition.

The precise current at which sparking commenced was indefinite. At 25 amperes there was definitely

no sparking. At 40 amperes there was slight sparking under the brush. At 50 amperes the sparking was still slight and under the brush. At 60 amperes the sparking was quite definite and at 75 amperes it could be described as very bad. In ordinary daylight, and without close examination of the brush, no sparking could be detected at 40 to 50 amperes.

Value of the Current at which Sparking would be expected to take place from the Tested Values of the Inductances L_p, L_s and L_a.

The time of short-circuit is

$$T = \frac{\text{width of brush} - \text{width of mica}}{\pi d} \times \frac{60}{\text{r.p.m.}} \text{ seconds}$$

where d = diameter of commutator = 3·2 inches.

$$\therefore \quad T = \frac{0 \cdot 5 - 0 \cdot 1}{10 \cdot 1} \times \frac{60}{\text{r.p.m.}} = \frac{2 \cdot 38}{\text{r.p.m.}} \text{ seconds}$$

If $2I$ is the current flowing in the field winding, the reactance voltage (V_R) is given by

$$V_R = \frac{2IL}{T}$$

$$\therefore I = \frac{V_R T}{2L} = \frac{V_R \times 2 \cdot 38}{2 \times 850 L}$$

The ratio $\frac{n_2}{n_1} = \frac{33}{440}$

$$\therefore L = (0 \cdot 0116 + 0 \cdot 0137) \left(\frac{33}{440}\right)^2$$

$$= 0 \cdot 000142 \text{ henry}$$

With a current density greater than 40 amperes per square inch the voltage-drop of a "link C4" brush is over 1·2 volts. If we take the maximum reactance voltage permissible to be 1·2, the current at which sparking should theoretically commence is

$$I = \frac{1 \cdot 2 \times 2 \cdot 38}{2 \times 850 \times 0 \cdot 000142} = 12 \text{ amperes}$$

or a total field current of 24 amperes. This leaves out of account the effect of the contact resistances of the gauze brushes and the resistance of the secondary winding, so that a slightly better result is to be expected in practice.

Conclusion.

The question of how far such a device as that described might be useful in practice, compared with others already in use, must, of course, be left to experience to decide. The object of the tests was to indicate, as far as they go, the practical workability of the arrangement. A further object is to remove much of the prejudice which exists against the use of rectifiers, even at low voltages, although there are many purposes to which they could be applied.

The difficulty of tapping the armature of a railway motor, and of insulating the tappings against the comparatively high voltage used, probably precludes the use of the device for railway work.

It is not within the scope of this paper to discuss the question of control. It may be mentioned, however, that it was found possible to run the motor in the ordinary way and to switch on the transformer and rectifier with the armature still connected to the field winding. With a suitable ratio in the transformer, and with the rectifier arranged to strengthen the field, the motor gradually became a generator. The armature could then be disconnected from the field and switched on to the line, giving the same arrangement as that used in the tests. The regenerative effect then became stronger.

From the characteristics as a generator it can be deduced that a comparatively large drop in line voltage would not involve heavy increase in regenerated current and braking effect, and some preliminary trials with changing voltage have borne this out.

A high brush pressure in the rectifier, though not so high as in these tests, is required. No evil effects resulted from the brush pressures used, and the rectifier ran for long periods without any blackening or smearing, and no attention was needed whatever under normal conditions.

In conclusion, the author would like to thank the directors of the Technical College, Dundee, for permission to carry out these tests.

DISCUSSION ON

"THE DRIVE OF POWER STATION AUXILIARIES."*

NORTH-WESTERN CENTRE, AT MANCHESTER, 20 NOVEMBER, 1923.

Mr. W. Eccles: Until now the opinions expressed by many engineers have been very confused, the real object of the various auxiliary systems being lost sight of under a cloud of words such as "heat balance," "house set," etc.; the whole question being generally confused with feed-heating. The present paper clears away a great deal of this confusion and gives us a picture of the whole problem as it occurs in a modern station containing turbo sets of from about 20 000 to 25 000 kW. The authors appear to be prepared to spend an unlimited amount of money to obtain reliability, but they do not attempt to state what the loss incurred by a shut-down is, and I should be glad if they would indicate the saving to be expected by avoiding stoppages and thus justifying the extra expenditure on reliability. It seems to me that the loss due to interruption of supply comes under two heads: (1) Loss of reputation by both the supply undertaking and the engineer. I have no doubt that these have a cash value, but I suspect that their influence on the design of the plant is felt to a greater degree than the cash value would indicate. (2) The aggregate loss sustained by the individual consumers. This is probably greater than the supply undertaking's liability and is different for each type of consumer. It depends, however, on the average to a large extent on the time of stoppage, although in some cases the maximum damage may have been incurred in the first few minutes. The liability to interruption can no doubt be greatly lessened by the adoption of a particular scheme of auxiliary drive, but the time of interruption depends more on the arrangements for controlling the power generation, distribution, conversion and application than on the scheme of auxiliary drive adopted, and I should say that this question of control generally and of auxiliaries in particular should be given more attention than it is to-day, if the extra expense for reliability is not to be thrown away by the increased duration of the stoppage. American practice would appear to be ahead of English practice in this respect. The time required to recover full load again seems to be some function of the number of attendants involved and the means adopted for each one to advise his colleagues what the position is. It would seem that in these large stations there should be more centralized control either by remote-operated valves, etc., or by detail signal from a central point to individual control points where the attendant is within reach of all the controls of the valves or switches, etc., to be operated. From accounts published in the Press it would appear that the larger the system the longer the period of stoppage whatever the cause, and for this reason the reliability of superstations as measured by the total stoppage time per annum may very well be no better than that of the smaller station. It would seem then that reliability cannot be dealt with alone and that ease of control must go with it. In regard to the question of working efficiency, the authors do not point out that there can be very large differences in efficiency between two similar systems each heating the feed water up to the same temperature, with prime movers of equal efficiency. The invisible loss which can occur is due to waste of heat-drop—not waste of heat, which is usually fairly obvious—and the easiest way to compare the efficiency of such plant is to note for each system the aggregate of such heat-drop losses. These losses mostly occur wherever steam is being transmitted from one place to another, through pipes and valves, or where heat is being transferred from steam to water, the loss at each point being proportional to the total number of heat units transferred, multiplied by the mean difference in temperature between the steam and the water. In other words, wherever hot steam is used in heating cold water there is a loss of potential work. This is one of the drawbacks of the scheme in which a house set exhausts into a feed heater, where a mean drop of 50 degrees F. may easily occur, due to the low ratio of feed water to steam condensed, or indeed at any point where the temperature of the water is increased by a large amount in one stage of heating. The authors do not appear to pay much detailed attention to capital cost; otherwise I think their views on the types of auxiliary supplies might have been more definite. I have put together some approximate comparative figures on capital cost and efficiency for the auxiliary supply for a 33 000-volt, three-phase, 25-period station, with steam at 250 lb. per sq. in. and a total temperature of 650° F., and with water at 75° F., the d.c. auxiliary motors totalling about 1 000 kW per unit of 20 000–25 000 kW. Comparing the auxiliary drive from the main busbars via transformer and motor-generator with that of a condensing house set of the same capacity, I find that with a main turbine of 80 per cent thermodynamic efficiency, an alternator of 96 per cent efficiency and a motor of 93½ per cent efficiency, neglecting switchgear and cable losses, the resultant comparative efficiency is 70 per cent at the generator coupling and the capital cost approximately £10·5 per kW. In the case of a geared condensing house set of 1 000 kW under the same conditions we get a thermodynamic efficiency of 70 per cent with gears of 98½ per cent efficiency. This gives a resultant comparative figure of 69 per cent efficiency at its corresponding generator coupling, and the capital cost approximately £5·7 per kW as against £10·5. In other words, it costs in capital nearly twice as much to obtain power for the auxiliary drive if it is taken from the main busbars, and the coal cost per unit is practically the same, or perhaps one should say that it costs £5 000 more to get 1 000 kW from the main busbars than it does to get it from a condensing house set. This particular case may be an extreme

* Paper by Messrs. L. Breach and H. Midgley (see vol. 61, p. 829).

instance, but in any case capital cost is a vital point for most station engineers to watch, and I should like the authors to say whether they consider it would ever pay to take auxiliary power or, indeed, any such small amount of power from the main supply of a super-station. Although the authors have limited their remarks to large stations, I should like to ask them if they can state at what size of smaller station or unit they would cease to advocate the use of divided auxiliary supply and double-auxiliaries. It appears to me that for 10 000-kW units the case is very doubtful. In fact, I do not think that one can make out a case for the divided supply or drive, except perhaps in the case of the circulating pump.

Mr. H. C. Lamb: Most of the good points in the paper may, I think, be fairly claimed as being already standard practice in Manchester. All who are engaged in power station work, and particularly those who have ever been in charge when a bad short-circuit has occurred on the high-tension system, followed by a shut-down of the auxiliary plant, are fully alive to the importance of this subject. The authors have given their view of the relative importance of the various parts of the plant and there is only one point to which I would take exception. The circulating water pump comes easily first, but they have included, as of equal importance to it, the air-extraction pump, which is hardly correct. I have known cases where the air-extraction pump stopped for several minutes while the plant was on load, without any very serious fall in vacuum, and I think that this auxiliary ought to come in Class B or Class C. I quite agree with the authors in deciding in favour of electric drive throughout; the steam drive, of course, has its merits, but there are some things which are decidedly against it. As has been mentioned, there is the high cost of maintenance and attendance, and, particularly with high-pressure schemes, the undesirability of adding further small pipes and valves. On page 834 the authors say, "any extra economy obtained by the use of steam-driven auxiliaries," and, in the paragraph below, "it is assumed that feed heating by steam from the main turbines is the case all through." There certainly is no economy in the use of steam-driven auxiliaries in such a case. For economy, the electric drive is easily first, and the drive through the combined house-service turbine and transformer, i.e. the double system, comes second. Certainly the all-steam drive comes last in economy. The authors rightly put reliability first, and some of these schemes are certainly not safe. In Schemes 2 and 3, for instance, the principal motors are all connected to the main a.c. system, and would very likely pull out and shut down if a bad short-circuit occurred in, or near to, the station. One would not like to place too much reliance on the scheme which the authors set out for a house-service set to be run up and put on the bars in 10 seconds merely by pressing a button. Presumably this would have to be done as soon as it was known that trouble was brewing, but the difficulty is that one never does know until too late. Schemes 1, 3 and 4 include a special generator on the main shaft. That is a particularly interesting proposal and, I think, a new one. It is, no doubt, very economical, but has one disadvantage in increasing the length of the main plant, and another in that the special generator would not be available for running the auxiliary plant during the preliminary starting-up of the station, when there is a great deal of running up and shutting down. Scheme 6 seems to be very expensive in switchgear and, like Scheme 7, has the objection that d.c. motors are used. The one advantage of the d.c. motor is, as the authors state, in speed variation, but there is not very much need for speed variation in the power station auxiliaries. So far as I know, there are only two classes of auxiliary plant which need a variable speed, and they are the stoker motors and boiler fans. With regard to the former, as these are small motors it is quite easy to get the regulation by means of a rotor resistance. In the case of the boiler fans d.c. motors are certainly a great convenience. They assist in keeping a steady steam pressure, and the draught can very easily be regulated. There is also some gain in economy by having variable-speed instead of constant-speed fans, but this economy is not very great. In a particular case, allowing a reasonable number of hours on a light load, the saving was only 0·1 per cent of the boiler output. If it is really desired to use a.c. motors this very small saving is hardly worth consideration. There is no doubt that a great many troubles are eliminated if direct current is not used. The authors sum up in favour of Scheme 7, which makes use of a house-service set. This has a great many advantages, particularly in starting up new plant. All the auxiliary plant can be run up and tried out and put into good order before the time comes for starting up the main plant. In my opinion the best scheme is the one given as the alternative to Scheme 7. There is no detailed description because, I suppose, the scheme is so simple that this is not needed. Alternating-current motors are used throughout with a house-service set and an alternative supply from a transformer off the main busbars. When dealing with this alternative arrangement the authors say: "Such a modification would probably reduce the first cost, but would entail additional complications in running, because of the necessity of synchronizing the a.c. supplies at times of emergency, and also because of the probability of any fault shutting down the motor-generators and so rendering the battery of no use at the very time when it is most needed." I wish the authors would specify exactly what the emergency is which would require the synchronizing of the two supplies, because it is an essential feature of such a scheme that the two supplies should never be synchronized. If one supply fails it is quite an easy matter to make good the essential parts of the auxiliaries from the other supply. Also, with such a scheme a battery is unnecessary. The authors say little on the subject of suitable voltages. Some large stations have used high pressures (2 000 volts or more) and have justified their action on the ground that it resulted in a saving in switchgear and cables. I had occasion to check a case of this kind where some 300-h.p. motors were used. For 2 000 volts, as compared with 400 volts, the switchgear and motors cost more, whereas the cable cost less, but, on the whole, the balance was 7 per cent in favour of 400 volts. Of

course everything depends on the length of cable which has to be used. In this case the total length of cable was 250 yards for the whole of the motors. Had 500 yards of cable been required the total cost of motors, switchgear and cables for the two cases would have been about equal, but no one would want to use 2 000 volts without some very considerable saving, because so high a voltage does introduce an additional complication, being unsuitable for motors below about 50 h.p.

Mr. A. Stubbs: The paper might be concisely expressed as follows: "An auxiliary supply must have reliability with economy, more or less regardless of the expense." The subject matter deals almost entirely with the relation between reliability and economy; indeed it would be safe to say that the paper could never have been written had not the large turbo-alternator set been accepted as being a more economical source of supply than the smaller turbo set. In the light of certain developments in the design of large turbines which have taken place within the past few months it would appear that the foundation of the paper may be cut away. Large turbines of, say, 20 000 kW and more are being offered and built as two-cylinder units, the special feature being that the high-pressure cylinder has a remarkably high efficiency so that the complete unit gives a thermodynamic efficiency of something over 80 per cent. The small back-pressure turbine may be made to operate at a high thermodynamic efficiency which would compare with the above figure. We may now consider the main double-cylinder turbine operating on the steam side in parallel with a back-pressure turbine driving the house-service generator. The low-pressure cylinder of the main set would exhaust to the condenser, whilst the back-pressure turbine would exhaust to the connection pipe between the high-pressure and low-pressure cylinders of the main set, or alternatively, in case of emergency, to atmosphere. Back-pressure turbines have previously been considered for house service, but must now be regarded in the light of the following new conditions: (*a*) Economy of the small unit. (*b*) Convenience of the double-cylinder design of the main set in so far as it provides a suitable point at which the exhaust from the back-pressure unit may pass to the low-pressure cylinder of the main unit. (*c*) The state of the steam from the back-pressure unit will be similar to that from the high-pressure unit of the main set, and ample provision can be provided for adequate mixing of the steam before passing to the low-pressure cylinder. (*d*) The high-speed turbine in conjunction with gears makes for a more efficient back-pressure unit. In addition to maximum economy the arrangement would also provide for: (*e*) Maximum reliability, since the back-pressure house set would be entirely independent of the condenser and its auxiliaries, also of the main alternator busbar and the large oil switches. (*f*) A number of back-pressure house-service sets could be conveniently paralleled and easily isolated in the event of a fault. (*g*) The back-pressure units would be almost equally suitable with either d.c. or a.c. generators, whilst the d.c. supply would be little, if any, more expensive than the a.c. supply. (*h*) The battery for the emergency supply to auxiliaries may be eliminated on account of the facility for immediate starting of the back-pressure sets. (*i*) The house set could be conveniently placed in the annexe between boiler house and power house, where space is probably not nearly so expensive as in the main power house. (*j*) It is not necessary to parallel the house service supply with the main power station busbars, and this should tend to reduce capital cost and increased reliability in so far as an additional link is removed from the chain.

Mr. S. L. Pearce: In regard to Mr. Eccles's remarks on the subject of reliability, I think that it is not a question of the engineer's reputation, nor is it one of the aggregate losses that may be suffered by the consumers on the system. The point is, that if a system gets a bad reputation for interruptions to the supply the undertaking will not get new and important business which it otherwise would do, and which it is very desirable it should receive. In reply to Mr. Stubbs, I do not think it necessarily follows that the house-service arrangement requires additional space. I know that it does not so far as the Barton station is concerned. The main dimensions of the turbine room would not have been altered if we had not adopted house-service sets. The foundations for these sets were not so expensive as Mr. Stubbs imagines. Whilst I think that the question of reliability of operation is the first requisite to be considered (followed by thermal efficiency and then capital outlay), at any rate in the case of stations that the authors have in mind, the type of drive and the source of power as affecting the station heat balance must not be lost sight of. Therefore it is most important to consider from every aspect the various methods of obtaining the auxiliary supply. There is no doubt that, from the thermal efficiency point of view, an auxiliary supply which is derived, either directly or indirectly, from the main generating plant, either through a service transformer supplied from the terminals of the main generator or from the main busbars, is the most economical. In passing, I think that we should now have to consider as a further alternative the question of the supply being obtained from an auxiliary generator coupled direct to the end of the main generator shaft. The remaining alternatives are (1) a dual supply from house-service sets and house-service transformers and (2) steam-driven auxiliaries. When we take into consideration the factor of reliability I think there can be no doubt that the former method is the better, viz. house-service sets in conjunction with house-service transformers, and I rather gather that that arrangement is the one considered by the authors to be the best—at the moment at any rate. The house-service generator as a source of power and of steam for feed heating has achieved a considerable measure of popularity, and it will in my opinion continue to warrant its adoption until such time as it can be definitely shown that the advantages to be derived from a system of multiple-stage "bleeding" of the main turbine for feed-heating purposes are so great as to preclude the adoption of other methods. A word or two with regard to the actual arrangement which has been adopted at Barton station may be of interest. The two alternative sources of auxiliary supply are, first, from three house-service

three-phase turbo-alternators, operating at 420 volts and exhausting into a condenser-heater which also receives the exhaust from the steam-driven boiler feed-pumps. The house-service sets therefore perform a most important function in connection with the heating of the feed water. As an alternative source of auxiliary power supply we have house-service transformers, stepping down the 33-kV busbar voltage to 420 V. All the motors—at any rate so far as they relate to services of primary importance—are divided equally between those two sources of supply. Auxiliary busbars are provided, one set of bars being energized and supplied from the house-service sets, and the other set from the house-service transformers. With regard to the duplicate motors for these important services—taking the circulating pumps as an example—one motor would be coupled to bars supplied by the house-service generators and the second would be coupled to the bars supplied by the house-service transformers. Normally these auxiliary power bars are kept isolated, and there are three sections of each corresponding to the three main units in the station. These sections are not normally coupled together, though provision is made for so doing in case of emergency. The total horse-power of all motors installed is 7 000, and of that total only 170 h.p. is for d.c. motors, these being in the main for the turbine house cranes. I do not see very much scope for the employment, on a large scale, of storage batteries for auxiliary purposes. At Barton we have only two batteries, the main battery being to provide a standby for excitation and for station lighting, and the second being a switch-trip battery. I agree with what has been said with regard to the method of coupling auxiliary power machines on to the end of the main turbo-generator shaft. Previous speakers have referred to certain objections to that method, e.g. the increase in the length of the set, and I should like to ask whether there are not two other difficulties. I take it that the machine would have to be of rather a special character, having regard to the speed of the main unit. Secondly, owing to the fact that the critical speed of the special generator shaft would not be that of the main generator shaft, it would necessitate the introduction of a flexible coupling and perhaps additional bearings. With regard to the use of steam-driven units, I think that the use of such sets for small auxiliaries must, in the future, decline with the advent of the higher boiler pressures now employed.

Mr. W. Dundas: The subject appears to me to have been considered principally in conjunction with the large station, and one speaker has mentioned that duplicate auxiliaries should not be adopted on units of less than 10 000 kW capacity. The smaller stations are equally important as regards reliability of supply, and should be considered. With a single set of auxiliaries the duplicate drive can be obtained by the employment of a motor and steam turbine coupled together. The steam to the turbine would be automatically controlled so as to bring the turbine into action in the event of failure of the supply to the motor. Such an arrangement enables advantage to be taken of the electric drive, which would be the normal running condition, and provide the reliability connected with the steam drive in cases of emergency. Arrangements would have to be made to prevent the motor from supplying energy to the line when the turbine was acting as prime mover.

Mr. G. A. Juhlin: The authors wish to have an expression of opinion on the suitability of d.c. generators for direct coupling to main turbo sets for the supply of power for certain auxiliaries. The answer depends, first, on the speed of the main sets and, secondly, on the output required from the d.c. generators. For 1 500-r.p.m. sets the scheme is quite satisfactory for any size of main sets that may be required. Units of 15 000 kW capacity have been in satisfactory operation for some years with d.c. generators direct coupled to main sets. The problem becomes much more difficult, however, when 3 000-r.p.m. sets are considered. The question of output required becomes of importance. Small units of, say, 150 kW at 500 volts which can be overhung on the generator shaft may be considered satisfactory. I understand that something like 500 kW would be required for the auxiliaries of a 25 000-kW set, and I do not think that one could recommend building a 500-kW d.c. generator at 3 000 r.p.m. There are, of course, d.c. generators of this output running at about 2 500 r.p.m., but one cannot say that the reliability is such as would be required for power station auxiliaries. The authors point out the absolute necessity for reliability of the particular auxiliaries supplied from the direct-coupled d.c. generators, and I should certainly hesitate to recommend the scheme. It should be remembered that the difficulties in operation of a d.c. generator direct coupled to a large mass such as a main unit are greater than when operating it as an independent unit. To sum up: For 1 500-r.p.m. sets the scheme is satisfactory, while for 3 000-r.p.m. sets it should be avoided if at all possible.

Messrs. L. Breach and **H. Midgley** (*in reply*): We think that Mr. Eccles rather underestimates the detrimental effects of a shut-down. We are fully in agreement with the remarks of Mr. Pearce on this point, and would add that the moral effect of a series of shut-downs is not conducive to efficiency of working; in other words, the effect is apt to be cumulative. We would also refer Mr. Eccles to the remarks of Mr. Brazil in the London discussion (vol. 61, page 846). That the time of interruption depends also upon the distribution arrangements, etc., is true, and, whether or not the distribution system be the greater factor, it is essential that the auxiliary system should be such as not to be affected by external disturbances, and the auxiliary arrangements must therefore be given equal attention.

We have to thank Mr. Eccles for the figures as to the capital costs of the two alternative arrangements. We would suggest that the true relative values are best realized by considering the costs as fractions of the cost of a complete power station, when it will be seen that the difference between the two arrangements is only approximately 0·5 per cent of the total cost of the station. The question of maintenance and attendance must also enter into the comparison.

Regarding the point at which divided auxiliaries would be recommended, it is suggested that this

depends upon two factors: (1) The importance of continuity of supply from the particular station and its relation to other generating stations (if any) on the system; (2) the possibility of detriment to the turbine through atmospheric running.

Mr. Lamb's point regarding the air-extraction arrangement has been dealt with in the reply to Mr. Jockel in the London discussion. The question of choice between alternating and direct current for auxiliary motors has already been dealt with so fully in the previous discussions on this paper that we do not consider it necessary to add anything further. The "synchronizing in times of emergency," mentioned in the paper in connection with the alternative to Scheme 7, refers to the possible necessity of changing over the auxiliaries and groups of auxiliaries from the main bars to the bars fed by the house turbine, without shutting these auxiliaries down. With direct current this could easily be done, but in the case of alternating current it would be practically essential to have the two supplies coupled, i.e. synchronized, in order to avoid shutting down when changing over. We are fully in agreement with Mr. Lamb's statement that a considerable saving in cost must be shown before it is worth while adopting a pressure of 3 000 volts for auxiliaries, in view of the fact that it is unsuitable for motors below about 50 h.p.

The suggestions of Mr. Stubbs are noted with interest, but, while we agree that they are worthy of consideration and comparison, they by no means cut away the basis of the paper. Incidentally, we rather suspect that the scheme would not be quite so simple of operation as Mr. Stubbs so optimistically suggests.

As already stated, we are in thorough agreement with Mr. Pearce regarding the effects of a shut-down. The information regarding the auxiliary arrangements at the Barton station is noted with interest. The question as to the effect of the size of the station upon the auxiliary arrangements, raised by Mr. Dundas, has been dealt with in the reply to Mr. Eccles. The suggestion by Mr. Dundas of having a turbine and motor driving the same auxiliary has been adopted in at least one large station in this country, and to the best of our knowledge the scheme is working satisfactorily. It has, of course, the same objections as have already been raised in the paper regarding a direct steam drive.

We thank Mr. Juhlin for the information which he gives as to the suitability of d.c. generators for direct coupling to main turbo-alternator units.

DISCUSSION ON

"THE LEAKAGE FLUX BETWEEN PARALLEL POLE-CORES OF CIRCULAR CROSS-SECTION." *

Dr. A. E. Clayton (*communicated*): I have read Mr. Hague's paper with much interest. The fact that poles of circular cross-section are now not generally favoured by designers does not in the least detract from the value of the simple expression deduced by the author for the leakage permeance per cm height of pole, or from the value of the graphs plotted in Fig. 3 of the paper. In practice, some designers utilize a value of the Hopkinson leakage coefficient based upon experimental results on previous machines. Others, as pointed out by the author, calculate the value of the leakage flux by the method due to Arnold, in which the leakage lines at the ends are assumed to have the form indicated in the second quadrant of Fig. 4, as suggested first by Forbes. Yet others employ a method in which the leakage flux at the ends is "scientifically guessed." At present, then, designers experience difficulty in calculating the leakage which occurs at the ends of the poles. For dealing with circular pole-cores, Arnold based his calculations upon the "equivalent square" pole, as indicated in Fig. 4. The assumed flux distribution at the ends is obviously incorrect, so that the leakage flux, as calculated by Arnold's method, is too low. This statement will also hold for all cases where the corresponding Arnold formulæ are used, and thus applies in particular to the case of square and rectangular poles. In this connection, emphasis may well be laid upon the author's statement that "the permeance calculated from any assumed distribution of lines of force other than the true distribution must of necessity be too small," as this important principle is often overlooked. When Arnold's method is applied to the case of circular poles, the calculated value of the leakage permeance per cm height of pole is too low. The actual error varies in amount by about 1·5 to 1·7 for the cases dealt with in Table 1. When the distance between poles is relatively great, however, the value calculated by the Arnold formula is worthless, the percentage error being enormous. This is, of course, to be expected, as under these conditions the leakage at the ends of the machine is very important. The percentage error, however, decreases rapidly as the relative value of the clearance between poles decreases. When the distance between poles is relatively small, it is natural to conclude that the

* Paper by Mr. B. Hague (see vol. 61, p. 1072).

actual configuration of the pole will have a relatively greater influence upon the actual value of the leakage flux than when the poles are very far apart. It may then, I think, safely be concluded that the actual value of the leakage flux for the case of circular poles will not differ to any serious extent from that obtaining in the case of the "equivalent square" poles. The error obtaining with the Arnold method may therefore safely be assumed to be due to the fact that this method, by assuming a wrong flux distribution at the ends of the machine, much under-calculates the corresponding leakage, and not to be due in any marked extent to the conception of replacing the circle by the equivalent square. By using the data given in the paper, therefore, we are now in a position to deal more exactly than hitherto, not only with the case of circular pole-cores, but also with poles of other section. Thus, for dealing with poles of square section, it would appear that the value of the leakage flux can be estimated more correctly than by means of Arnold's formula if the calculations are based upon the "equivalent circular pole." The value of the leakage permeance per cm height of pole can then at once be read off from the graph given in Fig. 3. Pole-cores with semi-circular ends can also be handled with sufficient accuracy without any difficulty, and a rectangular section may be replaced by the equivalent section having semicircular ends. I therefore regard the paper to be of value, not merely because it gives us a simple and at the same time more exact method of calculating the leakage flux of circular pole-cores, but also because the data given for circular poles enable us to calculate more exactly the leakage obtaining with pole-cores of other section. For reasons which are stated by the author and need not be recapitulated, the exact calculation of the leakage flux cannot be expected in practice, even for the case of circular poles. Still less can it be hoped to calculate exactly the leakage of a modern direct-current machine with interpoles. It would, however, be of interest if the author would give an estimate of the extent to which he would expect his results would have to be modified to deal with the case of short circular poles, of a height roughly equal to their diameter, joined by a yoke at one end and separated by a small air-gap from an armature at the other, the poles carrying a uniformly distributed winding; that is, for a case corresponding to the conditions actually obtaining in practice, with the exception that the poles may be assumed to be parallel and pole-shoes are absent. Naturally, I am asking for nothing more than a reasoned estimate, or "scientific guess."

Mr. B. Hague (*in reply*): The remarks of Dr. Clayton are of considerable interest and importance, since they enable the results obtained in my paper to be applied to a wider range of problems than I had originally visualized. With regard to the usual Arnold method of calculating leakage flux, I am quite in agreement with Dr. Clayton's conclusion, namely, that the error in the method is due not so much to the use of the "equivalent square" as to the fact that the flux assumed to issue from that square is totally incorrect. It is quite reasonable, in view of this principle, to treat other shapes of core by a kind of inverted Arnold method, using an "equivalent circle," since the solution of the problem for circular cores is so accurately known. I should like to state, however, that for square and rectangular cores the *exact* solution—found by the method of conjugate functions—is known and has been given by Dr. Douglas in the article cited in my paper. The final paragraph of Dr. Clayton's remarks raises a most important question which it is extremely difficult to answer. With a short pole-core attached at one end to an iron yoke while its other end faces an armature, the conditions of the problem become so profoundly altered that even a "scientific guess" is not easy. Dr. Douglas in his paper appears to have made an estimate of the influence of the yoke on the leakage, but his statement is not very detailed. While regretting that I cannot, at the moment, give Dr. Clayton the answer he desires, I would say that I have work in hand which will, I hope, provide a contribution towards a more complete knowledge of the leakage field. The results are not yet sufficiently advanced, however, to be usefully discussed. In conclusion, it is a source of pleasure to me to note that Dr. Clayton, as a practical designer, so thoroughly appreciates the difficulty and the importance of obtaining even approximate, but physically reasonable, solutions of flux-distribution problems.

SOME EXPERIMENTS ON THE SCREENING OF RADIO RECEIVING APPARATUS.

By R. H. BARFIELD, M.Sc., Student.

(*Paper first received 8th August, and in final form 28th November,* 1923; *read before the* WIRELESS SECTION *2nd January,* 1924.)

SUMMARY.

The chief object of the investigation was to obtain quantitative information on the effect of screens, of which the dimensions are small compared with the wave-length of the waves they are intended to screen. Some preliminary experiments are described, in the first of which the screening effect of a totally closed iron tank was investigated by an operator inside it with a frame coil receiver; and in the second an investigation was made on the effect of screening a square frame receiving coil by totally enclosing each of its four sides in a metallic envelope. A description is then given of the method employed in subsequent experiments of measuring the effect of screens based upon the employment of two receiving coils connected in opposition. This is followed by an account of measurements made by this method on some specially constructed screens of straight wires, open and closed loops, and wire-netting, etc. These measurements demonstrate the important part played by closed circuits in screening the magnetic field of radio waves, and show that an effective screen may be constructed of wire-netting. In this connection a description is given of the screening of the interior of a hut with this material to protect direction-finding apparatus within it from "direct pick-up."

Further experiments, in which the effect of screens on the electric field of the waves is measured, are then described. Three types of screen investigated were shown to reduce substantially the electric field without affecting the magnetic field, while, later in the paper, it is shown that a fourth type will screen the magnetic field but not the electric field. A cage of the former type is then described which is now in practical use as a means of eliminating "antenna" effect from a single-coil direction-finder contained within it.

A discussion of the experiments follows, some explanation of the various effects being given, and conclusions are drawn as to the general principles of screening and as to the essential points to be attended to in the design of efficient screens for various purposes.

INTRODUCTION.

The subject of the screening of long electromagnetic waves by conductors of relatively small dimensions has had little attention paid to it by theoretical or practical investigators. As far as the author is aware, no comprehensive theory of the action of such screens has been worked out, and very little in the nature of experimental data is available. In addition, it has been remarked that, in general, somewhat vague and contradictory ideas upon the subject at present prevail.

The experiments about to be described were therefore undertaken with two main objects in view. The first and most general was to obtain further light on the effect of conductors of various shapes and configurations on the electromagnetic fields of wireless waves, such information being chiefly interesting from a general scientific point of view. The second was to determine quantitatively the actual extent to which certain screens protect the region they enclose from the influence of radio waves of commercial frequencies, thus obtaining data which should be of some assistance to wireless engineers.

The first experiments on the screening of wireless waves were probably those of Hertz,* in which he shut off the rays of his transmitter from his receiver by means of a grating of parallel wires. With this may be coupled his experiments showing the innate tendency of high-frequency currents to concentrate on the outer members of a group of conductors in preference to penetrating within, thus demonstrating for the first time what is now known as "skin effect." More recently a considerable amount of theoretical and experimental work has been done on the effect of gratings on short electromagnetic waves. Examples of this are the mathematical work of J. J. Thomson,† and Lamb,‡ and the experimental researches of Schaefer and Langwitz,§ and that of G. H. Thomson.‖

In all the above work, however, the wave-length employed in the experiments or assumed in the calculations was always less than the principal dimensions of the screens employed; the results therefore have little or no bearing on cases involving the screening of long waves such as are used in practical radio-telegraphy where screening constructions must inevitably be small compared with the wave-length.

In this field Duddell and Taylor ¶ have measured the obstructing effects of trees to short waves; and Smith-Rose and the author ** have made observations on a wireless direction-finder receiver inside an iron airship shed and in a long metal tube, with a view rather to ascertaining the distortion produced than to determining the extent of screening. In addition to this, Smith-Rose †† has recently demonstrated the great difficulty of efficiently screening a local generator of high-frequency oscillations, by experiments which showed that even the smallest cracks in the screen would allow a considerable amount of energy to escape.

Some early experiments were carried out by Lodge ‡‡

on the penetration of waves through the walls of a cage to a receiver within, and quite lately Watson Watt and Herd * described some tests made with a frame coil and multi-stage amplifier in a specially constructed box. Campbell Swinton † has studied the directional properties of a small cylinder containing a loop receiver.

On the practical side, M. Dieckman used a screen of wires suspended horizontally above an aerial of **L** or **T** type to eliminate a certain type of atmospheric, and it is interesting to note that a paper ‡ describing this arrangement and read in 1917 gave rise to a vigorous discussion, in which those who took part apparently held distinctly contradictory ideas on the general subject of screening.

Again, many experimenters have found it necessary to employ elaborate screening arrangements for radio apparatus, and some have described their method of solving the problem, e.g. Hoyt Taylor § who employed specially screened huts for his apparatus used in connection with ground antenna. Finally, an account of work done on the subject is not complete without reference to the development of the "earth screen" as now used in modern transmitting stations. The experiments of Eckersley ‖ may be referred to in this connection.

Preliminary Experiments.

Receiver enclosed in tank.—The great difficulty of screening completely a generator of high-frequency oscillations has, as already indicated, been demonstrated by Smith-Rose. As a complementary experiment it was thought of sufficient interest to try the converse process of completely enclosing a wireless receiver in a metal case.

To make the experiment satisfactory it seemed necessary that the observer operating the receiver should be enclosed with the set. Accordingly a screen suitable for this purpose was sought for and eventually found in the form of a disused oil tank. This tank (see Fig. 1) was about 9 ft. long and 4 ft. in diameter, the thickness of the metal being about $\frac{1}{8}$ in. The only opening to the tank was in the form of a manhole 14 in. diameter fitted with an oil-tight cover and held in place by 36 nuts and bolts. The interior of the tank was divided into two compartments by means of a central partition $\frac{1}{8}$ in. thick and provided with a circular opening also 14 in. in diameter.

The receiver consisted of a square frame coil of 2 ft. 6 in. side and 30 turns, made collapsible so as to enable it to go inside the tank, and connected to a tuning condenser and a seven-valve amplifier of a standard pattern.

After preliminary tests with the apparatus in the open, this receiving set was introduced into the tank through the manhole, the operator, not without difficulty, following it. An investigation was then made of the ability to receive the spark transmission from Paris (wave-length 2·5 km) inside the tank, and the radiation from a small buzzer wave-meter situated a few feet from the tank.

The cover of the manhole was first left off. The spark transmissions from Paris could be picked up at good strength by the coil if some part of it was within a few inches of the opening, while the buzzer wave-meter could be heard loudly for all positions of the coil inside.* The cover was now put in its place, the cover bolts being inserted and screwed up one by one. Paris signals now became fainter and fainter but did not disappear until every bolt had been put in place and screwed up, while even then the buzzer could still be faintly heard.

The operator with the complete set then retired into the inner compartment through the small hole in the partition which was left unclosed. In this space no signal, local or otherwise, could be detected whether the outer manhole was open or closed. This experiment shows that the most effective way of obtaining a high degree of screening is to employ a screen within a screen.

Receiving loop with screened sides.—Two exactly similar frame coils were constructed each 2 ft. 6 in.

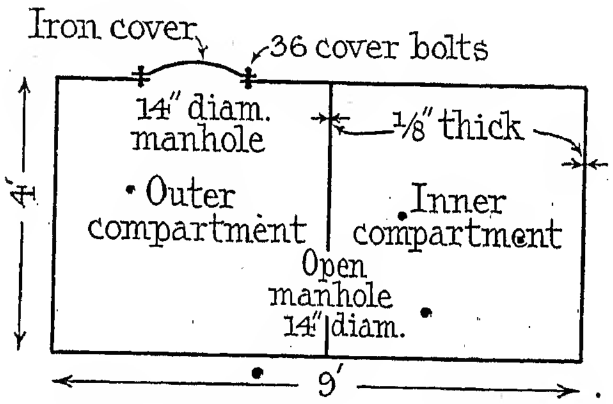

Fig. 1.—Iron tank employed in Experiment No. 1.

square by 3 in. deep and wound with 25 turns of No. 22 wire (d.s.c.). The four sides of one of these coils were completely encased in a metallic tube of rectangular section (5 in. × 3 in.) made of tinned iron (see Fig. 2), and all joints were well soldered so that the coil was completely encased except for two small holes through which the ends of the coil were brought out. The frame was carefully disposed inside the tube so that the wire was well clear of the sides of the screen. A receiving circuit with amplifier was arranged (see Fig. 2) so that it could be switched alternately from the screened to the unscreened coil, and vice versa. The tuning condensers and batteries were placed in a metal box.

Tests of this description over a wide range of wave-lengths from 1·0 to 5·0 km immediately demonstrated that the coil within the tube was perfectly screened so far as could be determined by means of this rather rough method of measurement.

The tubing was then sawn completely through at the centre of one of the sides and the test repeated. It

‖ T. L. Eckersley: *Journal I.E.E.*, 1922, vol. 60, p. 581.

* It may be as well to note that the signals received in the tank from the buzzer were quite definitely due to high-frequency oscillations and not merely to induction at the audio frequency of the buzzer, since it was necessary to tune the receiver to the buzzer wave.

was found that the screened coil now possessed a receptive power of roughly half that of the unscreened coil, i.e. the latter had to be turned to within 30° of its minimum position to get equal signal strength by the method of comparison. Varying the width of the gap in the tube from $\frac{1}{8}$ in. to the smallest possible value had no effect on the result.

The receptive power of the loop was reduced to an inappreciable value as soon as the two sides of the gap were made to touch one another, but if the gap was bridged by only a few inches of wire a distinct, though still small, pick-up was at once observable, which increased as the length of the connecting wire was increased.

The open-circuited single-turn loop formed by the metallic tubing was then tuned to the waves under

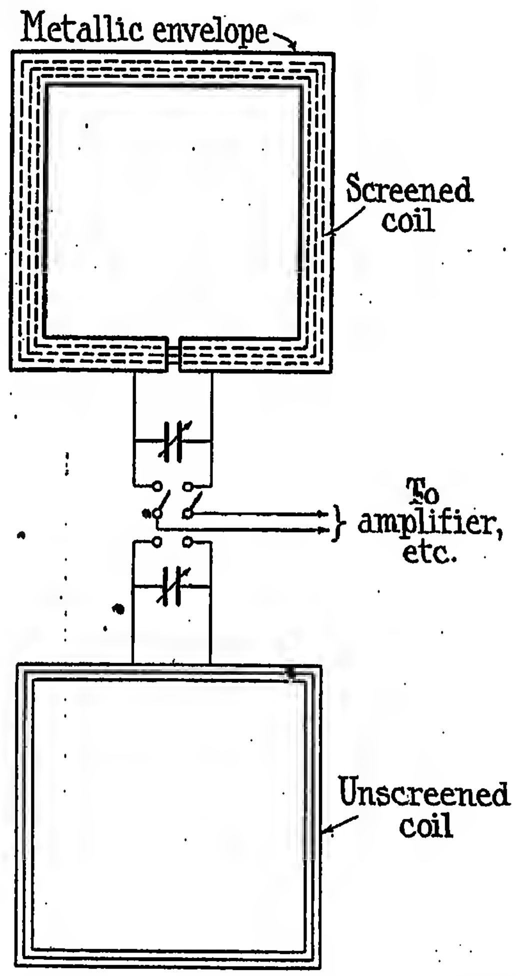

FIG. 2.—Screened loop and method of measuring effect of screen.

observation, by means of a condenser and a series inductance. The strength of signals received on the screened loop remained unaltered.

The amplifying detector was then disconnected from the inner coil (which, however, still remained tuned) and was connected to the tuned circuit, of which the outer screen now formed part. The signal strength still remained about the same, but when the inner coil was detuned, short-circuited or open-circuited, a large decrease in signal strength was noted, thus showing it was the coil and not the casing that was picking up the energy.

Since the thickness of the envelope was in each case sufficient to prevent all but a negligible amount of direct penetration of energy, that which was picked up by the coil within the casing must all have passed through the gap, thus illustrating once more how comparatively large amounts of energy in the form of oscillatory fields may readily pass through the smallest cracks in an otherwise opaque screen.

In each of the above cases it was ascertained that the screened coil possessed normal directional properties, and it was also found that with the screen connected to the amplifier box as in Fig. 3, the zeros were very sharp, showing that the "antenna" effect

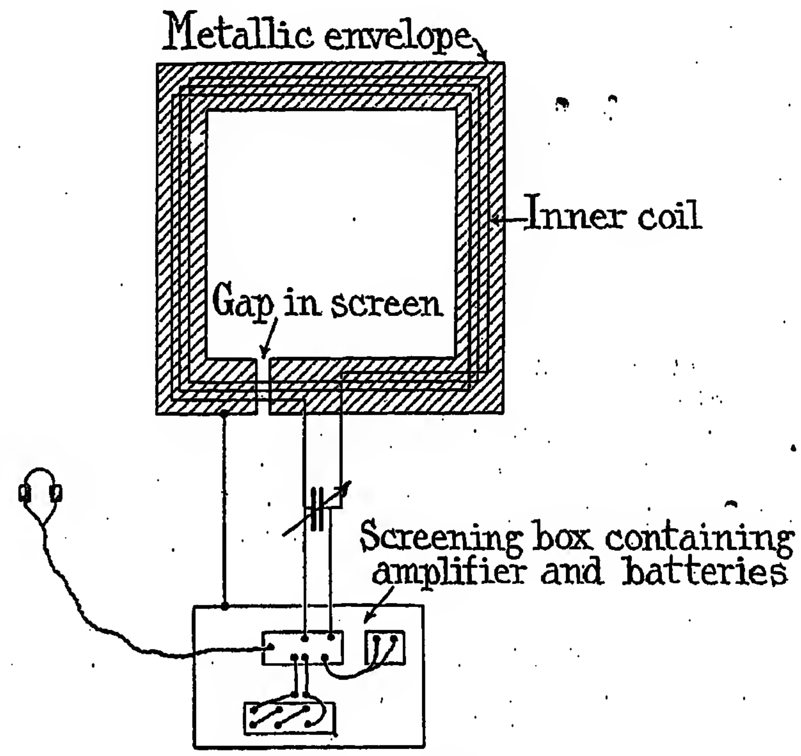

FIG. 3.—Reduction of "antenna" effect in directional receiver by screening sides.

had been practically eliminated by the action of the screen. The theoretical aspect of these experiments is discussed later in the paper.

MEASUREMENT OF THE EFFICIENCY OF SCREENING APPARATUS.

Improved method.—The rough method of measuring screening effects described above was found not to be sufficiently accurate for the more thorough experiments which had been planned. It was therefore decided to devise some more suitable apparatus.

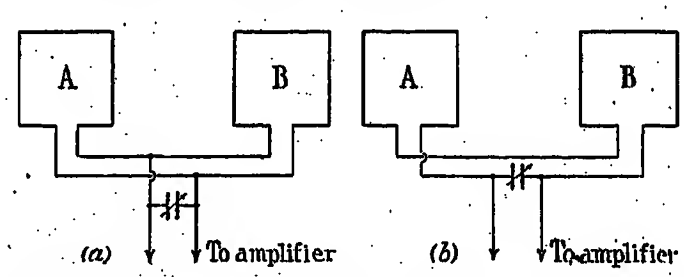

FIG. 4.—Method of obtaining a balance with spaced coils.

The basis of the method successfully adopted was to connect two receiving loops, A and B, in a common circuit so as to oppose one another when acted on by a given radio wave. This may be done in either of the ways shown in Fig. 4, i.e. the two coils may be connected either in series or in parallel across a common tuning condenser. They must in both cases, however,

be placed so far apart that the coupling between them is negligible.

The procedure was to fix one (A) in some definite position, then to rotate the other (B), which was generally the larger of the two, about a vertical axis until minimum or zero signals were obtained, noting the angular position for this condition. The coil A was then placed in the screen under investigation without altering its orientation or making any other change in the conditions. A balance was then obtained again by rotating coil B to some other position.

It is clear that the ratio in which the E.M.F. in coil B is reduced by rotation towards its minimum position will be equal to the ratio in which the E.M.F. in coil A is reduced by the screen, that is, to the ratio in which the magnetic field has been reduced by the screen. That is to say

$$\frac{H_2}{H_1} = \frac{\cos\beta_2}{\cos\beta_1} \quad . \quad . \quad . \quad . \quad . \quad (1)$$

where H_1 and H_2 are the field strengths before and after screening, respectively, and β_1 and β_2 are the corresponding angles made by coil B with the direction of the transmitting station.

It will be found on examination that the above relation holds good provided that the following assumptions are valid:

(1) That the direction and phase of the magnetic field inside the screen are the same as outside.
(2) That the screen does not appreciably affect the constants of the circuits.
(3) That the effect of any other E.M.F.'s in the circuit is of a secondary nature and may be neglected.

All these points were verified by simple experiments.

In practice it was found necessary to use compensating condensers in the manner adopted in ordinary direction-finding work for the purpose of reducing "antenna" effect. It was also found advisable to provide a switch by means of which the loop A could be reversed, thus enabling a double set of readings to be taken on each occasion, the mean of the two sets being taken for use in the calculation.

Test of accuracy of method.—A practical check on the method was obtained as follows:—

The two receiving loops, A and B, of Fig. 4, which differed considerably in the value of their "area turns," were mounted on vertical axes and separated by a distance of about 15 ft. The system was then adjusted to receive some convenient transmitter. The loop A was rotated from its maximum to its minimum position of reception in stages of 15° at a time. At each stage the E.M.F. in coil B was adjusted by rotation until a balance was attained. The angles α and β made by each coil with its maximum position were recorded for each balance position. It is clear that the ratio of the E.M.F.'s included in the two coils should be the same for each balance position, i.e. it should be found that

$$\frac{\cos\beta}{\cos\alpha} = \text{constant} \quad . \quad . \quad . \quad . \quad . \quad (2)$$

and the degree of accuracy with which this relation is found to hold will give an indication of the accuracy of the method.

The results of the experiment are recorded in Table 1, in which the value of $\cos\beta/\cos\alpha$ is found to remain very nearly constant (i.e. within 1 per cent) until the loops are within 10° of their minimum position, when divergences begin to occur. This experiment may be taken as satisfactory proof that the method is at least free from serious instrumental errors, and as evidence of the correctness of the third assumption as stated above.

Other tests for instrumental errors were carried out from time to time during the experiments, such as interchanging the two coils, comparing the results obtained from the series and parallel arrangements or altering the disposition of the leads and other parts of the circuit, etc., and in all cases it was found that no detectable variation was caused by such tests.

TABLE 1.

Again, one of the experiments (that of measuring the effect of a wire-netting cage) was repeated by another but rougher method, i.e. that already described of comparing the signal strength from two similar coils. The result agreed within the limits of the errors of the latter method, which were rather large.

FIRST EXPERIMENT: MEASUREMENT OF EFFECT OF SCREEN COMPOSED OF STRAIGHT WIRES AND OPEN AND CLOSED LOOPS.

A skeleton cube of side 6 ft. was constructed of light timber to serve as a frame for the different screens to be experimented upon. In the first place, four of its sides were covered with parallel wires (No. 20 S.W.G. copper) spaced 1 inch apart and with their ends left free, thus forming a sort of tube open at the top and bottom (see Fig. 5).

The "balanced-coil" measuring apparatus was set up as described, coil A consisting of 25 turns wound

on a 2 ft. 6 in. square frame, and coil B of 34 turns wound on a 4 ft. square frame, and the system was tuned to a transmitter working on a 4·5-km wave. A balance was obtained with coil A outside the screen, and the angular position (β_1) of coil B was noted. The screen was then dropped over coil A so that its

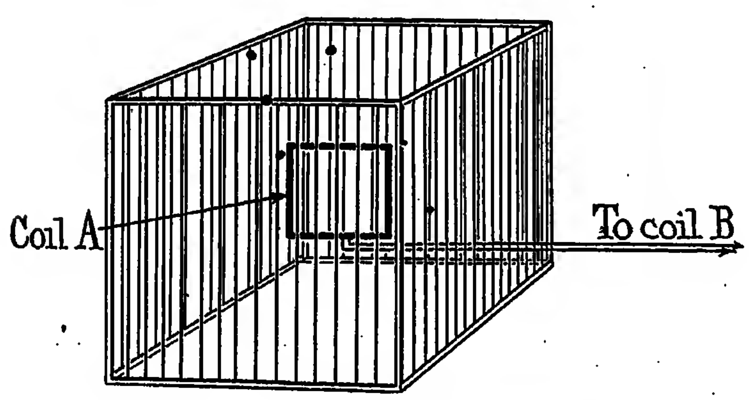

FIG. 5.—Screen of short, straight wires.

wires were vertical and so that the loop occupied the centre of the interior. A balance was once more obtained, the corresponding position (β_2) of coil B being recorded. The loop A was fixed approximately in its maximum position, but since it was not moved during the test it was not necessary to know its position exactly.

be in this case close up to it. The wires were spaced about 1½ in. apart and arranged in nine rows 2 in. apart and 6 ft. long. There were thus, in all, over 400 wires, so that the coil was situated in the centre of a mass of closely packed wires. A sketch of the arrangement is shown in Fig. 6. The method employed

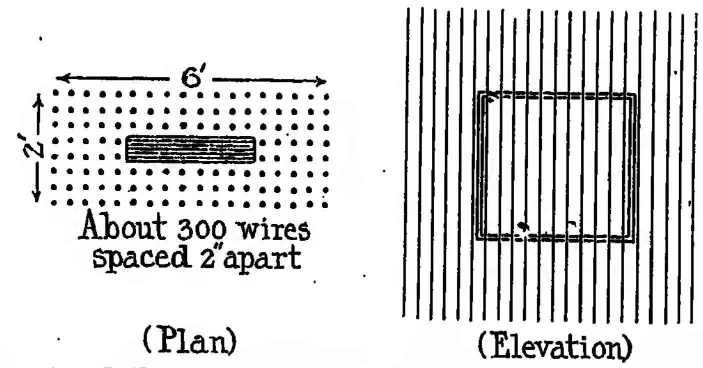

FIG. 6.—Coil surrounded by number of straight wires close together.

was quite well able to measure a change of 1 per cent in the field strength, but, as before, the screen appeared to have no effect whatever on the E.M.F. induced in the loop A, no matter whether the wires composing it were placed horizontally or vertically.

Using the same frame, a cage was now constructed of a series of conductors in the form of a three-sided

The experiments were repeated on a wave-length of 1·8 km and again with the cage modified by connecting all the wires together at their lower ends and earthing the junction point. The measurements are recorded in Table 2, which shows at a glance that no screening effect at all can be detected for this cage, the field inside it being shown to be the same as that outside, within the limits of accuracy of the method.

The coil A was now fixed rigidly at the centre of the wooden cube from which the wires had been stripped, and numbers of straight wires parallel to the plane of the coil were stretched between two opposite faces of the cube so as completely to surround the coil and

rectangular loop [see Fig. 7 (*a*)]. These conductors were, as before, spaced about 1½ in. apart and, being 44 in number, thus covered the whole of three sides of the cube; this cage was found to have no detectable screening effect (i.e. certainly less than 1 per cent). A fourth side was now added to each loop in the manner shown in Fig. 7 (*b*), a gap being left at one corner so as to make the loops discontinuous. This arrangement was also found to have no appreciable screening effect.

The gap in each loop was now closed [see Fig. 7 (*c*)] so that the cage now consisted of a series of 44 parallel, closed loops spaced 1½ in. apart. A marked screening effect was now noticeable which was a maximum when

the plane of the loops was aligned on the transmitting station, and zero when at right angles to this direction or when the loops were placed horizontally. In the position of maximum screening, the field within the cage was found to be reduced to about 1/10th its normal value. The cage was then once more modified by the addition of a second set of parallel, closed loops at right angles to the first set and equal in number and spacing to the latter.

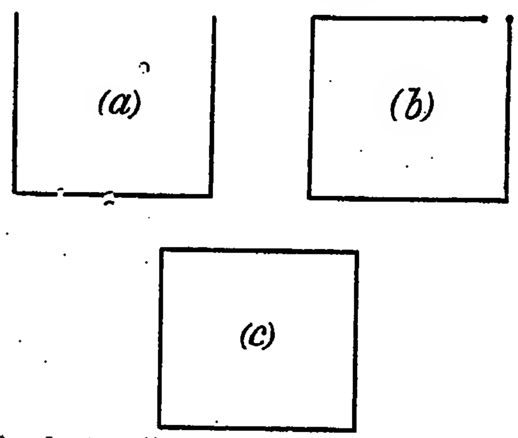

FIG. 7.—Conductor "elements" of some screens experimented with.

Tests showed that the screening effect of this arrangement was approximately constant for all orientations of the cage with the loops vertical, and equal in amount to the maximum value obtainable in the former case (i.e. with one set of loops). If the cage was turned so that one set of loops were in horizontal planes, the cage behaved exactly as in the former case when it had only one set of loops.

Further experiments were now carried out to investigate the effect of varying the number of loops forming the cage. That is to say, the overall dimensions of the cage were kept constant whilst the spacing of the loops was gradually increased by thinning them out. Measurements were made at successive stages of the process and are recorded in Fig. 8, which shows "screening ratio" plotted against spacing. It will be seen that the screening ratio falls off rapidly at first but more slowly as the spacing becomes comparable with the dimensions of the cage. With only one loop on the cage the resultant field at its centre was found to be 81 per cent of its normal value.

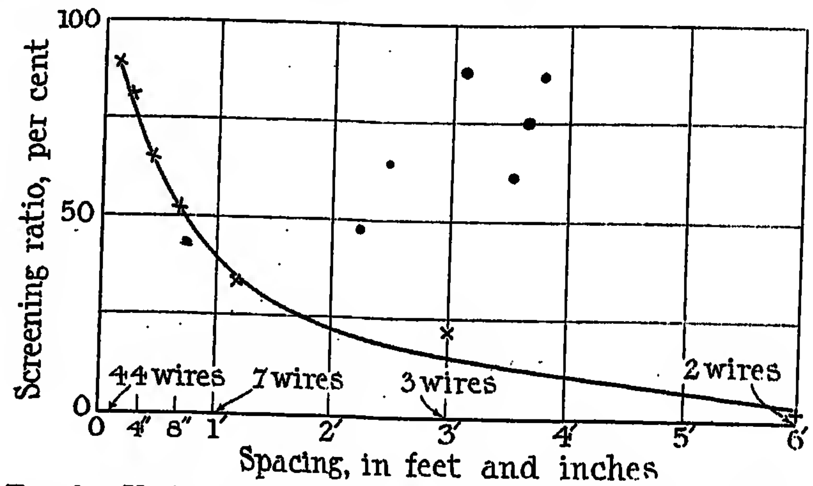

FIG. 8.—Variation of screening ratio with spacing of closed loops.

Since the value obtained for the screening ratio would be practically meaningless if the field within the cage varied greatly from point to point, a test was carried out in which the interior of the cage was explored by moving the coil A about inside it. This test showed that as long as coil A was not brought close to the boundaries of the cage the screening ratio obtained was independent of the point in the cage at

TABLE 3.

Effect of Open and Closed Loops.

Observations made on Ongar (GLO): $\lambda = 4 \cdot 5$ km.

(6) Cage as in (5) but rotated through 45°	39	83·2	0·15	85
(7) Cage as in (5) but rotated through 90°	39	83·9	0·14	86
(8) Cage as in (5) but one set of loops horizontal, the other aligned on transmitter	39	84·6	0·12	88
(9) Cage as in (8) but turned through 90° on vertical axis	39	38·7	1·00	0

The results of the experiments are given in Table 3. The ratio $1-(H_2/H_1)$ recorded in the last column as a percentage has been termed the "screening ratio" of the cage, as it was thought to be the value which most clearly expressed its screening properties.

which it was measured, thus showing that in all the central region the resultant field strength was substantially uniform. The screening was found to increase when loop A was brought close to the central wires of the cage, but became distinctly less at points near the open ends. (The experiment was carried out with only one set of loops on the frame.)

The experiments described above show very clearly that in order to screen a loop receiver it is necessary to employ closed conducting loops. In other words, they show that the presence of a system of conductors does not influence the magnetic field in its neighbourhood unless it contains closed conducting paths enclosing an appreciable area. The conducting system will even then affect only that part of the magnetic field which is normal to the plane of these paths.

sections of corrugated iron about $\frac{1}{16}$ in. thick, the sections being bolted tightly together so that the electric resistance at the joints should not be high. A comparative measurement of the field strength at the centre of each cylinder was made with the cylinder in at least two different positions. A test was also made to discover at what distance away from one of the cylinders its screening effect became inappreciable.

As before, it was assumed that the presence of the cylinders did not materially affect the constants of any part of the measuring apparatus. This was verified by the fact that no readjustment of tuning apparatus was required when the coil was set up in the cylinder. The results show (see Table 4) that a greater screening effect is obtained when the axis of the cylinder lies perpendicular to the direction of the waves than when

(11) Outside cylinder 10 ft. away on axis	(11)	Short (5 ft. dia. × 2 ft. 6 in. long)	1·00	0

A study of the curve for the screen of closed loops (Fig. 8) shows that by employing closer spacing it would be possible to obtain a screen of very high efficiency. As such a screen has marked directional properties, allowing undiminished reception from the direction perpendicular to the loops, it could be used at a radio station to protect the receiver from interference from the transmitter. This method of preventing interference could be used either as an alternative to those already existing, or in addition to them, so as to obtain a greater efficiency.

SECOND EXPERIMENT: SCREENING EFFECT OF METAL CYLINDERS WITH OPEN ENDS.

Three cylinders of diameter 5 ft. and lengths 2 ft. 6 in., 5 ft. and 8 ft. respectively, were employed in these experiments. Each cylinder was built up of curved

it lies parallel to this direction, but the difference is less for the long cylinder than for the short. Although the shortest cylinder has a maximum screening ratio as high as 90 per cent, those of the two longer ones are still higher. The difference between the long and medium cylinder is not very marked, but it is enough to show that the longer the cylinder the greater is the screening ratio.

The results in (3) and (5) in Table 4 show that the medium cylinder, when upright, screens to the same extent as when it is horizontal with its axis parallel to the direction of the wave. It seems probable that this would hold good for all sizes of cylinders. At a point outside the small cylinder only 1 ft. away on its axis the screening ratio falls to 49 per cent; at 3 ft. the effect is small but easily detectable, while at 6 ft. it is only just measurable and at 10 ft. cannot

be detected. It is assumed that the maximum effect of the cylinder occurs on its axis and therefore no other positions were tried.

Third Experiment: Effect of Wire-netting Screens.

The 6-ft. skeleton cube was now covered with galvanized-iron netting of 2-inch mesh. The seams between the various lengths were bound together with copper wire so that no gaps existed of dimensions comparable with the size of the mesh, and all joints made good electrical contact. The cage so formed was insulated from the gound by standing it on small, dry, wooden boxes, and the receiving coil A of the balancing system was introduced into the interior through a temporary gap.

In addition to investigating the state of affairs at the centre of the cage with regard to both strength and direction of field, measurements were made at various other points in the cage in order to obtain a rough idea of how the field was distributed throughout the screened region. In addition, the screening ratio as measured at the centre of the cage was compared for different wave-lengths between $6 \cdot 0$ and $1 \cdot 5$ km. A small gap in the nature of a vertical slit about 3 ft. high was afterwards made in one side of the cage, but its effect on the intensity of the field at the centre was not appreciable.

The results in Table 5 show that the cage reduces the magnetic field strength of waves of $4 \cdot 5$ km to 11 per cent of its normal unscreened value. This value was not appreciably altered by a movement of the coil to other positions of the cage even quite near the sides. This seems to indicate that the field is practically uniform throughout the cage except possibly at points within a few inches of the sides, as a considerable variation at such points would not be detected by this method.

The increase in the value of β_2 obtained in (7) and (8) of Table 5 shows that coil A was approximately in its maximum position when aligned on the transmitter and inside the cage, i.e. the field was not distorted by the cage. The result in (9) tends to show that the screening effect is independent of the direction of the arrival of the waves with regard to the screen, as would naturally be expected if the cage were symmetrical about a vertical axis. The result in (11) shows that outside the cage its effect becomes inappreciable at a distance of only 5 ft. away, i.e. a length of the same order of magnitude as the linear dimensions of the cage—a result in agreement with that obtained in the experiment with the cylinders (see page 255).

The variation of screening ratio with wave-length is shown in Fig. 9, which indicates a small though definite

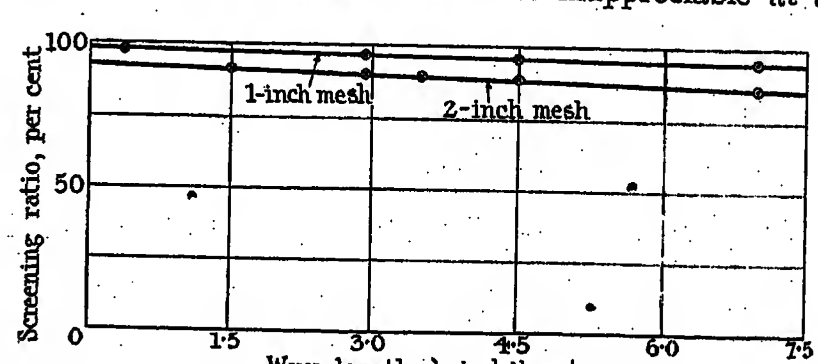

Fig. 9.—Variation in screening ratio with wave-length in wire-netting cages.

increase of screening efficiency with decrease in wave-length, the variation being linear. This seems to show that a very simple law connects screening ratio and wave-length, at least over this particular range.

One-inch mesh cage.—The 2-inch mesh netting on the cage was now removed and a 1-inch mesh put in its place. It was found that it now possessed a screening ratio of 96 per cent for a wave-length of 4·5 km, instead of 89 per cent as in the former case.

As the balance positions in this experiment occurred very near to the minimum position of the coil B in the region where, as had been shown, instrumental errors were likely to occur, several check observations were made both with A and B interchanged and with coils of different size in place of the original ones. The agreement was, however, very good, variations being in all cases much less than 1 per cent of the value obtained for the screening ratio.

The variation in screening ratio with wave-length was of the same nature as that found for the 1-inch mesh netting, and this also is plotted in Fig. 9.

Use of Wire-netting Cage as Screen for Direction-finding Apparatus.

It was demonstrated by the preceding experiment that a wire-netting cage was capable of producing more than a 95 per cent reduction of field strength and was therefore thought efficient enough to be employed for the practical purpose of screening direction-finding apparatus from the source of error known as "direct pick-up." To effect this satisfactorily it is desirable that the operator also shall be in the screen. A wire-netting cage was therefore erected inside the Bellini-Tosi direction-finding hut at Slough, being fixed as a lining to its walls, floor and roof. All seams and joints made good electric contact, as in the case of the cage in the above experiment, special spring contacts being fixed to the door, which was also lined with netting. This screen proved very efficient, for after its installation it was found that the screened apparatus did not by itself pick up any detectable amount of energy, whereas before the erection of the cage it was possible, with the apparatus entirely disconnected from the aerial loops, to obtain signals of considerable strength from ship stations and other low-power stations over 100 miles away. This type of screen possesses the advantage of being cheap and easy to construct, besides being suitable for enclosing a hut or room without interfering with its ventilation or lighting. The screen itself did not affect the accuracy of the directional measurements, since it was placed nearly symmetrically with regard to the two aerial loops and since its dimensions were small compared with those of the loops.

A Method of Measuring the Effect of a Screen on the Electric Field of a Wave.

The experiment with the screen of straight wires (page 252) demonstrated the fact which it must be admitted had not been clearly recognized before, that the strength of the magnetic field within a screen gives no necessary indication of the strength of the electric field at the same point; for in these experiments it was shown that the magnetic field was unaltered by the screen, whereas it is obvious that the electric field must have been considerably modified.

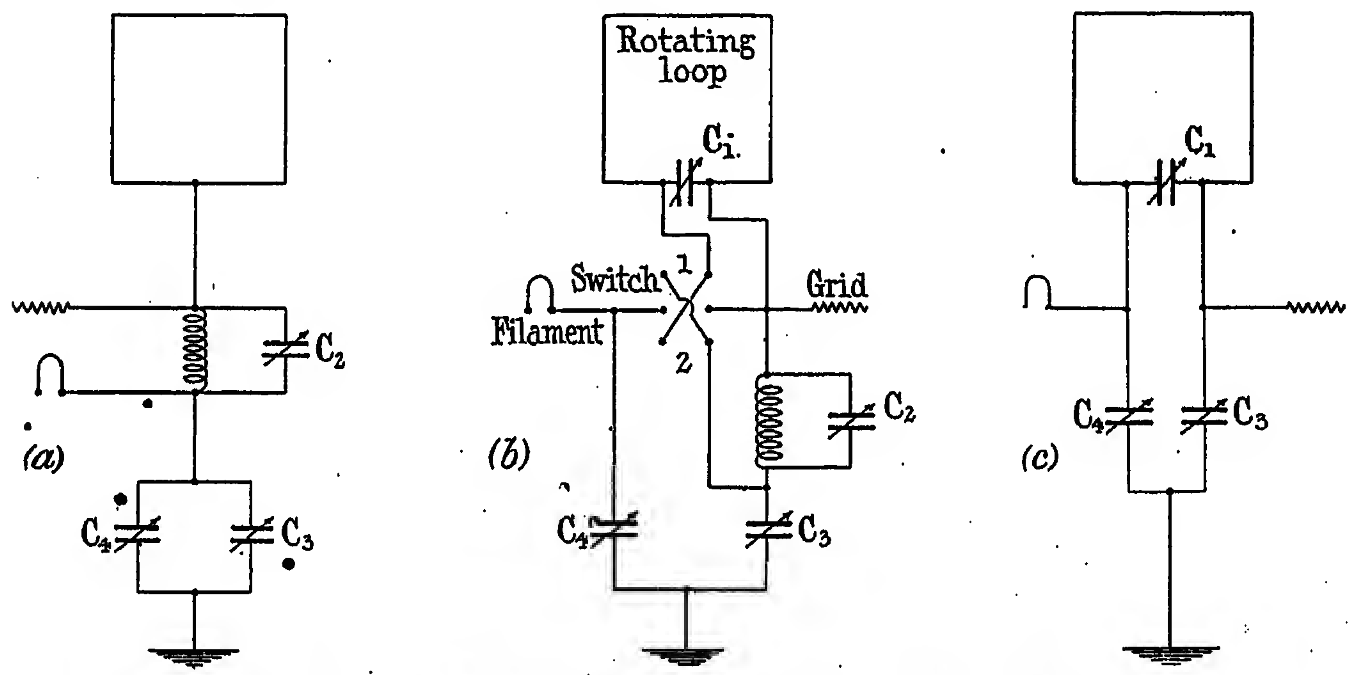

Fig. 10.—Measurement of effect of screen on electric field.

For this reason it became desirable to find a method of measuring the effect of a screen on the electric field of a wave as well as on the magnetic field. As a simple means of effecting this the circuit shown in Fig. 10 was set up. The complete circuit is shown by (*b*), while (*a*) and (*c*) show, in simplified form, the arrangements which come into operation in the alternate positions of the change-over switch.

With the switch in position (2) the apparatus is a simple single-coil direction-finder provided with compensating condensers (C_3, C_4) for the elimination of antenna effect [Fig. 10 (*c*)]. The signal strength will depend upon the P.D. (V_c) across the condenser C_1, which will be proportional to the circulating E.M.F. (E_c), for which we have

$$E_c = K_c H \cos a$$

where H is the resultant magnetic field, K_c a constant depending on the coil, and α the angle made by the coil with the direction of the wave. It is thus clear that V_c is proportional to $H \cos \alpha$.

With the switch in position (1) the apparatus is virtually an open antenna connected to earth through an auto-coupled, tuned, closed circuit and two condensers in

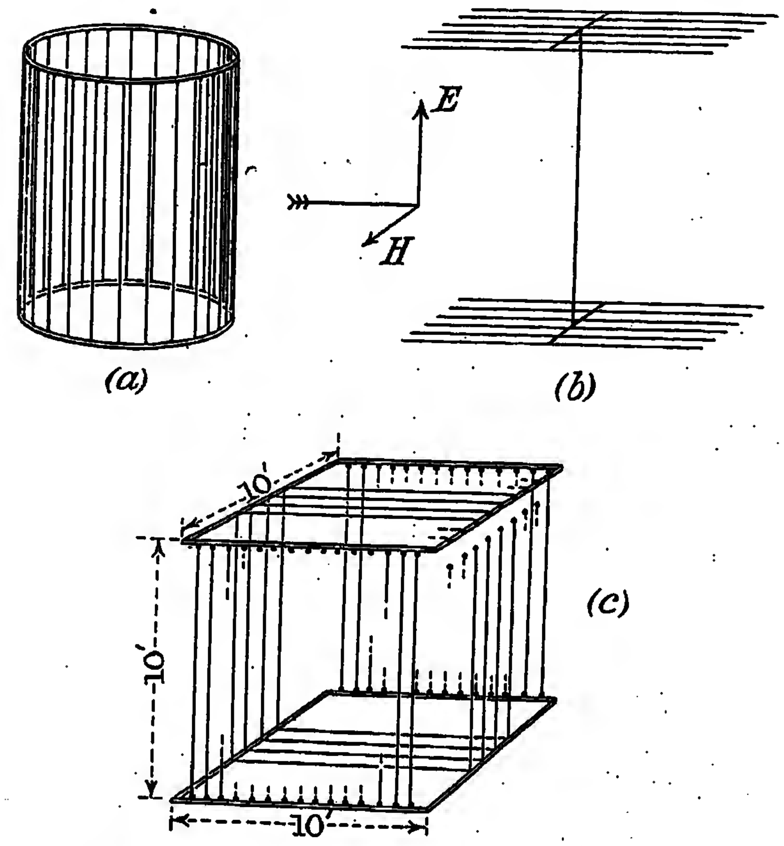

FIG. 11.—Screens which reduce electric field of waves without reducing magnetic field.

(a) Straight wire screen.
(b) "Condenser" screen.
(c) Combination of (a) and (b).

parallel [Fig. 10 (a)]. The signal strength will now depend on the P.D. (V_a) across the condenser C_2, which will be proportional to the antenna or vertical E.M.F. (E_a) induced in the system, which, in its turn, is proportional to the resultant electric field intensity E in the region in which the apparatus is situated.

To make the measurement, the procedure is first, with the apparatus unscreened, to adjust the compensating condensers with the switch in position (2) until the coil is free from antenna effect. The coil is then rotated until a position is found in which the signal strengths obtained on both sides of the switch are equal. The operation is then repeated with the apparatus in the screen under investigation. In order to obtain a fresh balance it will be necessary by rotation to reduce the E.M.F. induced in the coil in the same proportion as the antenna E.M.F. has been reduced by the screen. We shall then have:—

$$V_a = V_c$$

Thus, if E_1, E_2, and H_1, H_2 are the intensities of the electric and magnetic fields before and after screening, then

$$\frac{E_1}{E_2} = \frac{H_1 \cos \alpha_1}{H_2 \cos \alpha_2}$$

where α_1 and α_2 are the angles made by the coil with its maximum position in the two cases. The ratio H_1/H_2 can be determined by the method used in the preceding experiments, so that in this way it is possible to arrive at the effect of the screen on the electric field.

It is assumed that the intensity of the resultant electric field within the screen is substantially uniform throughout the region screened and that the screen does not affect the constants of the measuring apparatus.

FOURTH EXPERIMENT: EFFECT OF "CONDENSER" SCREEN ON ELECTRIC FIELD.

The method was then employed to investigate the properties of what may be called the "condenser" type of screen. This screen, which is of the type shown in Fig. 11, consisted of a number of wires 15 ft. long, spaced 6 in. apart and stretched horizontally about 1 ft. above the top of the coil. The set was placed under the centre of the screen and, near the centre point, all the wires were connected together by means of a single cross-wire, an extension of which formed the down-lead to the earth terminal of the apparatus. A switch was provided in the down-lead so that the screen could be earthed or isolated at will.

By means of this arrangement the general effect of the screen could be at once demonstrated, for on earthing

TABLE 6.

Screening Effect of "Condenser" Screen: $\lambda = 2\cdot 9$ km.

Arrangement		α_1	α_2	$E_2/E_1 \left(= \frac{\cos \alpha_2}{\cos \alpha_1}\right)$	Screening ratio	Remarks

7	6 in.	63·5	76·5	0·52	48	

the screen a large decrease in signal strength was observed if the apparatus was operating as an antenna [switch in position (1)], but there was no change at all if it was working as a coil receiver [switch in position (2)], thus showing that the electric field is screened while the magnetic field is not affected.

After investigating the effect of the complete screen, various alterations were made in it in order to get some comparative information as to the effect of different shapes and sizes of this type of screen. In all cases, since $H_2/H_1 = 1$, the relation $E_2/E_1 = (\cos \alpha_2)/(\cos \alpha_1)$ holds good. The results are summarized in Table 6. It will be seen that the greatest screening effect is obtained with the screen of largest dimensions, and closest spacing when the electric field is reduced to approximately 1/10th its normal value. On increasing the spacing, or decreasing the dimensions, the effect of the screen is distinctly less.

By making the spacing of the screen still less, and by increasing its dimensions, it is probable that any desired reduction of the electric field could be produced without appreciably affecting the magnetic field.

Effect of Vertical-wire Cage and Open-loop Cage.

A vertical-wire cage was now constructed similar in type to that already experimented with (see Fig. 5). It consisted of a 10-ft. cubic frame open at top and bottom and having vertical wires spaced 6 in. apart stretched over each of its sides. The wires were free at their top ends, but their lower ends were all connected together and to an earthed "mat" of wire netting forming the floor of the cage. The screen was found to have a screening ratio (electric field) of about 80 per cent, showing it to be slightly less efficient than the "condenser" type of screen previously experimented with.

A third type of screen consisting of a series of rectangular loops in parallel planes was now constructed on the same frame. This cage was made up of conductors of the type shown in Fig. 7 (*b*), i.e. the loops were not continuous but were interrupted by means of an insulator at one of their upper corners. This type of screen has already been shown to have no effect on the magnetic field of the waves, whereas for the electric field it was found to possess a screening ratio of well over 90 per cent. Thus this screen was the most efficient so far constructed. It also possesses the advantage over the condenser type, of occupying considerably less space. When a direction-finding coil was set up in this cage the minima were found to be extremely sharp, showing that, as was to be expected, "antenna" effect had been reduced to a negligible quantity.

These experiments clearly demonstrate that it is possible by the various arrangements described to screen a region from the electric field of an electromagnetic wave without reducing the magnetic field.

Use of Open-loop Cage as Anti-Antenna-effect Screen for Direction-finding Apparatus.

A cage of the type last described (open loop) has been set up at Slough as an anti-antenna-effect screen for a direction-finding set which is being employed to take accurate observations. In this case the screen has been constructed round the outside of the hut in which the set is working, this hut being raised several feet off the ground and resting on four large "shed" insulators. The framework on which the loops are mounted is a 12-ft. cube with the hut in the centre. There are two sets of 24 vertical loops spaced 6 in. apart, one set being at right angles to the other. A space of 6 in. is left between the horizontal wires of one set and those of the other. Each loop consists of a conductor bent into a square of 12-ft. side broken electrically at one corner by an insulator. Each successive loop is rotated through 90° in its own plane relative to the preceding loop, so that the gaps in the loops come at each of the four corners in turn. This rotation results in a greater symmetry of the whole structure.

This screen has now been in use for some considerable time and has proved very effective. The directional minima are very sharp, a swing of only 1° being necessary over the whole range of wave-length so far employed, viz. from 450 to 9 000 m. The presence of the cage has not reduced the signal strength or affected the accuracy of the bearings taken within it to any measurable extent.

Discussion of Experimental Results.

When a screen or any system of conductors is acted upon by electromagnetic waves, currents are set up in

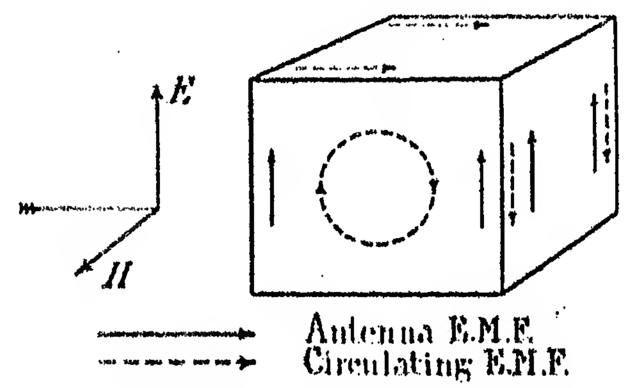

Fig. 12.—Conducting cube in path of long waves.

it which create secondary electric and magnetic induction fields in its neighbourhood and also re-radiate a certain amount of energy in the form of waves. Unless the screen is very close to the transmitter, or of dimensions comparable with that of the wave-length, this re-radiation can be entirely neglected. These last two conditions being ruled out as regards the experiments here described, it appears that in any screened region the actual field existing at any instant will be the resultant of two components: (*a*) the main field, as it would be in the absence of any screen, and (*b*), the secondary induction field due to the currents set up in the screen by the main field. Thus, a perfect screen would be one in which the secondary field was exactly equal but in the opposite direction to the main field at every point within it.

The particular phenomenon investigated by the experiments described is that of the screening of electromagnetic waves by a conductor of linear dimensions small compared with the length of the waves. Consider, therefore, a small block of copper placed in the path of long radio waves (see Fig. 12). Looking at the case

from the point of view of the electrical field of the waves, it is clear that, first, the block will behave as a short, squat, vertical antenna; that is to say, vertical oscillating currents will flow through or over its sides between its top and bottom faces; and secondly, owing to the phase difference of the part of the field arriving at the block and the part of the field leaving the block, circulating currents will be set up around the bounding surfaces of the block about an axis perpendicular to the direction of the waves and to that of the electric field. The first effect may be termed the "antenna" effect, the second the "closed loop" effect. Exactly the same result would, of course, be arrived at by considering the problem from the point of view of the magnetic field; in fact, it is perhaps rather simpler to consider the circulating currents in terms of the magnetic field, and the "antenna" currents in terms of the electric field.

On altering the shape of the conducting block, the relative importance of the two effects will be varied. If it be made very elongated, the "antenna" effect becomes of greater importance than the "circulating" effect, while the reverse holds if it be made short and broad. The consideration of two special cases actually dealt with in the experiments will, at this stage, most clearly illustrate the respective parts which these two effects may play in screening.

The case of straight wires.—The first case is that of a short and straight wire placed parallel to the electric force. Here the "antenna" effect is of sole importance, any circulating currents in the thickness of the wire being negligible. Under the conditions prevailing in the experiment, i.e. with the natural frequency of the wire large compared with that of the waves, the secondary electric field set up as a result of the "antenna" current will be 180° out of phase with the main field and, at points near the centre of the wire, in opposition to it. Such a wire will therefore reduce the electric field but not the magnetic field, since there are no circulating currents to produce a counter magnetic field, and any magnetic field resulting from the antenna currents will be 90° out of phase with the main magnetic field and of an entirely secondary order.

This argument may clearly be extended to the case of a number of parallel wires arranged as a screen or cage [see Fig. 11 (*a*)] and also to that of two horizontal plates connected by a wire [see Fig. 11 (*b*)] or to that of an earthed system of horizontal wires forming what may be termed a "condenser" screen, provided of course that the assumptions made above with regard to the natural frequency of the screen still hold good.

The experiments carried out with such screens are in complete agreement with these conclusions. The negative effect of a screen of straight wires on the magnetic field is demonstrated effectively on page 253, while the experiments on page 258 carried out as a result of this analysis illustrate the effect of this class of screen in reducing the electric field and show how it is possible to construct a cage which will reduce the electric force to a very small fraction of its normal value without appreciably altering the magnetic field. Again, it will be found that the above reasoning satisfactorily explains the experiment with the loop with screened sides (see page 250).

As further evidence supporting the conclusions, the experimental work of Blatterman * must be mentioned. In 1919 he succeeded in reducing "antenna" effect in a direction-finding set by means of a "grounded electrostatic shield" very similar to the type employed in the experiment described above. Blatterman, however, does not give the above explanation for the phenomenon, but ascribes it to the screen bringing about "a more symmetrical system electrically," from which it appears that he considers it to be acting in the manner of a compensating condenser. The fact that by regarding the phenomena as one of screening it has been possible greatly to improve the design of a shield as used for Blatterman's purpose, is, however, a strong argument in support of the correctness of this way of looking at it.

Case of closed loops.—The second case is that of one or more closed conducting loops. Let such a loop be placed with its plane parallel to the electric force and perpendicular to the magnetic force in the wave. It will be assumed that although the waves are long compared with the diameter of the loop, the frequency is still so high that its reactance is large compared with its resistance. It is then clear that the secondary magnetic field produced by the currents circulating in the loop will, at points inside the circumference, be almost exactly 180° out of phase with the main magnetic field, so that the resultant field will be less than the main field and the loop should screen its interior as regards the magnetic field of the waves.

Thus, if a be the radius of the loop, L its inductance, and if H_1, H_s and H_2 be the value of the main, secondary and resultant magnetic fields respectively, we have at the centre :—

$$H_s = \frac{2\pi I}{a}$$

where I is the circulating current.

Now $I = E/(\omega L)$ (neglecting R^2 in comparison with ω^2L^2) and $E = \pi a^2\omega H_1$, therefore

$$H_s = \frac{2\pi^2 a}{L} H_1$$

Now one of the single loops used in the final experiment is approximately equivalent to a ring of 1-metre radius, for which, by calculation, $L = 10^4$ cm (about). Hence, for this loop,

$$H_s = \frac{2\pi^2 10^2}{10^4} H_1$$
$$= 0 \cdot 2H_1$$

but $H_2 = H_1 - H_s$ (assuming H_s to be 180° out of phase with H_1) $= 0 \cdot 8H_1$.

The actual experimental result (page 254) was $H_2/H_1 = 81$ per cent, so that the agreement is good.

Extension to other cases.—If a number of parallel loops be placed parallel to and co-axially with the loop above considered, the screening effect at the centre of the

* A. S. Blatterman: *Journal of the Franklin Institute*, 1919, vol. 188, p. 338.

system will naturally become greater, as the experiment showed, since each loop will now contribute something to the total result.

If the loops are close together (though still isolated from each other) and sufficient in number to form a long cylinder, the secondary field at points not near the ends will be substantially uniform over the whole cross-section, and since the total secondary flux across such a section must be equal to the main flux (neglecting resistance) it follows that the screening ratio will be very nearly 100 per cent. The case of a solid cylinder has now been arrived at. It differs from the above, however, in one respect, for, whereas the series of loops will not screen at all if the magnetic field is perpendicular to their axis, a solid cylinder will screen even in this case, since paths for circulating currents exist in planes parallel to the axis.

All the above points relating to loops and cylinders were demonstrated by the various experiments already described.

The simplest method of making the screening independent of the direction of the magnetic field is to arrange three sets of loops in three planes mutually at right angles. If in such a screen as this the points of intersection of the wires of the loops are imagined to be electrically connected, the case of the wire-netting cage has been arrived at. Screening phenomena in wire-netting cages must therefore be of the same nature as those occurring with loops. A decrease in the size of the mesh is equivalent to an increase in the number of loops and should accordingly increase the screening effect, as demonstrated in the experiment, while at the same time making the resultant field more uniform throughout the region screened.

Finally, if the mesh is indefinitely reduced, the case of a completely closed box is arrived at. Since we know that in such a box the screening ratio may be made to approach as nearly as we like to 100 per cent, we may conclude that, as the theory would indicate, the secondary field within is perfectly uniformly distributed and exactly equal to the main field. If, however, the sides of the box were made very thin or of bad conductivity, the secondary field would be weaker than the main field and a considerable resultant field might exist within.

With regard to the effect of gaps or holes in screening boxes or cages, theory would appear to indicate that a long slit in a transverse direction to the circulating currents set up would cause a considerable reduction of its screening properties, but that if the slit lay along the path of the currents its effect would be negligible. The results of one observation confirmed this conclusion [see Table 5, line (10)].

The effect of wave-length variation on screening ratio disclosed in the case of wire-netting screens (see Fig. 9), which shows a slight increase of screening ratio with wave-length according apparently to a straight-line law, undoubtedly indicates that, as would be expected, the secondary field distribution varies with the frequency. This is no doubt brought about by the redistribution of current, which will tend to confine itself more and more to the outside surface of the cage at higher frequencies.

Antenna effect in loops.—So far, however, we have considered only the "circulating" effect in the loops and have as yet paid no attention to the "antenna" effect. The "circulating" currents, as we have seen, produce a magnetic field which opposes and therefore reduces the main magnetic field, but these currents cannot affect the main *electric* field of the wave, since any electric field associated with the circulating currents will be 90° out of phase with the main electric field, and of an entirely secondary order. It is here, however, that "antenna" currents are effective, producing under these particular conditions of dimensions and frequency a secondary electric field tending to oppose the main field within the loop. The extent to which the electric field is in this way reduced was not investigated by experiment in the case of closed loops, but this could be done if necessary by employing the method described on page 257.

Screening of magnetic field but not electric field.—Thus we see that a closed loop screens both the

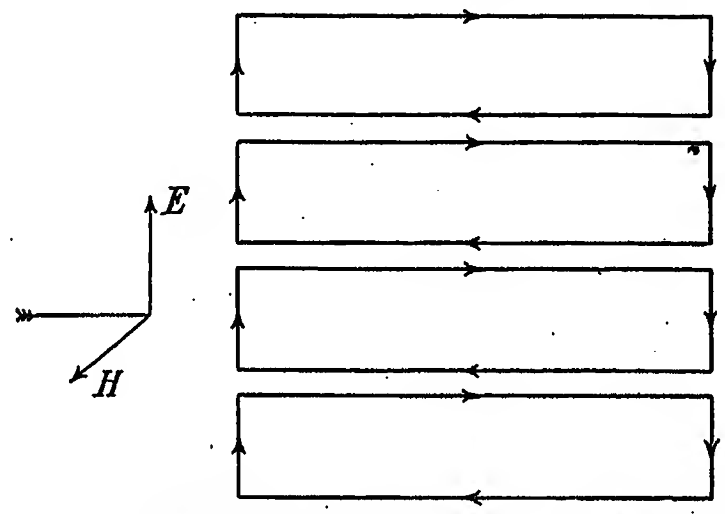

FIG. 13.—Arrangement for screening magnetic field without affecting electric field.

electric and magnetic field within it, whereas a straight wire or open loop screens the electric field only. It was suggested to the author by Professor Howe that the converse of this could be achieved by constructing a screen of loops arranged in the manner shown in Fig. 13, i.e. a series of elongated hoops of small height fixed in one plane and separated by small gaps. An examination of the direction of the arrows representing the current in the figure will show that the currents in any two adjacent horizontal members will have mutually opposing effects at points not close to them, thus leaving the current in the boundary conductors as the only effective ones. This arrangement should therefore act like a single-turn loop of area equal to that of the whole system as far as the secondary magnetic field is concerned, whereas it should produce little or no secondary electric field at such points since the path for antenna currents is broken. Such a system should therefore screen the magnetic field but not the electric field.

This arrangement was accordingly set up and tested. The overall area of the system was 10 ft. square and there were four loops, the size of each loop being 10 ft. long by 2 ft. high, with 6 in. between the loops. Its properties were found to be as predicted, for at a point 2 ft. from the centre of the screen the electric field

($\lambda = 3$ km) was not apparently affected, while the magnetic field was reduced by about the same amount as was obtained with the single loop in the first experiment. When, however, the loops were all connected together, the electric field was reduced considerably (by about 20 per cent).

A more efficient screen with this property could be made, if required, by constructing a series of screens of the above type in parallel planes.

General Conclusions.

The following conclusions may be drawn as a result of the experiments described in the paper.

(1) Since the problem of screening a given region from the magnetic field of a wave differs distinctly from that of screening the electric field, the design of a screen must differ according to whether it is desired to screen one kind of field only or both equally.

(2) The effect of a screen on the *magnetic* field of electromagnetic waves depends mainly on the existence of closed conducting paths surrounding the screened region. Any given path, however, screens only that component of the magnetic field which is perpendicular to its plane, so that it is possible to obtain a "directional" screen by an arrangement of single loops in parallel planes. The main point in designing an efficient screening box will therefore be to ensure that three such good conducting paths exist in three planes mutually at right angles. A metallic box with electrically good joints at all eight edges fulfils this condition very well. For such a box, a thickness of copper of less than 1 mm will reduce the field within to a fraction of 1 per cent of its normal value. If, however, the box is open at the top or at one side it will only screen efficiently magnetic fields perpendicular to the open face. A box with an ill-fitting lid will, of course, behave in the same manner however thick it may be. If there are a limited number of gaps or holes in the sides for control purposes, the parts of the interior at distances from such holes, large compared with their dimensions, will not be appreciably affected by the holes.

(3) A screening box or cage will be effective as regards the *electric* field of a wave, provided that each face is connected to its opposite face by a good conducting path.

(4) To protect a region from the electric field of a wave without affecting the magnetic field, the individual conductors in the screen must be "open" circuits, e.g. straight, insulated wires or open loops.

(5) To protect a region from the magnetic field of a wave without affecting the electric field, the screen must consist of a series of small loops arranged so that there is no electrical continuity in the direction of the electric field.

(6) It is extremely difficult to get a perfect screen. Even the smallest gaps allow a detectable amount of energy to enter, while joints or seams of low conductivity have the same effect. These facts were demonstrated by the experiments in the tank and with the loop with screened sides. On the other hand, even such coarse material as 1-inch or 2-inch mesh wire netting has a very considerable screening effect, namely, of the order of 95 per cent and 90 per cent. This value for such cages is practically constant over the greater portion of the range of commercial wave-lengths, decreasing slightly, however, with increase of wave-length according apparently to a straight-line law.

(7) A direction-finding coil enclosed in a screen of the type mentioned in (4) above (see Fig. 11) is rendered almost completely free from antenna effect, it being possible by suitably constructing the screen to ensure that such residual effect as may remain shall be quite inappreciable.

These investigations were carried out for the Radio Research Board under the direction of the Sub-Committee on Directional Wireless, the members of this Sub-Committee being as follows:—Mr. F. E. Smith, C.B.E., F.R.S. (*Chairman*); Mr. F. W. Davey; Mr. C. E. Horton, B.A.; Captain C. T. Hughes, M.C., R.E.; Dr. J. Robinson, M.B.E.; Dr. C. C. Simpson, F.R.S.; Dr. R. L. Smith-Rose; and Mr. O. F. Brown, M.A., B.Sc. (*Secretary*).

In conclusion, the author wishes gratefully to acknowledge the many valuable suggestions and general encouragement given to him by Dr. Smith-Rose throughout the work.

Discussion before the Wireless Section, 2 January, 1924.

Dr. R. L. Smith-Rose: The author and I were continually meeting this problem of screening in connection with our more general work on the propagation of waves, and, on reference to the literature on the subject, very contradictory ideas and statements were brought to light. One writer recommended a gauze screen to accomplish the same object which another writer insisted could only be obtained by using very thick iron and welded joints; in other cases screen boxes have been constructed of alternate sheets of copper and iron, with the idea of screening first the magnetic field and then the electric field. One of the causes that have given rise to this confused thought has been the misapplication of the term "Faraday cage." The original Faraday cage was, of course, only applicable to electrostatic conditions, and in such a case I think that the screening is practically perfect, even though the cage be constructed of wire mesh or gauze or perforated sheet. Immediately the electric field is alternating or varying, however, the electrostatic conditions have to be modified and the currents which flow in the screen itself have to be taken into account, in which case I think the term "Faraday cage" becomes a misnomer. The problem was first encountered in connection with the requirements of the extension of the direction-finding systems to continuous-wave working. It was required in that case to construct a local oscillator and so screen that oscillator that no stray field intersected the rotating loops used in the direction-finder. The stray fields were giving rise to false zeros,

and therefore wrong bearings. As a result of a great number of experiments carried out on the screening of such an oscillator, it was shown that solid iron sheet was considerably better than other metals, e.g. copper, and that the effect of large gaps and holes in the sheet, which are unavoidable if the oscillator is to be made of practical use, could be largely obviated by allowing a considerable overlap in the lid of the box and making tight contact all round the periphery of the box. The experiments described in the paper show that what is required to screen a space is to obtain a large ratio of reactance to resistance of the metal employed for the box, and copper would appear to be the best metal for that purpose. There appears, therefore, to be a slight contradiction in the results obtained in connection with the screening of a local oscillator and the screening of a space from an incoming wave. A little consideration of the details and conditions prevailing in the two cases shows, however, where the discrepancy arises. So long as the magnetic field has an air path inside the screening box, then the largest ratio of reactance to resistance is obtained by the use of copper; but if the path of the magnetic field lies for any appreciable length through metal, then iron has an advantage over copper, because advantage can be taken of the permeability of that metal. In the case of the screening of a space from a wave, the magnetic field is uniform over the whole portion of the screen, and thus, by arranging a number of conducting loops in planes at right angles to the direction of the magnetic field, one can obtain the necessary conditions. In the case of the screening of a source of oscillations, however, the direction and intensity of the magnetic field vary greatly from point to point over the surface which will be occupied by the screen; in fact, it is quite possible that inside the box the resulting primary field through the box may be zero. In this case the screening that is to be accomplished is rather in the form of local screening, which can be obtained by the eddy currents set up in the sheets of the metal. These eddy currents actually flow within the thickness of the metal, so that the path of the secondary magnetic field is a metal path. The penetration of the magnetic field in that case is given by the common skin-effect formula. Some of the author's work has a valuable application in sharpening up the minimum obtained on an ordinary rotating-frame coil, whether used for direction-finding or for the purpose of diminishing interference. The minimum obtainable on such a direction-finding set is not quite as sharp as that obtainable by the use of a compensating condenser, but it is possible that the zeros obtained by a compensating condenser are false balance positions. In any case the minimum has been reduced with this screen to as small a magnitude as is sufficient for practical purposes at present, and greater accuracy is not warranted because of other effects which occur in direction-finding.

Dr. J. Robinson: Most people who have made experiments with direction-finding have from time to time found the necessity for screening for various purposes. Some other aspects have not been definitely referred to in the paper, such as the elimination of magneto noise on aeroplanes and the elimination of noises produced by neighbouring electric motors. It will be interesting to know whether the author has found that his methods have any influence on the latter form of disturbance. The paper at first sight appears to give the impression that it is possible to eliminate the magnetic component of electromagnetic waves without touching the electric component, and vice versa. Such a statement would appear to be in direct contradiction to Maxwell's theory. Closer examination will, however, show that there is no intention to upset Maxwell's theory, for practice in direction-finding has led to the general impression that certain effects which one obtains with loops are the results of the magnetic fields, and other effects are the results of electric fields, whereas it is fundamental that any of the effects produced in a loop can be explained from either the magnetic or the electric standpoint.

Mr. L. Bainbridge-Bell: The company with which I am associated has for some time been fitting direction-finding sets in ships, and it may be of interest to give some particulars of the screens used for protecting the rotating coils from antenna effect. These screens are fixed to the inside of a watertight box, which protects the coils, and are very similar to that shown in Fig. 11 (*c*). The screen on each side of the box is formed by 20 vertical wires (20 S.W.G.) about 2 in. apart. The lower ends of these are connected to a horizontal wire running round the four sides of the box, but broken at one point to avoid a closed loop. A similar screen is placed inside the top of the box and connected to one of the vertical wires. The horizontal wire is earthed. In order to ensure symmetry in the down-leads from the coils, a transformer is placed between the coils and the first valve of the amplifier. It is of special construction, the primary being split and the tuning condenser being connected between the two halves. In reply to Dr. Robinson, who asks whether a screen is effective in cutting out disturbances from neighbouring electrical machinery, I should like to say that I have not found that it reduces these disturbances at all. This, I think, is only to be expected, as the electrical machinery appears to "shock-excite" the conductors near the direction-finding coils, which radiate waves that affect the coils somewhat as do those emanating from distant wireless stations.

Captain C. T. Hughes: I think that Dr. Smith-Rose, in drawing a comparison between the effectiveness of a screen such as that described by the author and that obtained with compensator methods, has overlooked the extreme convenience of using a compensator on small portable installations. I should like to ask the author whether it is really necessary to have an outside construction quite independent of the hut. Purely from the point of view of ease of erection, it would be a very much more convenient arrangement to rig up a screen on the walls inside the hut.

Admiral Sir H. B. Jackson: Has the author any idea how large or how small a screen will be efficient for the ordinary direction-finder 4 ft. square? In other words, would an 8-ft. cube be equally as efficient as a 20-ft. or a 50-ft. cube if the wires were spaced at the same angular distance from the centre?

Major A. G. Lee: The author's explanation of the

action of the screen, viz. that it produces a counter field 180° out of phase with the main field, and therefore cancels out the main field, appears to be very sound. Has he ever considered the effect of a screen in the case where a field arrives tilted, which sometimes happens? That is to say, does the screen work effectively in this case, or does it exhibit any tendency to exaggerate the errors due to the tilted wave-front?

Mr. R. H. Barfield (*in reply*): I agree with Dr. Smith-Rose that the problem of preventing a high-frequency electric field from entering a small enclosed space is quite different from that of preventing the energy of a local source contained in that space from escaping. As I have not investigated the latter problem, I am unable to give any information to Dr. Robinson on the screening of motors and magnetos.

I certainly believe that, as Dr. Robinson says, there is no action attributable to the magnetic field of the wave which cannot also be explained in terms of the electric field, but I think he will agree that certain phenomena are much more simply explained in terms of one kind of field than of the other. This, I think, applies in particular to the case of the loop with screened sides, and to the screening action of the straight-wire type of screen described in the paper.

It is interesting to learn from Mr. Bainbridge-Bell that the development of the Blatterman screen has been carried on by others than myself and to find that the form at which they have finally arrived is very similar to that which has been found most successful at Slough. I would, however, regard as an unnecessary precaution the provision of a "break" in the horizontal loop which Mr. Bainbridge-Bell describes, since such a loop, whether open or closed, can have no screening effect whatever on the coils of the direction-finding set to the planes of which it is perpendicular.

As Captain Hughes suggests, an anti-antenna-effect screen erected within the direction-finder hut should be quite as effective as one outside. The screen should, however, be large enough to contain the operator, and the spacing between the wires should be small compared with the distance of any part of the apparatus from the side of the cage.

In reply to Admiral Jackson, I should say that provided the above precautions are taken in its construction the effectiveness of a screen will be independent of its size.

In reply to Major Lee, the cage now in use at Slough which I have described in the paper is so constructed that its screening effect on the electric field is independent of the direction of that field in space, while, on the other hand, whatever the direction of the magnetic field it will remain unaffected by the screen.

DISCUSSION ON "LOUD-SPEAKERS FOR WIRELESS AND OTHER PURPOSES,"

WITH INTRODUCTORY PAPERS BY

(*Joint Meetings of* The Institution *and the* Physical Society of London, 29*th November*, 1923, *and* 14*th February*, 1924.)

GENERAL PRINCIPLES INVOLVED IN THE ACCURATE REPRODUCTION OF SOUND BY MEANS OF A LOUD-SPEAKER.

By Professor A. O. Rankine, D.Sc.

The task of opening this discussion is not an easy one. My difficulty arises, no doubt, largely from the mistake of supposing that a mere lively interest in the subject constitutes a sufficient qualification for making the introductory remarks. But I have also an uneasy feeling that there may be in relation to loud-speaking devices many important discoveries which continue to be withheld from public knowledge because of their commercial value. Consequently I may say things which might immediately be proved from practice to be wrong, if only everyone would reveal what he knows. The problem is, in fact, one in which practice has outstripped theory, as in the beginnings of aerial flight. A sudden great public demand has had to be met, and the problem has approached solution, so far as we know, by trial-and-error methods and without much appeal to the theorist. But few would deny that the products leave room for considerable improvement, except, perhaps, those responsible for advertisements (frequently to be seen) in which certain loud-speakers are described as "perfect in tone" and "absolutely faithful in reproduction." The real position seems to be that there is rather wide-spread discontent with the loud-speaking devices which are in use; and the purpose of this discussion is, I take it, to endeavour to identify the defects and suggest means for their elimination.

I think that the most useful thing I can do—in fact the only thing I am able to do—is to present certain considerations, mainly theoretical, which will be admitted to have an important bearing on the question before us. Some of them are rather obvious, and have probably already been taken into account by manufacturers. But few who have worked in acoustics have not, at some time or other, been faced with apparent contradictions between theory and practice; it is wise, therefore, sometimes to pause and reconsider what is fundamental and true. First of all, what is the practical problem? We wish to procure at one place the emission of sounds which are a sufficiently faithful copy of those originating at another place. It is not enough that the imitation should be agreeable; we do not want, to take an extreme example, a piccolo played very badly to reappear as a performance on a bassoon completely above reproach. Whatever the original sounds are, we want the reproduction to be like them. Besides this—and it is here that apparently the chief difficulty presents itself—we require that the reproduced sounds should be of considerable intensity. Although there is no need to specify this intensity precisely, we may, perhaps, for the purpose of argument, say that the sounds emerging from a loud-speaking device (if it is to deserve the name) should be at least as loud as those emitted by the original source. In other words, the ideal loud-speaker would be a secondary source in every acoustic respect equivalent to the primary source, whether speaker, singer or musical instrument. Put into the language of mechanics this means that the vibratory movements of the air at any specified distance from the loud-speaker should be identical with those which would occur if the original source were substituted for the loud-speaker. This statement of the case, it is true, leaves out of account the important question of the spacial distribution of a large sound source such as an orchestra. It is not easy to see how any practicable loud-speaking device could imitate this effect. But this aspect of the subject has been deliberately ruled out of the discussion by its limitation to the field of reproduction, and I shall not break the rules in this respect. Nor shall I enter into psychological considerations further than to remark that it is conceivable—perhaps probable—that perfect fidelity of sound reproduction alone may never lead to complete satisfaction by compensating for missing factors. It is at least arguable that visual conditions are not entirely unimportant; the sight of the lips or of the instrument manipulation may be needed to complete the effect.

The point at which our inquiry begins is, as I have already said, not earlier than the stage in which there

are at our disposal, in electrical transmission at any rate, certain electrical fluctuations corresponding to the original sounds. The question is how to manipulate these electrical vibrations so as to procure a satisfactory copy of them in aerial vibrations of large amplitude. For I think that for present purposes we may take it that already we have available sufficiently good reproduction if we are content with feeble intensity. There is, in my view, little cause for complaint in the behaviour of good-quality telephone receivers applied close to the ear and emitting sounds then just comfortably audible. Again, it will probably be generally admitted as true that the quality of the sounds given out even from a loud-speaker may be improved by reducing the output attempted. It is when large emission intensity is required that the distortion becomes too marked even for non-critical ears. I am no believer in the practical necessity of attaining the ideal case in which the aerial vibrations are copies, perfect in every detail of frequency, amplitude and phase, of those which gave rise to them. My own small experience has led me to the view that considerable latitude in this respect is permissible. On theoretical grounds, too, it would appear that to procure reproduction absolutely perfect in the physical sense, as distinct from the acoustic, is not possible, having regard to the variety of transformations which are in practice necessary. But there must be a limit for this physiological latitude, and there is evidently a danger, in seeking loudness, of departing too much from similarity. The various stages in the process each give rise to the possibility of distortion, and the effect is presumably cumulative; thus each stage requires careful consideration.

Broadly speaking, there are, from the point at which the field of discussion opens, three operations. There is first the amplification of the electrical fluctuations; in the second place there is the process whereby the current excites corresponding variations of air pressure; and thirdly, we have the treatment of the aerial vibrations after they have been created. With regard to the first I am not able to speak at any length; it is a question of using one fluctuating current to impress its own features on another of greater power, usually in several successive stages. Most of us who have occasion to use thermionic amplifiers are aware that the later stages become more and more difficult, and we are fortunate to have the prospect of hearing later from Professor Fortescue what ought to be done. Perhaps he will be able to tell us also what are the limits of this type of amplification from the point of view of the subject in hand.

Our second question—that of the transformation of a portion of the electrical energy into sound energy—is so broad that it is difficult to choose a point of departure. Each mode of transformation, according to whether it is by electromagnetic, electrostatic or thermal means—to mention only some of the better known—provides a different field for investigation; and it would be impossible for me in the time at my disposal, even if I had the knowledge, to deal with them. In all cases, however, it is a question of forced vibrations, and I propose to make some general remarks on this subject which inevitably have a bearing on the problems of transmitting as well as those of receiving. I cannot do better than take as a text two quotations from Lamb's "Dynamical Theory of Sound."

"The reason for the pre-eminent position which the simple harmonic type occupies in Mechanics is that it is the only type which retains its character absolutely unchanged whenever it is transmitted from one system to another,"

and later, in elaboration of this point, after determining the forced oscillation under the action of a force composite only in the sense that it requires more than one different simple harmonic term for its representation,

"This is an illustration of the remark made in par. 1 that the simple harmonic type is the only one which is unaltered in character when it is transmitted, the character of the *composite* vibration . . . being different from that of the generating force. In particular if one of the imposed speeds p_1, p_2 . . . be nearly coincident with the natural speed n, the corresponding element in the forced vibration may greatly predominate over the rest."

Thus we cannot reproduce sounds in general with complete precision; all we can do is to take steps to avoid too great changes of character in the often very complicated vibrations which we sometimes dissect for convenience into harmonic components. And the quotation just given directs attention to one of the chief dangers, namely, resonance. In aiming at loudness there is, no doubt, a temptation to resort to resonance as a means to that end. In the majority of telephone diaphragms, for example, there are natural frequencies where they ought not to be, i.e. within the range of frequencies of the sounds used, and the corresponding components of the sounds inevitably get preferential treatment. This, of course, can be rectified to some extent by damping the diaphragm, a process which diminishes the selectivity of the resonance by broadening the range of frequencies over which it occurs. But inevitably the general sensitivity is thereby reduced, and it seems to be at least worthy of greater consideration whether, especially in view of the fact that in operating loud-speakers it is usually possible to detect one or more diaphragm notes, advantages might not accrue from plans alternative to permitting resonance and only partially suppressing it.

There are two obvious ways of proceeding. One is to increase the natural frequencies of the mechanism to values above the upper limit of audibility, or at least as far in that direction as may be practicable. The other is to choose mechanisms of very low natural frequencies, so that none but the relatively high overtones—which are not very liable to be excited—reach the lower limit of audibility. On theoretical grounds the former method is to be preferred, since it would give displacement components more closely corresponding to the exciting force. Where loudness is not important this procedure has, I believe, proved very satisfactory; it remains to be seen whether the sensitivity necessary for loud-speakers is attainable under like conditions. Perhaps others with more knowledge of the mechanical

properties of, for example, a diaphragm, will be able to say what are the prospects in this direction.

The other alternative, that of using mechanisms of very low, i.e. nearly zero, natural frequencies, is also worthy of continued consideration as possessing, at any rate, advantages over more resonant arrangements. One device of this type is to be exhibited at this meeting, and there is another, of which I heard not long ago, which presents certain features novel enough to be worth mentioning. It is attributed to Siemens Halske, and is said to consist of a strip of thin metal foil suspended between the poles of an electro-magnet, as in the Einthoven galvanometer. The plane of the foil is parallel to the magnetic field, and the incoming telephonic current, doubtless properly transformed to suit the arrangement, flows through the foil. This responds by mechanical movements perpendicular to its plane, and is the equivalent of the ordinary telephone diaphragm. Its fundamental natural period is 2 seconds, or thereabouts, and it is reported to operate efficiently without a horn. I mention this instrument for the purpose also of directing attention to the fact that the diaphragm (i.e. the foil) suffers no transverse forces except those due to the telephonic currents. In this respect it differs rather fundamentally from the ordinary telephone receiver in which the diaphragm, or reed, is actuated by comparatively small increments and decrements of an attractive force of large magnitude, which is present in order that the sensitive part of the magnetization curve may be utilized. Under these conditions a really sensitive diaphragm, i.e. one which at its centre responds with large displacement to the operation of a small force, seems to be ruled out, for it would be pulled over permanently into contact with the magnet poles. The modification of the system so that the diaphragm experiences no average force, as, for example, in the gramophone diaphragm, might lead to valuable results.

It is difficult to choose points for consideration from the many that present themselves. I will content myself with mentioning one more in this part of the argument, namely, the question of exciting forced vibrations in the air by means of an intermediate mechanism, a diaphragm being typical. It is said that in ordinary telephony only a very small fraction of the electrical energy received is converted into sound energy. In the pursuit of intensity of reproduction there appear at first sight to be grounds for high expectations in this direction, if only we could increase largely that proportion. I venture to suggest that it may not be wise to follow this line too far, otherwise complications arising from reaction may appear. Our forced vibration should presumably not be sufficiently energetic to be capable of altering appreciably the character of the forcing vibration. This consideration applies both to the current-diaphragm system and to the diaphragm-air system, if we have so to subdivide the process. I have sometimes wondered whether, in this latter case, a departure from the above condition may be involved by using a horn in conjunction with a diaphragm. With a horn there is an undoubted considerable increase in sound output; it is not merely a re-distribution of the sound in a particular direction. Is it not possible that the horn increases too much the amount of energy transferred by the diaphragm to the air, and thereby, quite apart from the well-recognized horn resonance, brings about distortion ?

I have only a few remarks to make with regard to the third subdivision, that is, the treatment of the aerial vibrations after they have been developed. Of horns I will say no more than that they ought, if at all possible, to be dispensed with, possibly for the reason just mentioned, more certainly because of their resonant character. Of course, they may have their uses in this respect if, after all, we have to rely on resonance for intensity, and to adopt the plan of multiplying resonances so as to cover the range of frequencies used in transmission, thus making the best of a bad job. But the ideal sound radiator would be a spherical one which in some way could be excited by the electrical vibrations so as to impart to the neighbouring air symmetrical fluctuations of pressure of large enough amplitude. I am sorry to say that I have no practical suggestions to make on this basis.

A problem of importance is that of the conditions of listening to a loud-speaker, as, indeed, it is also in listening to a live speaker. It seems reasonable to suppose that in either case ideal listening would consist of hearing speech, at any rate, by the direct effect alone, without any reverberation or echo. For this we should have to damp out all room reflections both at the sending and the receiving stations. This is, in effect, frequently done in broadcasting, if we limit the case to that of listening on receivers applied close to the ear. But a considerable proportion of listeners appear to be asking for echo effects. Although I do not agree with them I can admit the argument, more particularly in relation to music as opposed to speech, that the custom of listening in a hall has led some to prefer the admixture of a certain amount of reverberation. No doubt Mr. Sutherland will deal with this and similar questions. All I would point out now is that in practical circumstances, if we admit the desirability of appropriate "room effect," as it is sometimes called, we must recognize that the problem is different according to the mode of listening, whether with head-receivers or with a loud-speaker. With the former the echo effect, if wanted, must be imparted at the transmitting station; with the latter it is liable to develop in the listening room also. Doubting as I do the value of even one system of echoes, I cannot be expected to tolerate two different ones superimposed, such as would arise, in the absence of suitable precautions, in a room or hall in which was operating a loud-speaker emitting sounds already bearing an echo impress. My submission is that for loud-speakers, as a general rule, echoes and reverberation should be eliminated at one end at least. For broadcast opera, for example, where transmission already unavoidably has the effect, the listening room should be draped much in the same way as transmitting rooms usually are.

I should like to say a few words in conclusion with regard to methods of testing results. Audition as a test of the degree of perfection of reproduction is liable to be a matter of opinion as between one person to another. From a scientific standpoint it would be

much better to adopt a plan of taking simultaneous records of a visible type both of the original sounds and their reproduced copies, and comparing them. Even if feasible, however, I am not convinced of the value of this method except as a matter of scientific interest. Unless we could attain the ideal of identical records, a degree of attainment probably quite unnecessary for present purposes, and, indeed, theoretically impossible, we could be sure of nothing. After all, the problem is to deceive our auditory mechanisms by offering imitations; a listening comparison therefore constitutes the most direct test. It ought, of course, to be as nearly as possible a direct comparison; the original and the reproduced sounds ought to be capable of being heard not, perhaps, simultaneously, but at least alternately at frequent intervals. Our problem will be solved when the inventor is able to deceive the most critical ear, so that its owner does not know whether he is listening to the original or to the copy. It remains to be settled who is the severest critic. Those of us who have heard his recent lectures, and know of his almost uncanny faculty of mentally performing Fourier analyses, would probably nominate Sir Richard Paget.

THEORY OF LOUD-SPEAKER DESIGN: SOME FACTORS AFFECTING FAITHFUL AND EFFICIENT REPRODUCTION.

By L. C. Pocock, B.Sc., Associate Member.

If it is assumed that properly amplified and undistorted speech voltage is available in the output circuit of a final amplifier, the problem is to procure the reproduction of speech efficiently and faithfully. The exact criteria for the reproduction of speech are better known than for music, but it is probably safe to say that a system capable of reproducing speech perfectly will give a highly satisfactory performance with music.

If V is an impressed voltage of any frequency or amplitude within the region to be amplified without distortion, and P the resulting alternating air pressure outside the system, the conditions are

$$P = AV$$

where A is an efficiency constant independent of the frequency and amplitude. It is also necessary that there shall be no asymmetric distortion, that is, any single frequency V must produce only the corresponding single frequency P. This condition is also expressed by the equation above.

Present-day electromagnetic loud-speakers are, without exception, a compromise between relatively good efficiency and good quality, such efficiency as can be secured being obtained only with the aid of mechanical resonance, which is contrary to the criterion for faithful reproduction given above. Further, although telephonic speech has generally been handled in the past as a steady-state problem, recent improvements in transmission have rendered the transient phenomena associated with consonant sounds and every change of amplitude of some importance. The reproduction of severe transients cannot be perfect in any resonant system or in any system containing mass and stiffness, even though the damping be such as to prevent any natural oscillation; the severity of transients actually encountered in speech is dependent on the damping of the vocal resonances, and information on this subject, together with like information on the auditory mechanism, might indicate the desirable degree of damping from the point of view of transient phenomena. It is clear that the use of resonance to increase the efficiency cannot be pushed too far.

Practical loud-speakers consist of a rather sharply resonant system working into an acoustic load, namely, a horn. It is not quite accurate to describe the horn as a load, because the useful work is the energy transmitted through the horn. The horn is operating in a capacity analogous both to an electrical transformer and to an electrical transmission line. The likeness to a transformer is seen in the passage of energy from the high mechanical impedance of the diaphragm to the low impedance of the open end through a coupling device, which reduces energy reflection to a minimum and aims at obtaining the greatest possible transfer of energy. The likeness to a transmission line lies in the propagation of waves across the non-uniform section of the horn; the analogy is to a non-dissipative line containing distributed inductance and capacitance, the line constants changing steadily from end to end of the line in such a way that the impedance measured at one end of the line is high, and that measured at the other end is low. Such a system would form a maximum energy coupling between two different electrical impedances.

The acoustic impedance of a horn at its small end depends a good deal on the cross-section and also varies with the solid angle and the form of the horn, but, as in the electrical analogies, the impedance is also a function of the impedance into which energy is delivered, i.e. at the open end. Another view of the acoustic impedance at the small end is to regard it as the impedance of the large end modified by the

horn through which it is measured. In general, the horn impedance also varies with frequency, and, though horns of approximately uniform impedance can be made, it is clear, from a consideration of the varying mechanical impedance of the diaphragm, that such a horn is not necessarily the best.

These are some of the factors which enter into the performance of a horn. The practical considerations are usually those of size; for indoor use the horn must not be too long, so that the problem is equivalent to attempting to obtain an electrical line of length equal to a wave-length or less and having a very much higher line impedance measured from one end than when measured from the other end. The acoustic impedance is virtually coupled to the diaphragm, so that some idea of its variations with frequency can be obtained by observing the motional impedance of the receiver. A

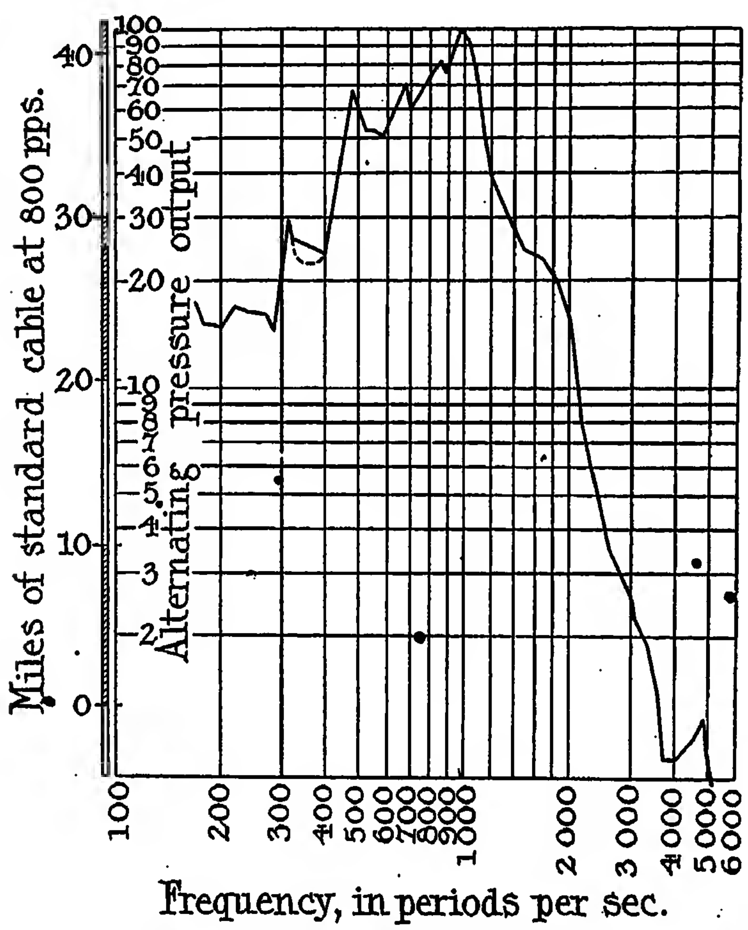

Fig. 1.—Alternating pressure output of loud-speaking receiver corrected for impedance of circuit and receiver. (Average of 5 receivers.)

large number of horns, of a size suitable for use in private houses, have been examined in this way, and resonances of varying degree have been found in all; larger horns might, however, be expected to show lesser effects.

The resonance of a receiver without horn may be such that the diaphragm vibrates with more than 50 per cent of the amplitude at resonance over a frequency region about 100 periods wide. When the horn is put in place, the diaphragm is made to do more work and the resonance is made much less sharp. The new damping coefficient cannot be simply expressed, because the resonance is no longer simple but is complicated by the coupled horn resonances.

The actual pressure variation in the air when the receiver is excited at different frequencies can be measured. Figs. 1 and 2 show the characteristics of two types of receiver. Fig. 1 is for a receiver having a flexible diaphragm driven by a small armature supported on a spring. The effective moving mass is not appreciably greater than that of the ordinary telephone receiver. The curve is an average of the results of five receivers and shows definite peaks in the lower frequency region, due to the horn. It is seen that the distortion due to these resonances is small compared with the general effect, due to the mechanical resonance of the system. This is an important point: horn distortion can be brought within reasonable limits; the receiver mechanism is often responsible for defects of tone for which the horn is blamed.

In connection with Fig. 1 it may also be stated that the perfection of reproduction is a great deal

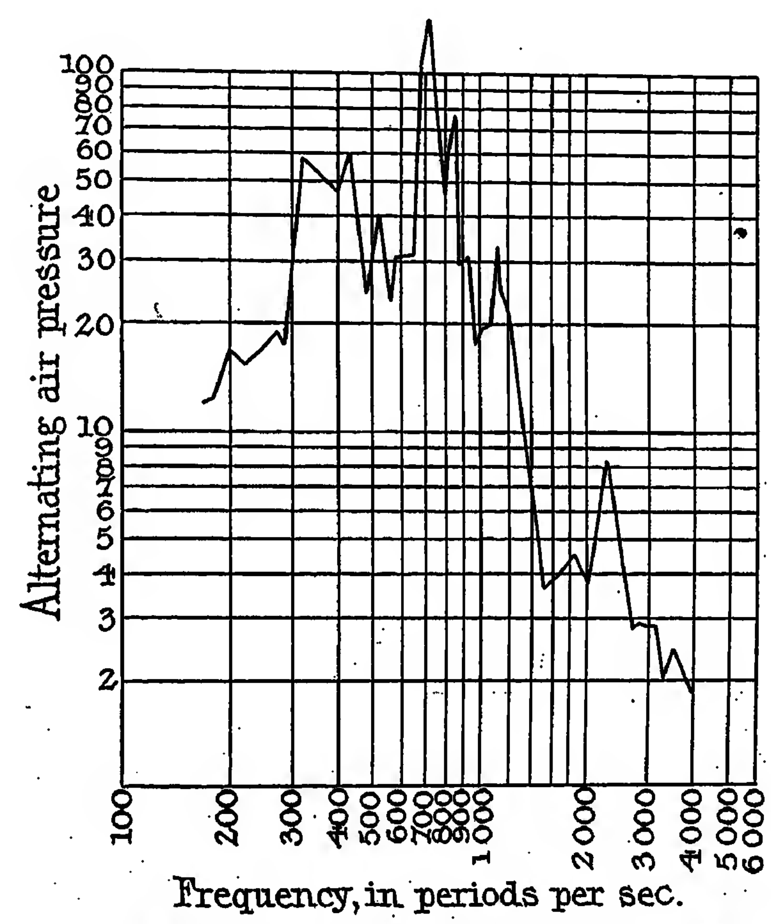

Fig. 2.—Alternating air-pressure variation with frequency for an iron-diaphragm receiver, corrected for impedance of circuit and receiver.

better than the appearance of the characteristic would suggest; the contracted logarithmic scale disguises the really rather gradual fall of the curve at the higher frequencies; even at the extreme end of the curve the highest frequency shown is reproduced with sufficient intensity to add greatly to the quality of reproduction.

Fig. 2 is the characteristic of a loud-speaker of the iron-diaphragm kind, similar in principle to the ordinary telephone receiver; in this case the curve is an average of several tests taken on the same receiver. The frequency of maximum response is seen to be a little lower than in Fig. 1, and the curve drops somewhat steeply between 1 000 and 2 000 periods per sec. (p.p.s.).

In both the above cases the receiver output is corrected for the impedance of the associated amplifier, that is, a fixed voltage is operating on the loud-speaker through a fixed resistance representative of the amplifier output impedance that would be suitable for use with the receiver considered. Since the impedance of most receivers at about 4 000 p.p.s. is two, three or more times as great as the impedance at 1 000 p.p.s., the reproduction of the higher frequencies is somewhat impaired due to this cause.

It must be recorded that Figs. 1 and 2 are relative in value, rather than absolute; in particular no correction has been applied for the variation with frequency of the absorbing power of the material used in the highly-damped chamber in which the measurements were made.

Receivers have been constructed in which large vibrating surfaces are used without a horn. It appears that the vibrating surface must be of such dimensions that there is difficulty in securing the necessary lightness of the moving parts, especially when the added mass, due to the reaction of the air, is taken into consideration. In any case, the very important distortion due to the use of mechanical resonance to obtain good efficiency remains in evidence.

With regard to the mechanical construction of an electromagnetic receiver, the ordinary construction of a telephone receiver requires considerable modification if it is to handle more than a very small amount of power and, even when so modified, there is danger of distortion due to the asymmetrical forces called into play by the passage of symmetrical currents. A receiver of the type giving the characteristic shown in Fig. 1 is capable of handling about 10 watts without asymmetrical distortion, because the armature is driven by symmetrical forces. The amplitude of vibration may be of the order of 0·01 inch.

To sum up, with present-day constructions of receivers, faithfulness in reproduction cannot be obtained beyond a certain degree without making receivers very inefficient. Reproduction can, by careful design, be made very satisfactory, but to obtain the very last degrees of perfection, e.g. by filters, enormous increases in the power amplification would be necessary to operate the receiver, in fact, valves of far higher power capacity than are used in any radio receiving sets. As it is an easy matter to obtain the present amount of amplification, it is seen that the chief interest in raising the efficiency of loud-speakers is to permit the application of quality-correcting devices, provided of course that increased efficiency is obtained without sacrifice of quality.

With regard to the overall efficiency obtained in loud-speaking receivers, it is probable that 1 per cent is a high estimate and that a few tenths of 1 per cent would generally be nearer the mark. The principal loss is iron loss, and, though eddy currents may be reduced by lamination, hysteresis still accounts for a very considerable loss on account of the high frequencies concerned. It does not seem likely that any great improvement in real efficiency can be obtained unless a magnetic material with exceptionally low hysteresis loss and good permeability is discovered. Small improvements are possible by building receivers on a larger scale and using more powerful magnets, but the necessity of making some part of the moving system of iron and of low mass makes the employment of high alternating flux density in this vital part unavoidable.

THE SOURCES OF DISTORTION IN THE AMPLIFIER.

By Professor C. L. Fortescue, M.A., Member.

(1) Scope.

In this note the output P.D. from the rectifying valve or crystal is taken as the starting-point. With an ideal amplifier this P.D. is magnified and a current of precisely the same wave-form is supplied to the loud-speaker. In many actual amplifiers, however, the wave-form is not faithfully reproduced and distortion is introduced.

(2) The Causes of Inaccurate Reproduction.

These may be put under the following headings:—

(a) Curvature of the valve characteristics.
(b) The use of intermediate circuits having more or less clearly defined natural frequencies.
(c) The unavoidable reaction effects present in most designs of note magnifiers.
(d) Unsatisfactory reproduction in the last (or output) transformer.

(3) The Effects of Curvature of the Anode Current Characteristics.

(a) *Resistance amplifier.*—The ideal resistance amplifier is as shown in Fig. 1, and consists of a valve with a non-inductive and capacityless resistance, R_a, in series with the anode and a condenser of very large capacity across the battery terminals. The valve characteristics may be conveniently plotted as a characteristic surface in terms of V_b and V_g, allowance being made for the resistance R_a.

The surface shown in Fig. 3 is the ordinary charac-

teristic surface, the lines corresponding to constant anode current, but allowance is made for a series resistance of 10 000 ohms. The fluctuations of the grid P.D. above and below the mean value may be plotted below the diagram of Fig. 3 as at G. Then, by projecting up to the line PQ, corresponding to the given value of the battery voltage, the values of the anode current can be plotted above and below the mean value at C. A reference to Fig. 3 shows that the anode current wave-form can only be an exact replica of that of the grid P.D. when the constant-current lines are equally spaced along the line PQ. Thus, if the surfaces are (which are the ones under consideration) is, however, very much greater than the resistance of the anode winding as measured by direct current. The resistance must be ascertained by a.c. bridge methods at the resonant frequency. Some transformers having a direct-current resistance of the order of 2 000 ohms are found at the resonance point to have effective resistances of 200 000 to 300 000 ohms when loaded on the secondary side with resistances corresponding to the grid resistance of the next valve. The representative characteristic surfaces must therefore be plotted for this high value of R_a and not for the d.c. resistance;

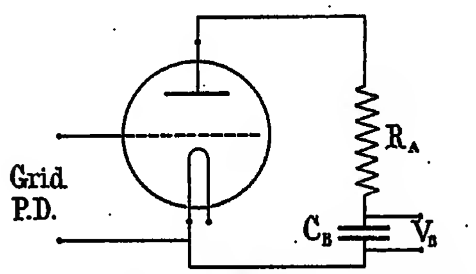

FIG. 1.—Resistance amplifier.

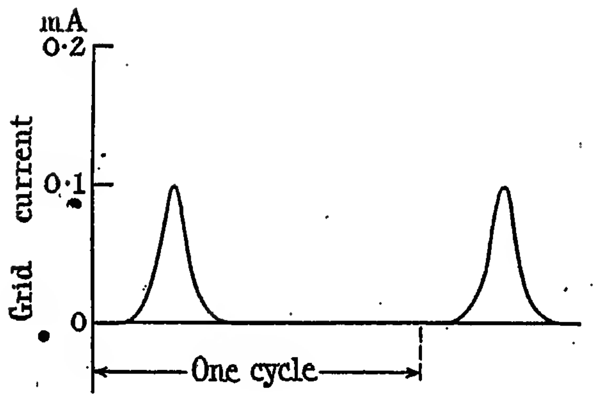

FIG. 2.—Wave-form of grid current with conditions of Fig. 3.

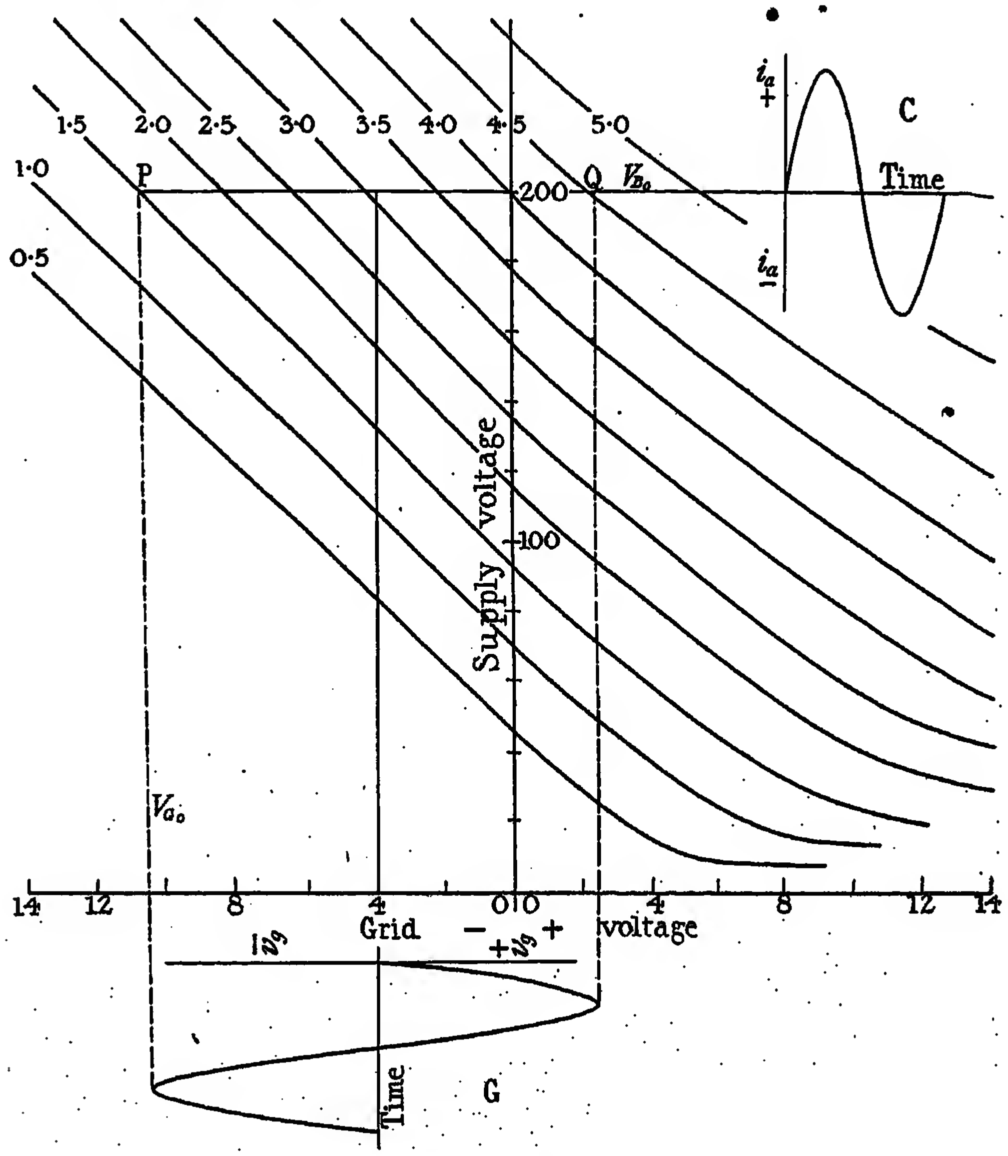

FIG. 3.

plotted out for any given valve, the possible range of anode current and grid voltage over which faithful reproduction can be obtained will be easily seen and the appropriate values of V_{g_0} and V_b can be chosen. The values taken in plotting Fig. 3 are $V_b = 200$, $V_{g_0} = -4$. The amplitude of the fluctuations of V_g is 3·5 volts and of i_a, 1·75 mA.

(*b*) *Transformer amplifier.*—Except in the last stage, a transformer in the anode circuit should closely approximate to a resistance. When very heavily damped, due to its own losses and the load of the valve, and when near the resonant point, this is actually the case. The effective resistance to the alternating P.D.'s the latter is only used to obtain the effective starting-point for any actual battery voltage.

For frequencies other than the resonant frequency of the transformer the conditions are more complicated, and merely plotting the characteristic surface with a correction for a series resistance is insufficient. The surface must be plotted without correction and both the grid and anode fluctuations must be allowed for. The line PQ of Fig. 3 becomes a curve—an ellipse in the case of two pure sine waves—and so long as this curve remains within the zone where the constant-current contours are equally spaced the reproduction will be satisfactory.

(4) Effect of Curvature of the Grid Characteristics.

If the grid voltage fluctuations have any considerable positive values the grid currents will be quite appreciable, and the wave-form of the grid current will differ very widely from that of the grid P.D. Fig. 2 shows approximately the curve of grid current corresponding to the conditions assumed for Fig. 3. The grid currents will generally react on the source of P.D. and lead to heavy distortion. With many amplifiers the peak of the positive half cycle of the grid-filament voltage wave is practically cut off at $V_g = 0$.

The only way of avoiding this difficulty is to render the effect of the grid current negligible. Valves have not yet been produced in which the grid current is negligible when the grid is positive and the anode voltage low, and consequently positive values of the grid voltage must be avoided. This gives another limitation to the range of the anode current characteristic curves that can be used, and indicates that the anode battery voltages should be high, and that the mean grid voltages should be considerably negative.

(5) Effect of the Natural Period of the Intermediate Circuits.

This trouble arises in the case of a transformer amplifier. In the first place any marked resonance means that the effective impedance in the anode circuit is dependent upon the frequency. The impedance—and therefore the amplification—will be greatest at the resonant frequency. Thus any sustained harmonic having this frequency will be unduly pronounced and the speech will appear "tinny" or "drummy," depending upon the pitch of the accentuated harmonic. The larger the number of stages of amplification that are used, the more marked is the effect. In the case of those high-frequency components which are not sustained, the effects are less pronounced. This effect is thus most noticeable with musical sounds and with the vowel sounds.

Secondly, for frequencies other than the resonant frequency, the transformer is no longer equivalent to a resistance, and complications arise from the relative phase of the grid and anode potential fluctuations on account of which it becomes very difficult to determine the wave-form of the anode current when the amplitudes are fairly large.

(6) Reaction Effects.

It is well known that reaction plays an important part in all amplifiers. In the note magnifier the effect is to accentuate the resonance effects mentioned in the previous paragraph.

(7) Distortion in the Last Stage.

The last stage is not unfrequently a source of serious trouble for two reasons :—

(i) The amplitudes are large.
(ii) The "load" on the output transformer—viz. the winding of the loud-speaker—is inductive and this inductance is not constant.

With regard to (i), the output required for a sustained musical note is of the order of 10 mA (R.M.S.) at 5 volts (R.M.S.). To give an equivalent volume of sound with

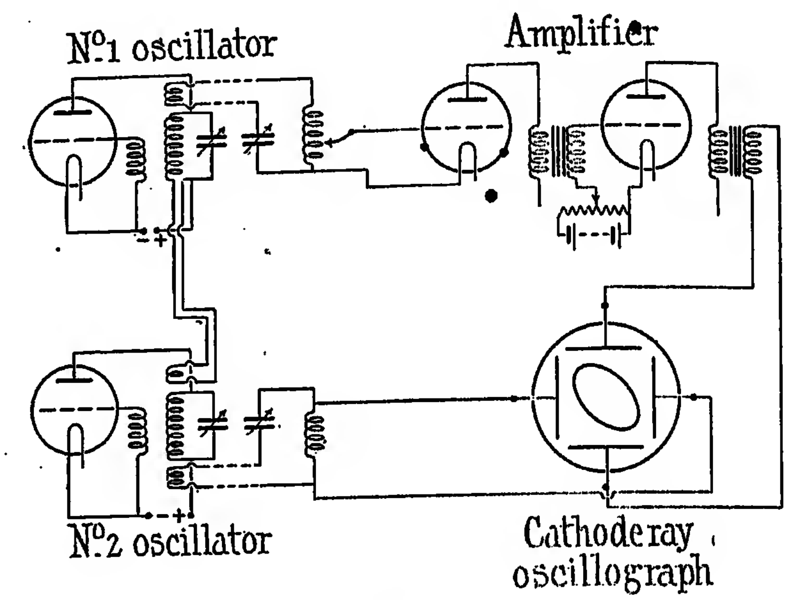

Fig. 4.

ordinary speech a peak value of perhaps double these figures will be necessary, and after allowing for the losses in the transformer it seems that the output from

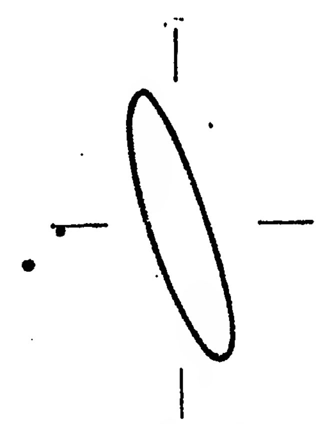

Fig. 5.

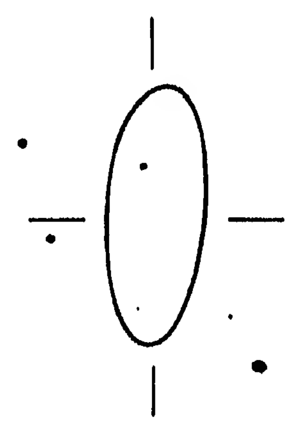

Fig. 6.

the anode circuit of the last valve will be equivalent to an alternating current of peak value 30 mA at an alternating P.D. of peak value 15 volts. A transformer

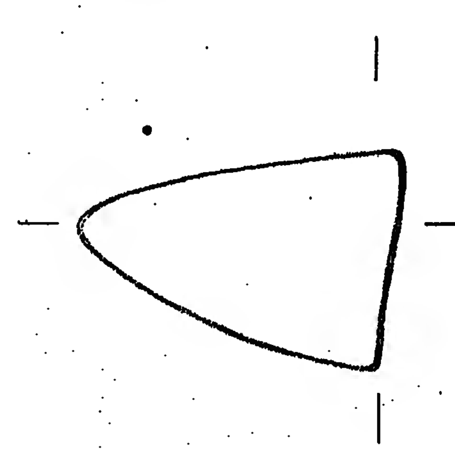

Fig. 7.

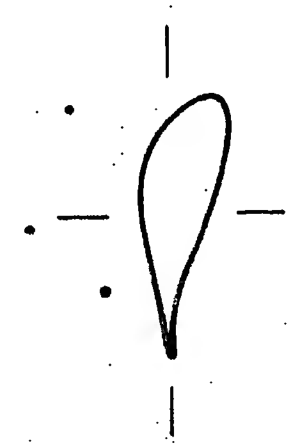

Fig. 8.

is almost invariably used and the actual values would more probably be 10 mA at 45 volts. This involves a valve giving an emission current of perhaps 50 mA

with a fluctuation of anode current over the range 15 to 35 mA; and a voltage at the anode of perhaps 120, fluctuating between the limits of 75 and 165. General numerical considerations such as these show the necessity for valves of considerable output in the last stage.

High battery voltages are also necessary—in the above case the steady fall of P.D. in the anode circuit would be of the order of 50 to 100 volts, and a battery giving something in the neighbourhood of 200 volts would be unavoidable.

With regard to (ii), owing to the inductive nature of the load the last stage cannot be regarded as being even approximately a resistance, and the same effects are noticed as with a transformer operating out of resonance.

(8) Conclusion.

With properly designed valves and circuits it does not appear that any serious distortion can be charged against the amplifier. Valves giving considerable power output must, however, be used in the last stage.

This conclusion has been verified by an oscillographic investigation of a two-stage transformer amplifier. A cathode-ray oscillograph was used, the circuits being given in Fig. 4. In the first instance the output voltages from the oscillators were applied to the deflecting plates of the oscillograph and gave a good ellipse on the screen, thus showing that both were good sine waves. This ellipse is shown in Fig. 5. The amplifier was then brought into use and the output wave when properly adjusted again gave an ellipse as shown in Fig. 6, proving that the sine wave-form was preserved. Unsuitable adjustments or excessive amplitudes showed very marked departures. In Fig. 7 the amplitude was too large and the sharp cut-off in one direction is due to the grid current effectually preventing the grid from becoming appreciably positive. Fig. 8 shows the ellipse closed in at one end owing to bad adjustment giving a mean position near the bottom of the curves of anode current.

THE ACOUSTIC PROBLEMS OF THE GRAMOPHONE.

By H. L. Porter, B.Sc.

In this brief paper it is proposed to give an outline of the work done on gramophone reproduction by P. Rothwell and myself, whilst in the service of the Gramophone Company, Hayes, Middlesex. It is hoped that in this way the problems and difficulties of the subject will be made clear. I am limited by certain restrictions, in that the details of particular methods used cannot be published, neither can the lantern slides exhibited be reproduced. The general method and results which can be given may, however, prove useful in the consideration of the analogous problem of the loud-speaker. The gramophone problem is acoustical and mechanical in nature; in the latter respect it differs from that of the loud-speaker. For the purposes of this discussion I will confine myself almost entirely to the acoustical problem.

The simplest form of commercial recording apparatus consists essentially of a single conical horn in conjunction with a diaphragm. If such an apparatus be set up and its response to a series of simple tones emitted by organ pipes be measured by a suitably mounted mirror attached to the centre of the diaphragm, the characteristic curve shown in Fig. 1 * is obtained, the amplitude of vibration being plotted against frequency of pipe. Preliminary work had been done on the simplification of room acoustics and maintenance of uniformity and purity in the tones. Curve 1 may therefore be accepted as a typical curve under these conditions. The response is very irregular, and it is clear that such an apparatus as we have used would give a very imperfect record. In commercial practice the matter is much worse, for the following reasons:—

(1) The acoustics of the recording room is an unknown and complicated factor.
(2) Many tones are recorded simultaneously.
(3) The tones are complex and are very rarely uniform in intensity.
(4) The characteristic curve is further modified by recording on wax.
(5) In reproduction no needle could possibly pass along the large-amplitude waves in the high peaks, so that further modifications have to be made with further loss.
(6) The reproducing apparatus has its own characteristic response.

The final curve of reproduction from a commercial record must therefore be much worse than shown in curve 1, and in view of this it is surprising that gramophone reproduction is as good as it is. Doubtless the ear is very generous in its behaviour in this respect.

From a study of this curve and many similar ones we decided that the gramophone problem was not, as it had been in the past, a question of improving the "sound box" (as the diaphragm and its housing is termed) independently of the recording horns, or of improving the recording horns independently of the

* The figures referred to in this paper were shown as lantern slides.

sound box, or of both independently of the room conditions. The combination—and here the room must be included—had to be considered as one acoustic system and treated as such. We therefore took a system in its simplest form and sought to arrange its response so that it should be uniform in terms of sound energy over the great range for which the gramophone must cater. This meant approaching the problem in three stages: First, to find to what each large response or peak was due; secondly, to ascertain whether we could control these responses, and, if so, to arrange them to give as much uniformity of response as possible; and thirdly, to reduce the peaks to a suitable value and, if possible, raise the response in the troughs and so smooth out the curve.

Considering these in turn, the "placing" of the peaks led us to an examination of the influence of the diaphragm, its housing, the needle system, the connecting tubes, the recording horn and the room. Each played its part. It was not an entirely easy matter, for the slightest modification in the system often brought about big local changes due to the acoustic proximity of some other factor. However, each peak was successfully "placed," and we found we had gained during the course of the work a good deal of control over the whole system. Next we tried to arrange these peaks in some sort of order, and Fig. 2 shows the result we obtained.

There is a very important point to bear in mind here. If any system is set up in a haphazard manner, i.e. without any acoustical knowledge of the system whatever, one is more likely than not to get two peaks (due, of course, to different factors) falling together or near each other. When this happens a curious placing of peaks occurs and a tremendous massing of response, out of all proportion to the rest of the response, takes place over quite a number of neighbouring tones. In addition it often results in a large reduction of response in regions near at hand. This is shown clearly in Fig. 3.

It was also found that the recording apparatus would react upon the source of sound itself and modify its pitch. Again, it was found difficult to keep the recording apparatus constant in its response for some of our work. The deviations were not such as to affect the general form of the curve, but for later work any changes at all were very serious. Thus temperature had its influence, and many idiosyncrasies of the apparatus had to be investigated before we were satisfied that readings could be repeated from day to day.

Finally we had to eliminate the peaks in the general response curve obtained so far. Mr. Rothwell evolved a very useful plan to reduce these peaks and fortunately, in so doing, found that by the same method he could raise the response in some of the troughs. The final curve for the simple tones is shown in Fig. 4.

The readings from which this curve was drawn are, as in all the curves, amplitudes as ordinates against frequencies as abscissæ. The amplitudes are read on the scale from the deflection of the mirror. Much work was, however, done in tracing out the amplitudes on the waxes, matrices and final records. After certain minor corrections were applied to the system, Fig. 4 can be taken to represent the actual amplitudes obtained on the record. So far, then, we felt satisfied that our corrected system gave us a very good approximation to uniform response over a large range of frequencies. We were not sure, however, whether the balance of response given by Fig. 4 was true for normal hearing; that is to say, we may have allowed for too much in the lower frequencies and too little in the higher, or vice versa. Only a practical trial would settle that. We therefore proceeded to record. We chose the pianoforte as it presented many elements of difficulty and had a great range of frequency, and, moreover, we had made an attachment so that the instrument could be struck one note after another with an even, definite, blow which could be repeated. Here we were confronted with two serious difficulties, one of which we had not anticipated. We expected, of course, that the presence of such a large obstacle as a pianoforte in front of our recording apparatus would make a great difference and we found this to be so. We were troubled, however, to find that the impulsive nature of the pianoforte note was so different in its action from the steady uniform note of the organ pipes, since it made the elimination of the response peaks much more difficult. At last we made a record of the whole series of pianoforte notes where the amplitudes on the records were theoretically of uniform intensity; only a few notes at the top were missing. When we played this record on a gramophone we were confronted with the other half of the problem. We found that the gramophone itself had its own peculiar response, which greatly disturbed the carefully graduated tones on the record. The loud responses and the general distortion depended upon the reproducing instrument used, some instruments being much worse than others.

THE RELATIVE IMPORTANCE OF EACH FREQUENCY REGION IN THE AUDIBLE SPECTRUM—MEASUREMENTS ON LOUD-SPEAKERS

By E. K. SANDEMAN, B.Sc.

THE RELATIVE IMPORTANCE OF EACH FREQUENCY REGION IN THE AUDIBLE SPECTRUM.

The system of ideas bearing on the question of the criteria involved in sound reproduction, which is outlined below, is by no means to be regarded as absolute but is merely an attempt to classify the types of sound characteristic to be preserved and the relative importance of the corresponding physical properties of sound.

The relative importance of each frequency in the audible spectrum depends on what function of hearing is to be served.

There are three essential characteristics of reproduction which naturally occur to anyone considering the matter:

(1) The first is probably intelligibility of speech; it must be possible to exchange ideas with reasonable facility.

(2) The second is naturalness of reproduction of music (and also of speech), which, as we shall see, is a more searching requirement.

(3) The third is the reproduction of speech at correct volume, which is bound up with the first two requirements and involves consideration of the energy of speech.

It is perhaps a surprising result in the case of speech that the importance of a frequency region, from the

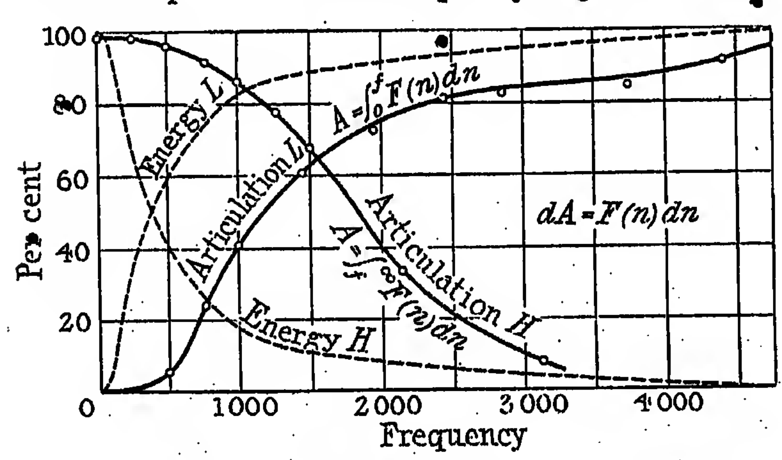

FIG. 1.—Effect upon the syllable articulation and the energy of speech of eliminating certain frequency regions.

point of view of intelligibility, is by no means proportional to its relative importance from energy considerations.

The first requirement of intelligibility is that each isolated syllable shall be correctly interpreted. Syllable articulation may be defined as the percentage of such syllables correctly understood when read from a series of lists of unconnected syllables.

Similarly, word articulation may be defined as the percentage of words correctly understood, while intelligibility is the percentage of ideas correctly interpreted.

Fig. 1 shows the effect upon articulation and the energy of speech of eliminating certain frequency regions.

The full-line curve sloping up to the right shows the effect on articulation of transmitting only those frequencies below the point plotted, and so is of the form

$$A = \int_0^f F(n)dn \quad . \quad . \quad . \quad . \quad . \quad . \quad (1)$$

where $F(n) \times dn$ is the percentage articulation carried by the frequency region n to $(n + dn)$.

The full-line curve sloping down to the right shows the effect on articulation of transmitting only those frequencies above the point plotted, and so is of the form

$$A = \int_f^\infty F(n)dn \quad . \quad . \quad . \quad . \quad . \quad . \quad (2)$$

Differentiating we get

$$\frac{dA}{dn} = F(n) \quad . \quad . \quad . \quad . \quad . \quad . \quad (3)$$

so that the slope of the curve is a measure of the importance of each part of the spectrum in carrying articulation.

If we try to interpret Equation (3) rigidly we are brought face to face with the fact that the slope of the articulation curve for the passing of high frequencies is different from that for the passing of low frequencies. This seems at first to be inexplicable or else due to an error in observation on the part of those who made the tests. The following considerations will, however, make this clear.

By the above treatment we have tacitly assumed that articulation may be expressed as a function of frequency such that the articulation carried by any two regions is the sum of the articulations carried by each individual region. This is actually not the case, since articulation depends on the relative efficiency of reproduction of each frequency region. Hence a discrepancy creeps in if this fact is not allowed for, and practically it is not convenient to do this; actually it will be appreciated from these curves that the error introduced is not serious.

The dotted lines show the energy function in the same way as the articulation. It at once becomes evident that the greatest slope of the articulation curves is not at the same frequency as that of the energy curves; in other words those frequencies that carry greatest energy are not proportionally important from an articulation point of view.

There is as yet no information on the function of frequency portraying naturalness, and it is questionable if such is conceivable or could be of any practical value; we know that perfect naturalness can only be obtained by the uniform transmission of all frequencies within the music or speech range. It is a matter of fact that it is possible to reproduce any one frequency nearly 10 times (energy ratio) better than another before the

ear can detect any departure from naturalness. If we had any measure of æsthetic pleasure, we could obtain a function of considerable value in rating the performance of a loud-speaker by its power to please, simply through an examination of its response characteristic.

The absolute response characteristic of a system may be defined as being a curve plotted between frequency and the efficiency of reproduction at each frequency, this efficiency of reproduction being expressed as the ratio of output to input power. It may thus be greater than unity in the case of an amplifier but is always less than unity in the case of a transmission line.

It is sometimes more convenient to plot the square root of this ratio, which is then spoken of as the voltage or current ratio. In actual practice it is more convenient to plot relative response instead of absolute response as defined above; the shape of the curve obtained is similar, the only difference being the scale.

Referring again to Fig. 1 we see that if we cut off all frequencies below 500 cycles the effect on intelli-

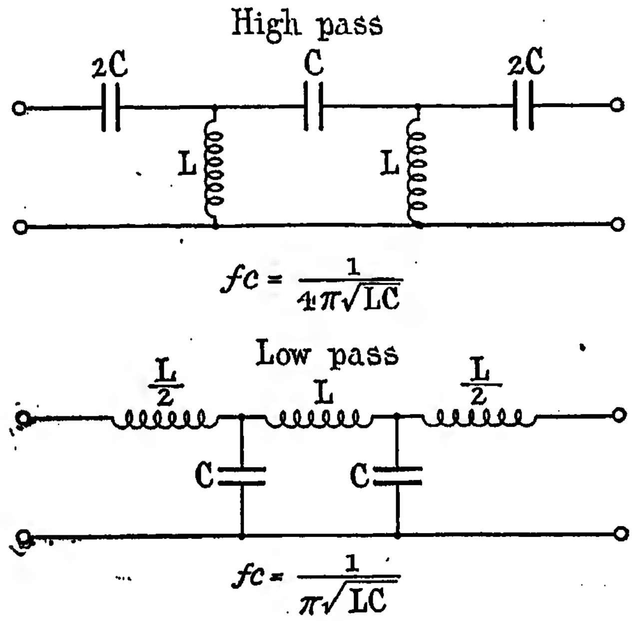

FIG. 2.—Campbell wave filters.

gibility will not be appreciable, although the naturalness with its more rigid requirements is noticeably impaired. If we eliminate all frequencies above about 1 700 cycles we reach very nearly the limit of commercial speech, and any further considerable reduction in cut off produces speech difficult to interpret. The intelligibility is about the same if we cut off all frequencies above 1 500 cycles as it is if we cut off all frequencies below 1 500 cycles.

Fig. 2 shows the type of " high pass " and " low pass " wave filter of the Campbell type suitable for experiments of this kind. The theoretical cut-off frequencies of such filters are given by the following formulæ :—

High pass $\quad f_c = \frac{1}{4\pi\sqrt{(LC)}}$ $\qquad$ Low pass $\quad f_c = \frac{1}{\pi\sqrt{(LC)}}$

MEASUREMENTS ON LOUD-SPEAKERS.

We are now in a position to interpret with some degree of discretion the meaning of the response characteristic of a system, and the next question that arises is how to obtain such a characteristic. The method of obtaining the response characteristic for an amplifier is well known and there is no need to discuss it here.

What we are concerned with is the response characteristic of a loud-speaker operating in its associated circuit; it is necessary to lay stress on this owing to the variation with frequency of the impedance of an ordinary loud-speaker.

Dr. A. E. Kennelly has dealt with the subject of impedance measurements on telephone receivers very thoroughly, and has shown that it is possible to relate the shape of the resonant peaks of the response characteristic to the impedance frequency curve of the loud-speaker. It is, however, a rather laborious process and does not give the complete response characteristic. This method is probably very valuable in analysing the cause of inefficiency and distortion, but as a measure of performance a direct measure of the response characteristic is much more informative.

The most obvious way to do this is by means of a calibrated microphone, that is to say one in which the ratio of output electrical energy to maximum excess pressure due to sound energy is known. It is then

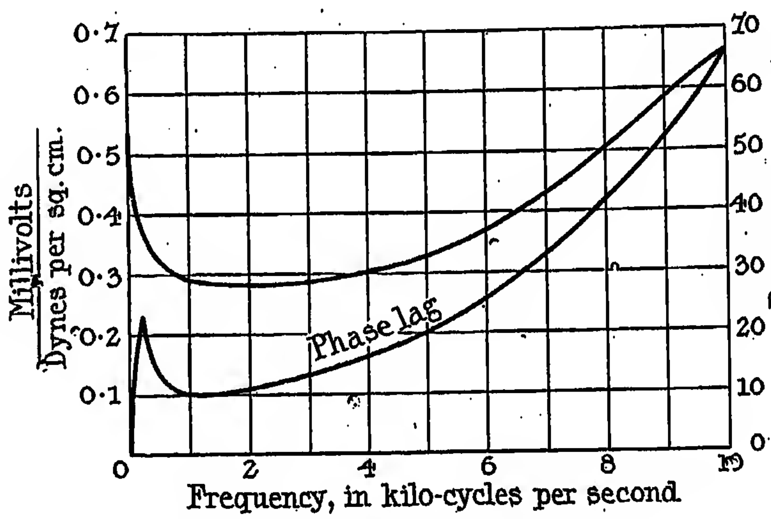

FIG. 3.—Electrostatic transmitter.

only necessary to supply known energy to the loud-speaker and to measure the output sound energy by means of the calibrated microphone in order to obtain a calibration of the loud-speaker. Fig. 3 shows the calibration of a condenser microphone suitable for the purpose. This calibration is accomplished by comparison with a piston-phone and a thermophone.*

Such a calibration would be absolute; that is to say, the actual efficiency of transmission between the input to the loud-speaker and the microphone would be known. This is valuable if we wish to measure the power efficiency of the loud-speaker, but if we are only concerned with frequency distortion then we only require to know the relative efficiency of transmission of each frequency.

In theory this sounds extremely simple, but in practice difficulty is experienced owing to the production of standing waves, resulting in a system of nodes and anti-nodes. The result is that while the microphone may be situated at what is a node for one frequency or

* E. C. WENTE: "The Thermophone," *Physical Review*, 1922, vol. 19, p. 333; also E. C. WENTE: "The Sensitivity and Precision of the Electrostatic Transmitter for Measuring Sound Intensities," *ibid.*, 1922, vol. 19, p. 498.

set of frequencies, it may be also at an anti-node for another frequency or set of frequencies. The result is to produce waves in the response curve; an obvious but rather laborious method of eliminating the effect of these nodes is to take a series of characteristics, moving the position of the microphone slightly each time, and then to draw a mean curve.

It is, however, possible by means of suitable damping material on the walls of the room in which the test is made to reduce the effect of nodes and anti-nodes to a degree where they are practically negligible.

Fig. 4 shows a curve obtained by a combination of these two methods, where the damping was only partial.

The effect of nodes and anti-nodes may be avoided to a large extent by making the test in a large room with the microphone placed very near the horn of the loud-speaker, in which case the volume of emitted

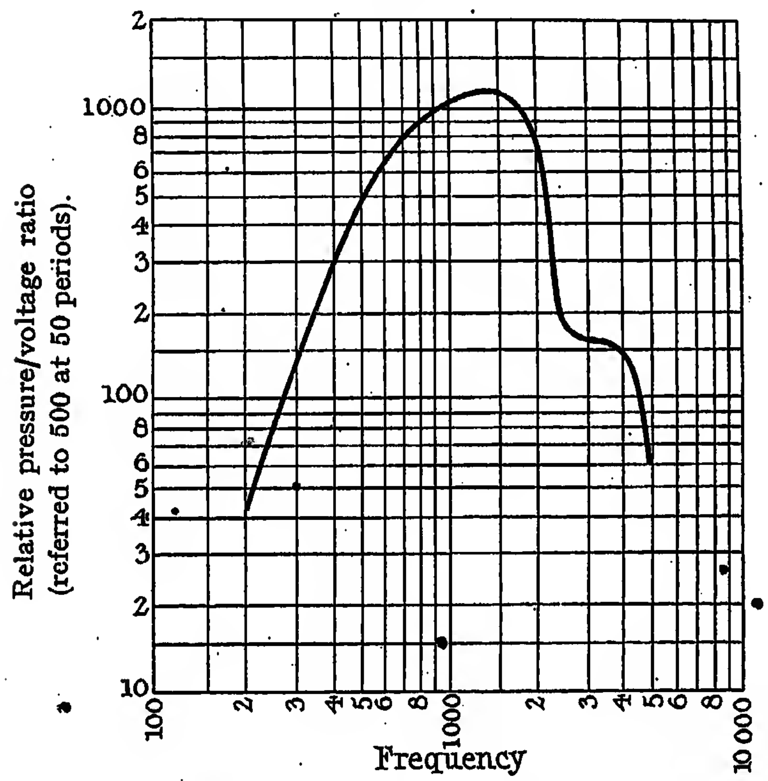

FIG. 4.—Transmission characteristics of loud-speaking telephone receiver.

energy is very much greater than the volume of reflected energy; there is, however, a danger of standing waves being formed between the horn and the microphone.

Another method which has been very successfully used by Mr. L. C. Pocock is to employ a band of frequencies, the frequency applied varying sinusoidally in time between two frequencies at equal distances on each side of the frequency, the response of which is to be measured. Such a method automatically takes an average, eliminating the effect of nodes and anti-nodes and actually tending to prevent their formation.

The formation of nodes and anti-nodes may very easily be demonstrated in a room of ordinary size by connecting a valve oscillator to a loud-speaker. It is found that the intensity of sound varies very considerably from point to point in the room, the nodes being roughly of the order of a wave-length apart, so that the frequency of occurrence of nodes is proportionally greater in the case of high frequencies than in the case of low frequencies. The effects may be best observed if one ear is blocked up, in which case it is possible with quite a loud note, if it is sufficiently pure, sounding in a room, to find a position where a single ear can detect practically no sound. On changing the frequency, an ear in this same position may be found to receive quite a large volume of sound, and the whole system of nodes and anti-nodes will be different.

Returning to the statement that a loud-speaker must be tested in its associated circuit, we can make a modification if we are prepared to make an impedance run on the loud-speaker. In this case we can, if we like, make a test supplying constant current to the loud-speaker at each frequency, and then make a correction for its impedance and that of its associated circuit at each frequency. This is not so direct as testing the loud-speaker in its associated circuit, but it is sometimes more convenient. For instance, if we have a loud-speaker operating in the plate circuit of a valve, we can regard the voltage in the circuit comprising the loud-speaker and the plate circuit as being constant at μ times the a.c. grid voltage, V_g, applied to the valve (assumed to be constant with frequency).

Then the current through the loud-speaker, instead of being constant as was the case under test, is given by

$$\frac{\mu V_g}{Z_P + Z_L}$$

where Z_P is the impedance of the plate circuit, and Z_L the impedance of the loud-speaker at any frequency; and the power input to the loud-speaker is

$$\frac{(\mu V_g)^2}{(Z_P + Z_L)^2} \times Z_L \cos \phi$$

where ϕ is the angle of the impedance instead of $I^2 Z_L \cos \phi$, where I is a constant (i.e. in the case of a test under constant current).

Hence if the ordinates of our response characteristic are expressed in simple power ratios we must make allowance for the variation in impedance of the circuit by dividing each ordinate by the value of $(Z_P + Z_L)^2$ at each frequency and by multiplying each ordinate by some constant (to give a convenient scale), possibly the value of $(Z_P + Z_L)^2$ at some chosen frequency.

If, instead of power ratios, pressure/voltage ratios are plotted, then we must divide each ordinate by the value of $(Z_P + Z_L)$ at each frequency.

We have described this method because it is the one generally used, but it would appear to be much quicker in the commercial case to test the loud-speaker in circuit with its associated amplifier, since all this correction is thereby avoided and all that is required is the response characteristic for the amplifier, which can generally be made sufficiently flat to be negligible.

Fig. 5 shows the circuit arrangements for a test of this nature. M_1 and T_1 show the position of the meter if the test is to include the amplifier A_1, which must then, of course, be calibrated, while M_2 and T_2 show the position for the constant-current test already described.

In actual practice there may be a large number of variations of this method. One that has been very successfully applied is to arrange that the amplification

is such that the net result from the input of amplifier A_1 to the output of amplifier A_2 is a loss at all frequencies. Then it is only necessary at each frequency to insert an amount of standard cable between the oscillator and a headphone to give the same loudness as when the headphone is connected to the output of A_2. It is thus possible to measure the loss in standard miles at each frequency.

Then if P_1 is the input power to amplifier A_1,
P_2 is the output power from amplifier A_2,
$P_2 = P_1 e^{-2 \times 0 \cdot 109\, m}$

where m is the number of miles of standard cable.

The standard cable used in this case is distortionless and has an attenuation per mile equal to the attenuation of standard cable per mile at 800 periods per second. By determining the distortion in the rest of the circuit we can calculate that in the loud-speaker.

It has been attempted in this paper to present the difficulties involved in their most elemental form, rather than to give instances of any very special methods of overcoming them, it being thought that this would be more productive of fresh effort; and it is hoped that the particulars given in the small part of the subject that it has been possible to cover in the time available will be fruitful in this direction.

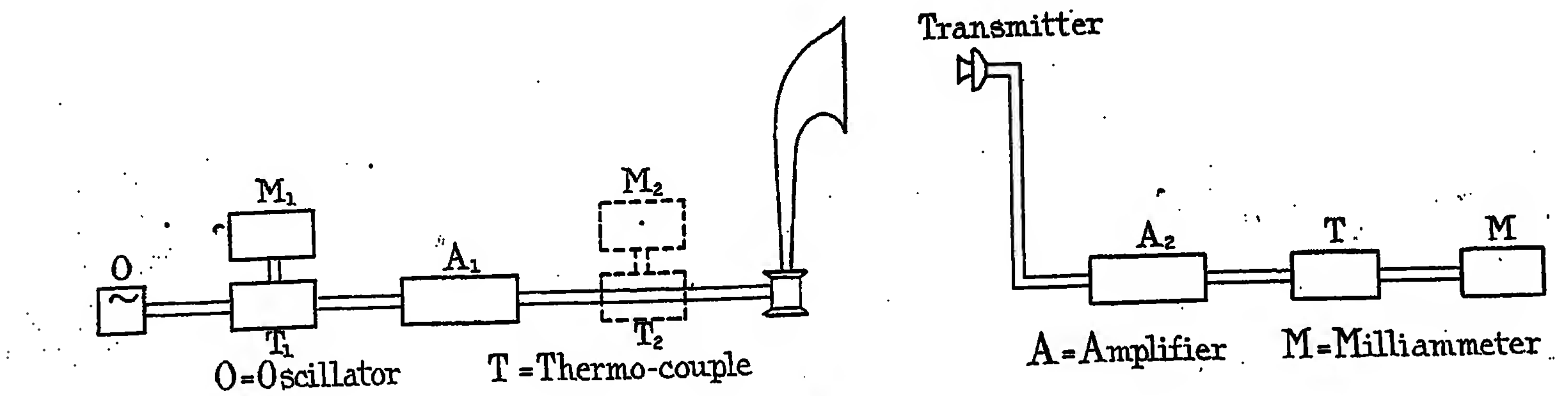

FIG. 5.

THE OVERTONES OF THE DIAPHRAGM OF A TELEPHONE RECEIVER.

By Professor J. T. MacGregor-Morris, Member, and Professor E. Mallett, M.Sc.(Eng.), Member.

It is well known that plates and diaphragms in vibration exhibit resonance at various frequencies, and that at the frequencies of resonance the vibration amplitude under a given impressed force is greater than at others. The frequencies at which resonance occurs, unlike the resonance in the vibration of strings or of columns of air, are not harmonic, i.e. the various overtones are not in the simple proportion of the numbers 1, 2, 3, etc., and the resonance occurs by the plate or diaphragm

✳	Normal	$g''''\sharp+$	a''''				

NOTE.—The plus sign means that the note is sharp but by less than half a semitone, and the minus sign that the note is flat by less than half a semitone.

* Further experiments have shown that the fundamental observed, marked c''' above, is in error owing to masking from a wide band of resonance due to the cap and casing of the receiver, and the actual fundamental is at 686 for the diaphragm. The following values were obtained :—

By inductance bridge without sand : 688·5
" " " " : 684
By inductance bridge with sand : 668

vibrating in portions and not as a whole. These various modes of vibration can be exhibited by the well-known method of Chladni, simply by sprinkling sand on a diaphragm. We are much indebted to Mr. Dutton of the City and Guilds (Engineering) College for assistance in this matter.

The point arises as to what bearing, if any, this has on loud-speakers. Many loud-speakers use a diaphragm or vibrating plate of some kind or other. In some the plate is directly actuated by the electromagnets as in the ordinary telephone receiver, while in others it is moved by a reed or a moving coil. But whatever the means employed to impart the motion, the facts are the same, that a diaphragm of some form or other is maintained in vibration by an impressed force and so a sound wave is produced.

It seems natural to conclude, therefore, that all loud-speakers of these types must have resonant frequencies which are to be ascribed to the various modes of vibration of the diaphragm. The question as to how sharp these resonances are, depends on the damping. In the case of the ordinary receiver, considerable damping is introduced by the closeness of the ear cap to the diaphragm, and still further damping is introduced when the receiver is placed to the ear. In at least two different types of relatively successful loud-speakers (A and B) a similar device is adopted to introduce damping.

It would therefore seem to be a question of a judicious balancing of the damping against the resonance. Without the resonance, i.e. with very strong damping, the response would be very poor, but uniformity over the frequency range would be assured. With resonance the response is great, but there is lack of uniformity.

That the frequencies at which resonance occurs with an ordinary diaphragm are within the necessary range in music seems to be certain, as Table 1 * would indicate, and as will have been heard during the demonstration.

There are four methods of obtaining the resonant frequencies of a telephone receiver diaphragm :—

(a) By intensity of sound produced.
(b) By Chladni's sand figures.
(c) By Western Electric cathode-ray tube indicating sudden change of power factor.
(d) By inductance bridge measurements.

In all cases an alternating current is supplied by a valve oscillator and the frequency is gradually increased, when the various overtones become apparent at their respective frequencies.

In the inductance bridge method the passage through a particular mode of vibration is rendered evident by a sudden drop in the inductance and a return to the smooth curve, and a sympathetic change in the effective resistance curve. These changes have been examined very thoroughly by Dr. Kennelly for the fundamental mode of vibration.

In the accompanying curves (see Fig. 2), determined by Mr. M. Stern at East London College, these changes are shown for a number of the overtones as well, and the sand figures belonging to the respective modes are also shown on the graph. Two pairs of curves are given, one with the two coils in the receiver connected in the usual way and the other pair with the two coils in opposition. It will be seen that owing to lack of complete symmetry in construction of the receiver, certain modes are evident in both pairs of curves.

The above results are given in the pitches of the various overtones in Table 2, and it will be seen that the plate theory is in close agreement with the observed values; only in one case is there a difference of more than a semitone.

* Extracted from a paper published in the *I.E.E. Journal*, 1923, vol. 61 p. 1314.

AUDITORIUM ACOUSTICS AND THE LOUD-SPEAKER.

By G. A. SUTHERLAND, M.A.

The conditions of good hearing in an auditorium are: first, uniform and adequate loudness; secondly, distinctness, which means freedom from undue overlapping of successive sounds; and, thirdly, freedom from distortion, i.e. the preservation of the proper relative intensities in the simultaneous components of a complex sound. A pre-requisite to the attainment of such qualities is the ability to express them in definite form, and also to express with definiteness the way in which the shape and the lining and furnishing of a room contribute to produce these effects.

Uniform loudness is associated in practice with the absence of curved walls, which produce main and subsidiary foci, and, unless suitably covered, always constitute a menace to good acoustics. With flat walls the distribution becomes sensibly uniform within a small interval of time, and, when a source commences to emit sound, the energy density has been shown by Jäger,* making assumptions as to conditions that are sufficiently close approximations to those actually occurring, to grow according to the equation

$$E = \frac{4A}{avS}\left(1 - e^{-\frac{avS}{4V}t}\right)$$

where E is the average energy density at time t, A is the energy emitted per second, V is the volume of the

* S. JÄGER: *Sitzungsberichten der Kaiserl. Akad. der Wissenschaften in Wien*, 1911, vol 120.

room, v is the velocity of sound, and e is the exponential. S is the total surface presented by walls, ceiling, floor, furnishings, etc., and a its average absorption coefficient. If there are surfaces S_1, S_2, S_3, S_4, etc., with coefficients a_1, a_2, a_3, a_4, respectively, then clearly

$$aS = a_1S_1 + a_2S_2 + a_3S_3 + a_4S_4 + \ldots$$

Similarly, when the source is stopped the time of decay is given by

$$E = \frac{4A}{avS} e^{-\frac{avS}{4V}t}$$

The value of the maximum intensity attained, $E_{max.}$, which is $4A/(avS)$, varies directly with the rate of emission of energy by the source, and inversely as the total absorbing power of the room.

If a room be very large, S is necessarily large and the maximum intensity can be changed only by varying A or a. Thus it will be impossible to fashion too large a room satisfactorily for sounds of limited strength (i.e. where A is small), since to make $E_{max.}$ large a

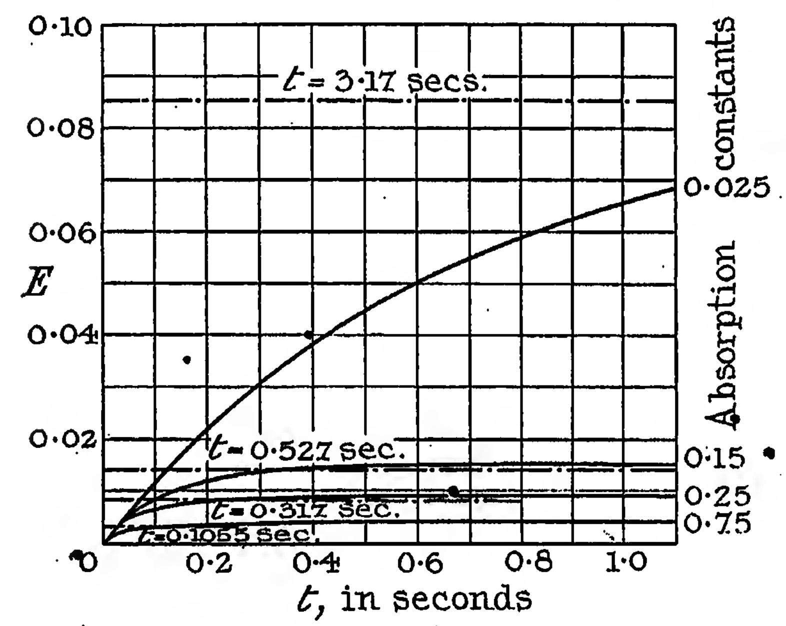

FIG. 1.—Growth of sound intensity in a room for various degrees of absorption of its boundaries. The time-values associated with the horizontal dot-and-dash lines give the time in which the intensity grows to 99 per cent of the saturation value.

would then have to be made small, the effect of which is, as will be seen, to increase the rates of growth and decay and so militate against distinctness. The term "adequate loudness" has no meaning except when considered in relation to distinctness. The rates of growth and decay also depend on the value of S/V, which is smaller the larger the room. Thus two rooms having the same proportions and lined with the same material will have different acoustic properties unless they are identical in size.

The meanings of these expressions for growth and decay can perhaps best be appreciated by reference to the following curves, most of which are due to Eckhardt.* The first series (Fig. 1) shows how the rate of growth in a room of volume 1 000 cubic metres changes with the average absorption coefficient of its walls, the conditions varying from an empty room with bare hard walls to a room with a full audience and a large amount of absorbent lining material. It will be seen that the maximum intensity attained is greatest for the empty room, but that the time to attain this maximum is also greatest. If the decay curves, which are the same curves inverted, are plotted, then the time of decay is clearly seen to be greatest for this case also.

The effect of varying the volume of the room is shown by the next series (Fig. 2). The intensity is seen to rise most slowly in the case of the largest room and also to attain the smallest maximum.

In speech, where the emission is discontinuous, the effects may best be demonstrated by drawing a separate curve for every syllable and summing these to show the variation in total intensity. The result is shown in Fig. 3. The dotted curve represents the resultant. In the case selected it will be noted that at any

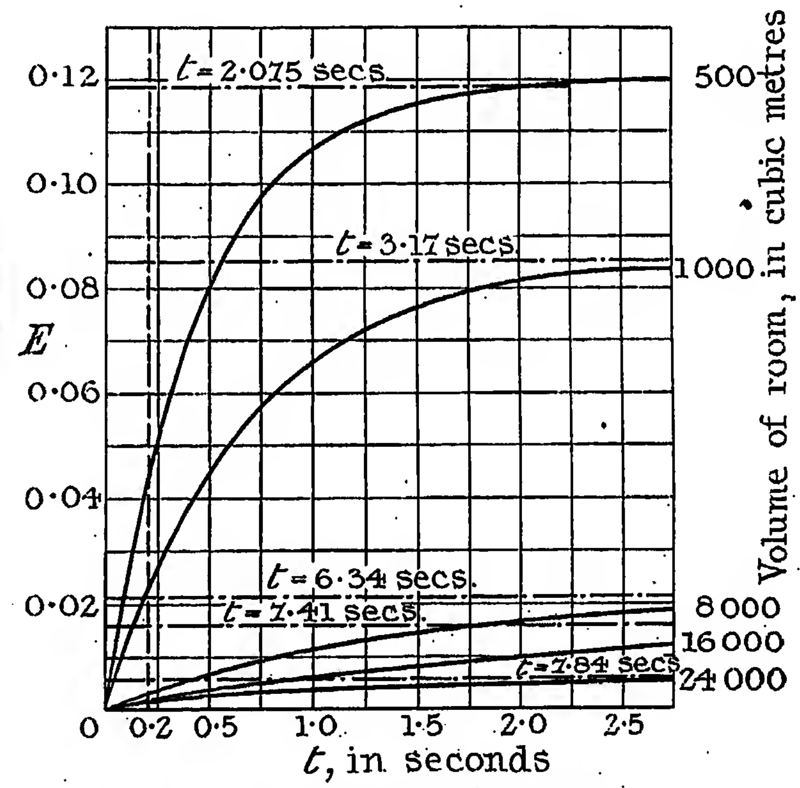

FIG. 2.—Growth of sound intensity in rooms of different volumes, the boundaries being of the same poorly absorbing material in all cases.

instant about 60 per cent of the sound heard is due to previous syllables and only 40 per cent to the syllable actually being uttered, also that the variation in intensity due to the discontinuous articulation is only a small percentage of the total intensity, conditions which inevitably mean indistinctness.

The effect of speaking at half the rate in the same room is shown in Fig. 4. The maximum intensity is only about half what it was, but the syllable actually being uttered contributes 60 per cent of this. This represents an improvement, the variation between syllables being 40 per cent of the maximum. It is to be noted here that although the discourse seems disjointed to the speaker it will not seem so to the audience.

If we take a room of the same size but of higher absorbing power the maximum attained may be reduced to one-tenth of the previous value, as indicated in

* E. A. ECKHARDT: *Journal of the Franklin Institute*, 1923, vol. 195, p. 799.

Fig. 5, but each syllable contributes 94 per cent of the sound heard at any instant, and the variation between syllables is about 45 per cent of the maximum. This represents a state of affairs in which hearing is satisfactory, and it will thus be seen that, for speech, distinctness is more important than loudness.

It is possible to carry the process further, and in this case we get the effect shown in Fig. 6. The resultant

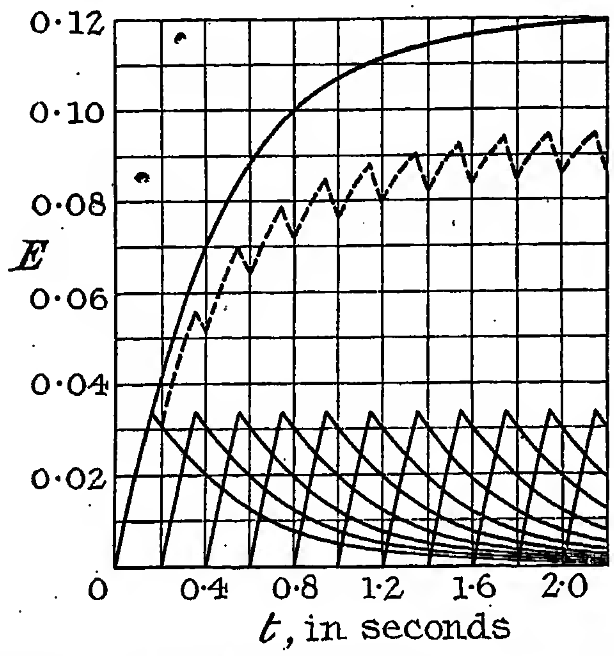

FIG. 3.—Growth and decay of sound intensity for syllable emission in a room of too small absorbing power.

curve differs so little from the components that it has not been drawn. Here the peak intensity is about one-third that of the previous case, but the drop between syllables is about 90 per cent of this. By common agreement such a state of affairs is assumed to be inferior to the previous state, partly, perhaps, because of the small peak intensity, partly, too, because we are

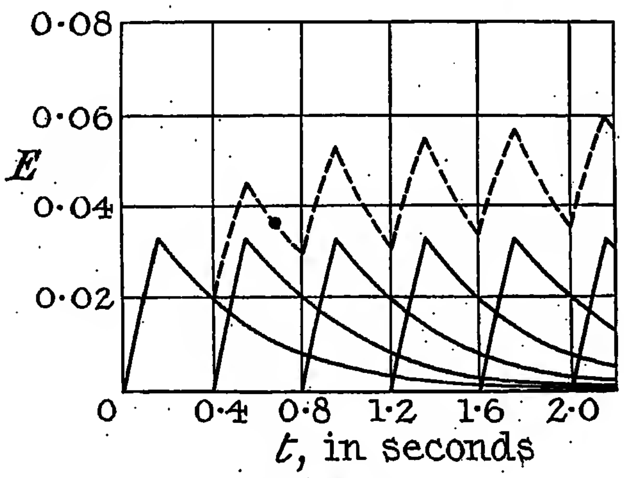

FIG. 4.

so accustomed to a certain amount of overlapping that a condition in which it is absent seems unnatural, but undoubtedly also because ideally a speaker's utterance should have in it something of the character of music, and everyone would unite in condemning as "dead" a passage of music in which there was no blending of successive sounds.

To the slow decay of sound in a room indicated by the foregoing series of curves the name "reverberation" has been given, and exhaustive experiments by Sabine * have shown that the best condition as regards distinctness is associated very approximately with a particular reverberation period which in a room of a given volume has one value for speech, another for chamber music, and a third for orchestral music. A logarithmic curve like these is completely determined if we can measure the time of decay to $1/e$ of the initial value.

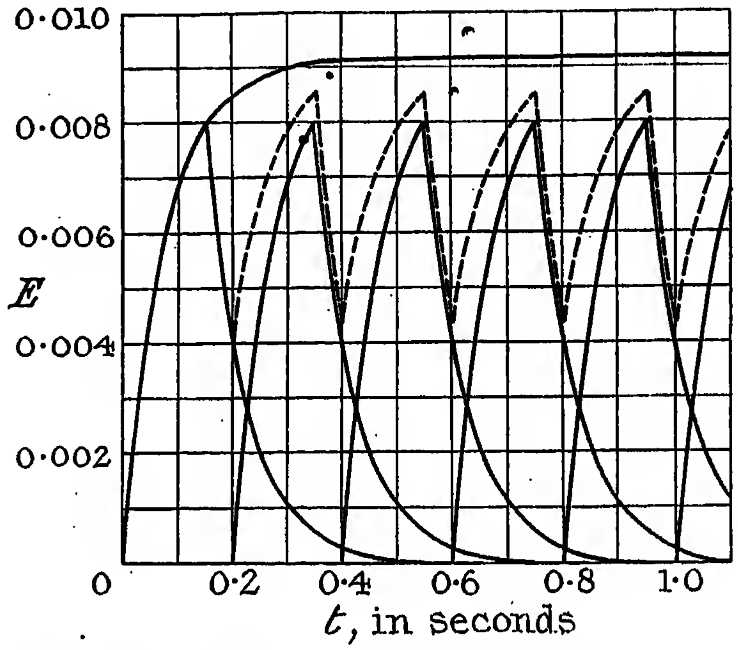

FIG. 5.—Growth and decay of sound intensity of syllable emission in a room of proper absorbing power.

In any ordinary room this time is too short to be capable of accurate measurement, and Sabine measured instead the time of decay to inaudibility of a sound initially 10^6 times the minimum audible intensity. This he calls the "period of reverberation." By doing this in rooms lined with different materials he was able to assign absorption coefficients to linings commonly used. This enables calculation to be made in advance of construction

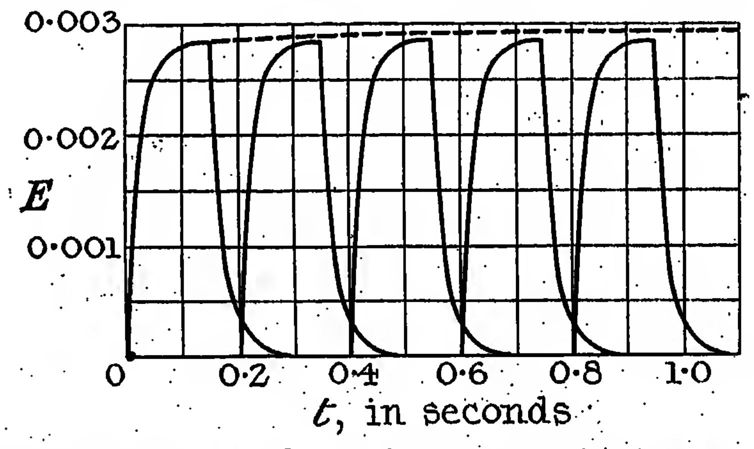

FIG. 6.—Growth and decay of sound intensity for syllable emission in a room of too great absorbing power.

and the desirable reverberation period to be assured from the start. Sound, being a form of energy, cannot be got rid of by the scattering produced by irregularities in the walls, etc. It remains audible until converted either directly by air friction into heat, or into some other form which will eventually become heat. Thus the most effective absorbents of sound are porous linings and furnishings, the relative merits of different linings

* W. C. SABINE: "Collected Papers on Acoustics," 1922.

being indicated by the curves in Fig. 7. Curve 1 is for a painted brick wall; curve 2 is for plaster on tile with a finishing coat; curve 3 is for wood panelling; curve 4 is for a special tile called Akoustolith; curve 5 is for a special hair felt; curve 6 is for hair cushions; curve 7 is for cotton wool cushions, and curve 8 for an audience as ordinarily seated. It will be seen that an audience is the best absorber of sound.

Where speech is concerned the difficulty usually is to introduce sufficient absorbent material, a difficulty which, as we have seen, increases more than propor-

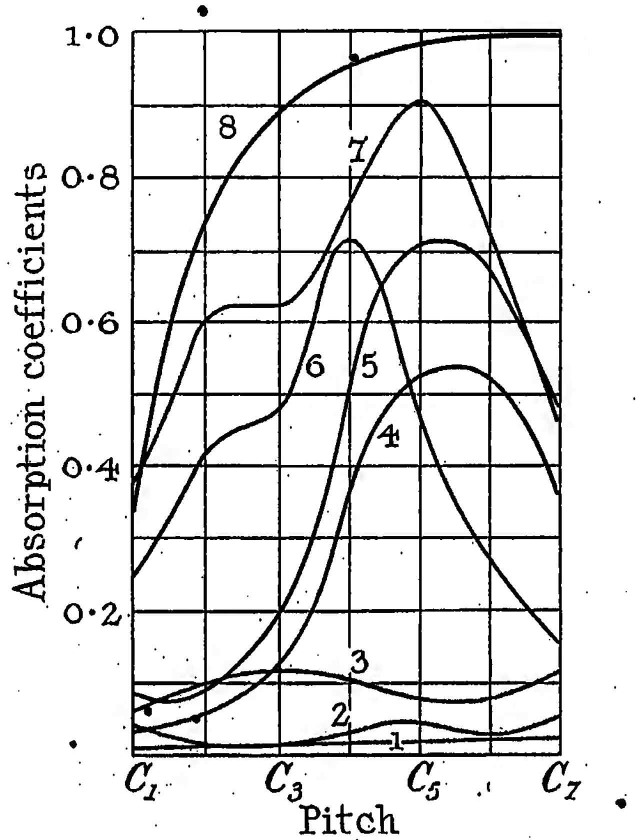

FIG. 7.—Showing the absorbing powers of different materials.

tionately with the size of the room, since the times of growth and decay depend on S/V, and V increases more rapidly than S. When we come to consider the possible function of the loud-speaker we see that much more satisfactory hearing is likely to be attained by distributing an audience into a number of small rooms with a loud-speaker in each, than by attempting to accommodate all in a large hall. Even if the large hall be full the audience is not so effective in reducing reverberation as in smaller rooms. If the room is partly empty the situation is considerably worse.

For music, where a longer reverberation is desirable, the opposite arrangement may give the better results. It is impossible to generalize, however; each case would have to be settled on its merits.

One thing that stands out quite clearly is that nothing is to be gained by having a loud-speaker with a rate of emission of energy many times that of the human voice. Almost all halls suffer from excessive reverberation and the louder the initial sound the greater is the confusion produced, since the louder sound lasts longer and there is more overlapping. This is a matter of common experience; in fact a sure indication that a room is suffering from excessive reverberation is furnished if increasing the loudness is found to increase the defect.

A point to which we have not yet directed our attention, and which can be touched on only briefly, is the question of accurate rendering or freedom from distortion. It is customary for physicists to regard the quality of a note as being completely determined by the relative intensities of the different vibrations leaving the source. Clearly the sound heard depends on the relative intensities of the vibrations reaching the audience. The different wave-lengths, as Fig. 7 shows, are far from being absorbed equally. Sabine quotes a case where with an 8 ft. organ pipe the introduction of felt into an empty room reduced the ratio of the first overtone to the fundamental by 40 per cent, that of the third overtone by 50 per cent, and the fourth by 60 per cent. With a 6 in. pipe, on the other hand, the effect was to accentuate the overtones, whereas all notes below the 6 in. fundamental were purified. The effect of an audience was still different, viz. to purify all notes up to C4, 512, and to have very little effect on tones above this. For C1, 64, the first overtone was decreased 65 per cent relative to the fundamental, and the second was decreased 75 per cent.

Generally we may say that if the sound from a loud-speaker tends to be too rich in higher-pitched notes, then the presence of a large audience is likely to have a corrective effect. As before, it will be advantageous to use several smaller rooms rather than one large one. The case of music is too complicated for treatment here. So far as the author is aware, the judgment of musical authorities has never been expressed in such a form as would make it applicable. No doubt the relative numbers of the different instruments in an orchestra have been fixed empirically, having regard to the conditions normally prevailing in concert halls.

SOME DIRECTIONS OF IMPROVEMENT IN THE LOUD-SPEAKING TELEPHONE.

By S. G. BROWN, F.R.S., Member.

It is difficult to discuss the problem of the loud-speaker in the short time available, and accordingly my remarks must be confined to one or two general aspects which occur to me.

It may be remarked that, for the want of the perfect transmission system, it is not possible to determine the real inefficiency of the present-day loud-speaker. We presume that it is inefficient because in the electrical transmission to it we have never approached the perfection of listening direct to, say, the music of the orchestra itself.

The loud-speaker consists, among other things, of a diaphragm which operates in an enclosed chamber in the manner of the piston of a pump. A hole is provided

in the cover of this chamber, and air is forced in and out through it as the diaphragm vibrates. The smaller the hole, within reason, the greater will be the velocity of the air as it leaves the chamber, and, as the sound energy is proportional to the square of the amplitude, the output of the loud-speaker can be materially raised by a suitable size of hole.

Connected with this hole is a tapering funnel or trumpet. The object of this is to transmit the sound energy to the outer space with as little loss as possible. The air in the funnel vibrates as in a double open-ended tube. The natural period of the air enclosed in the trumpet is similar to that in an unstopped organ pipe.

This natural vibration of the air column is superimposed upon the vibrations set up in the air by the diaphragm. It can, however, be removed by drilling suitable holes in the tube along its axial length. The first hole would be mid-way along the trumpet in order to eliminate the natural frequency of the column. The next overtones are removed by drilling holes respectively one-quarter and one-eighth of the way along the axial length, their diameter being made smaller as the diameter of the trumpet diminishes. The improvement brought about by this device is recognizable by a trained ear.

As regards the material of the funnel, a rigid wall is desirable for the proper enclosure of the vibrating air column, and to this end it should be of heavy metal and of thick cross-section. If the trumpet walls are too thin the force of the air expanding as sound will distort or swell them, causing them to resonate. (We are speaking, of course, of ideal conditions, and manufacturers, from considerations of weight, etc., must use lighter material.)

The vibrations of the diaphragm are not all imparted to the air, but escape into the metal enclosure and thence up the metal of the trumpet. It is therefore a good plan to insulate the sound-producing element from the trumpet and casing. One manufacturer fits his funnel on by means of a rubber sleeve; this appears to be a good arrangement.

Even the best of modern loud-speakers causes a certain amount of distortion which I attribute to the free vibrations of the diaphragm. If we could obtain the necessary air waves with less amplitude of movement at the source, greater freedom from distortion would result. Possibly this might be done by employing a larger diaphragm, suitably stiffened without sacrifice of lightness.

Alternatively, we can produce sound vibrations by other kinds of pressure devices, such as the "Frenophone." This instrument consists of a rotating glass disc and a steel-backed cork pad resting in contact with its surface. The cork is linked to a loud-speaker movement. A telephone receiver presses on the back of the cork by means of an elastic steel pin. Telephone currents, therefore, by operating the receiver, alter the pressure of the cork on the glass disc, thereby varying the frictional drag and working the loud-speaker. It is believed that this combination gives greater clearness in the sound emitted, and the Frenophone may be regarded as a step onwards in the direction of the perfected loud-speaker.

THE CHARACTERISTICS OF A NEW TYPE OF LOUD-SPEAKER.

By Captain P. P. Eckersley.

There seems to me to be no doubt that the weakest link in broadcasting at the present moment is the receiver, and that the weakest link in the receiver is the loud-speaker. The British Broadcasting Company is certainly transmitting on an arbitrary basis, but a basis on which remarkably good results can be obtained if the loud-speakers are properly designed. The problem of loud-speakers is balanced between two ideas: Is the aim to be efficiency, i.e. are sounds to be intelligible, or is the transmission to be perfect from the point of view of music? There appear to be two absolutely distinct types of instrument: the efficient resonant loud-speaker which will fill rooms of large size, and the loud-speaker which will be just sufficient for an ordinary drawing-room. In the former type I think that much must undoubtedly be sacrificed. It has, however, been pointed out by one speaker how difficult it is to get efficiency and at the same time perfect quality. I propose to demonstrate a loud-speaker of the drawing-room variety which gives very good quality. I feel that it has some qualities that no other loud-speaker has, in that there is a certain warmth in the bass. Many loud-speakers are very resonant at about 1 000 p.p.s. This loud-speaker seems to be resonant somewhat lower in the scale, and I think that this is good from the point of view of music. A really efficient and perfect-quality loud-speaker, although it would probably be most expensive and consume a very great amount of power, would be a great achievement. If this meeting helps to bring about that achievement I shall feel that it has not been called in vain. An efficient instrument is possible theoretically, and I think that it will come in time.

[Captain Eckersley then demonstrated on the Gaumont-Lumière loud-speaker.]

Discussion at the Joint Meeting of The Institution and the Physical Society of London, 29 November, 1923.

Dr. W. H. Eccles: The loud-speaker of to-day is really an immense achievement and does in an almost perfect manner what could not have been done 20 or 30 years ago. By its aid the science and practice of communication is being revolutionized. It is now possible for a single voice to speak to millions of people; in every country in the globe it must now be realized that the orator, the politician or the preacher, can address audiences of a size that was undreamt of a few years ago. This is being done in two ways. In this country we have the loud-speaker combined with wireless broadcasting to carry the speaker's voice to hundreds of thousands of people; but in America the loud-speaker has also been largely developed in what is called the "public address" system. In that case a speaker may be in a great auditorium or hall, or possibly in the open country; he speaks in ordinary tones to a microphone, and the speech currents are passed through amplifiers to a large loud-speaker or a series of loud-speakers. By that means an audience of 700 000 people gathered on the spot has been enabled to hear the speech. This is bound in due course to produce in every country a profound change in our political and social conditions; the voice carries personality so very much better than the printed word. It seems to me that the loud-speaker will become the great rival of the printing press, which is not an unadulterated blessing, especially in these days when large organizations of capital can to a large extent dictate public opinion by means of innumerable journals. Let us by all means have something to compete with that, even though it may be equally liable to fall into bad hands. I thought it would be appropriate for me in opening the discussion on the technical side to point out the enormous task that the loud-speaker has to attack. Its construction is faced with such exigent demands, that one would say in advance that it would not be possible to make an instrument to meet the requirements. For instance, the periodicity of speech waves varies from 100 to 6 000 per second. No engineer attempts to make an alternator to operate over such a range of frequency. In music the frequency-range is greater; it may be from 40 to 10 000 periods per second, but in fact the ear is sensitive, in middle life at any rate, from 40 to 20 000 vibrations per second. A loud-speaker designed to give a natural effect must be capable of some such range as that. In addition, the loud-speaker which is to satisfy the ear must have an enormous range in the energy of the air pressures. The air pressures in ordinary speech have been measured, and they range from the one-thousandth part of a dyne per square centimetre to 100 dynes per square centimetre. In other words, a loud-speaker to give a natural effect must be capable of producing a range of pressures about a millionfold. Again, the minuteness of the energy stream is very surprising; in a quiet room every word can be heard at several yards' distance if the speaker pours into the ear of the listener a volume of sound equivalent to about 10^{-8} watt. With an orchestra it is estimated that the ratio of power required between *fortissimo* and *pianissimo* is 50 000 to 1. Speech is quite intelligible if the sound is 100 times that which leaves an ordinary speaker's mouth, or even if it is one-millionth of that power, i.e. a ratio of 10^8 to 1. This can be emphasized in the following manner: Suppose that a loud-speaker on a building emits sounds of an energy of 1 kW. At three miles, speech would be easily intelligible by the unassisted ear, supposing the ear to have an effective area of about 1 cm^2 for receiving direct-energy air waves. If an ear trumpet were used which would collect the energy falling on 1 m^2, then speech would be intelligible at a distance of 200 to 300 miles. That shows how very sensitive the ear is and how much it expects. If we find that the human voice, the larynx and other organs, can make these variations of great range of power and frequency, we ought to be sufficiently encouraged to say that mechanism will, no doubt, in time be evolved to do the same. It has, in fact, been evolved. Or we ought to say that if the mechanism of the middle ear can work, it should surely be possible to make a machine that will perform similar feats, seeing that the problem is a physical one and not a physiological or psychological one. That task has been largely accomplished in the past few years. The Western Electric Company's laboratory in New York has probably done more than any other laboratory in the world to accomplish this task, and I think that it will be useful to make some reference to the work that has been carried out there. Their public address system takes speech energy into a microphone, and the currents in that microphone represent an energy of about 10^{-8} watt. After being amplified they finally reach the loud-speaker. The loud-speaker responds excellently between 200 and 1 600 periods per second, and the electrical energy put into it is 40 watts. This represents a ratio of magnification of 4×10^9 to 1. The result is so good that the voice coming from the loud-speakers in an open space, if the listener is the correct distance away, is indistinguishable from the voice of the person speaking. Now we have to compare what has been accomplished with what has been said in the various papers read during the meeting. It seems that there are three points to be considered in improving loud-speakers. The first is that we require to amplify all frequencies equally, or substantially equally, even over a wide range. In addition, the instrument must work in such a manner as to give the energy to the air equably. The second is that it must not introduce asymmetrical distortion. Helmholtz in his "Sensations of Tone," in discussing the human ear points out that it is a diaphragm which is heavily loaded on one side with the bones in the inner ear. He sets down two differential equations, and deduces the rather surprising fact that the asymmetry

introduces harmonics and combination-tones. If one has those in a loud-speaker, i.e. if one has a diaphragm which is acted upon very unsymmetrically and responds to equal currents in opposite directions with unequal movements, then these combination tones will be obtained. That is what I call the second difficulty in the design of loud-speakers. The third difficulty is that impulsive sounds produce damped trains of oscillations of the diaphragm. If those are not rapidly damped out they provide another source of trouble. In conclusion, I should like to say that it is surprising to think that the efficiency of a loud-speaker reckoned in the ordinary way, i.e. the ratio of the electrical power which is put in, to the mechanical power which is got out, is only about 0·1 per cent. If that is so, it seems to me that the improvement of the efficiency of the loud-speaker is the next task confronting the investigator and designer.

Adjourned Discussion at the Joint Meeting of The Institution and the Physical Society of London, 14 February, 1924.

Sir Richard Paget: I entirely agree with Mr. Sutherland that audibility is a matter of precision of aural resonance rather than of amplitude. For example, whispered sounds can be heard, as I have experienced, over long distances and by large audiences, provided they are whispered properly so that the resonances are clear. Many of the human speech sounds, especially the consonants, are really essential transients. They depend not upon any one group of resonances, but upon how those resonances are changing. In other words, we recognize the shape of the frequency-time curve for that particular sound. Take, for example, the consonant sounds in "t," "p" and "kee." Those sounds differ only in the shape of the curve of approach of the resonances to the ultimate resonances of the vowel sound "ee." Similarly, the consonant in "la" is essentially a transient, and if we extend the time curve of the resonances of that sound we get what is practically a diphthong. The "l" sound is entirely lost to our ears and it becomes merely a succession of vowel sounds. From that it would follow that the ideal reproducer must be sensitive to frequency changes and, as Mr. Pocock points out, it must be free from any resonances which would cause this or that component to linger beyond its allotted span. On the question of "imitation" which Professor Rankine raises, it seems to me important that what is given in that imitation shall be true. The same applies to painting; it does not matter how much an artist leaves out as long as he does not put anything in which is wrong. Further, the scale of magnitudes may be fundamentally altered without the faithfulness being apparently affected. A constant component, e.g. the scratching of a gramophone needle, is permissible, provided it is not too loud. Ultimately the ear becomes accustomed and ignores that. An interesting example was given of the ability of the ear to take certain components for granted, in Dr. Eccles's experiments for producing artificial vowels in a telephone by means of electrical resonance. Dr. Eccles produced quite recognizable successions of vowel sounds by using only the upper components of my vowel chart, and the human ear filled in the lower resonance, provided that the upper resonances were not ambiguous. As to horns, the vice of these seems to me to lie, not in the fact that the horn possesses resonances of its own, but that it gives them an exaggerated importance when they come along in the ordinary course of speech. Mr. Sandeman's Fig. 1 refers, as I understand it, to syllabic articulation as a whole. If that chart had been limited to the syllabic consonants, such as "s," "z"; "th," "dh"; "f," "v"; "p," "b"; "k" and "g," his curves would have indicated that a much greater importance is to be attached to frequencies of between 2 000 and 3 000 as the lower limit, and 6 000 or 7 000 as the upper limit. For instance, in my own voice "s" has a principal resonance of over 6 000; "sh" has a principal resonance of over 3 000; "f" has a component of between 5 000 and 6 000; while "th" has a component of between 2 500 and 3 400, varying with the vowel with which it is associated. Similarly, "k" has an initial resonance of something like 3 000, and "t" has a resonance of between 3 000 and 6 000. On the other hand, some of the nasal resonants are down below 200. We have therefore to deal with a rather long and formidable range of resonances. Now a word as to amplitude. In "t," "d," "p," "b," "k" and "g" the difference between each of those is only, or almost only, one of relative amplitudes. The resonances themselves are practically the same. The reproducer must therefore be faithful also to rapid changes of amplitude as well as to rapid changes of frequency. It is the high frequencies and the rapid transients which form the difficulties of speech and the difficulties of interpretation. The system must therefore be sensitive, not merely to those frequencies from 2 500 up to about 6 800, but also, for the sake of the vowels, from 200 up to 2 500. I feel confident that if faithfulness of that type can be obtained the amplitude may be enormously reduced without loss of intelligibility.

Captain B. S. Cohen: As an independent observer who has had occasion to test many of the different types of loud-speakers on the market, I may perhaps be permitted to make a few remarks on the present state of the loud-speaker. At a meeting of this Institution in the early 1900's Sir Oliver Lodge demonstrated his hornless loud-speaker, which consisted of a moving-coil electromagnetic system coupled to a wooden diaphragm, and I think it will be agreed that the articulation of that device was of a very high quality. A small number of loud-speakers of the present day are operated on this principle, but Lodge's thin and large wooden diaphragm is presumably considered uncommercial and its replacement by a metal diaphragm and the addition of a horn has not been particularly

advantageous. The great majority of present-day loud-speakers have diaphragms of the usual pattern, either magnetic and operating direct on the magnetic poles or, in the largest types, linked to an armature. In spite of Professor Scripture's dictum that a diaphragm is unsound, as it is bound to produce a distorted wave-front, and that the correct device is a stiff piston, very few attempts have been made in this direction. Novel types of loud-speakers unfortunately have, so far, generally produced novel types of articulation, i.e. novel to the received wave-form. I should like to supplement what has already been said regarding the fundamental basis of operation. To get perfect articulation we require our loud-speaker to have uniform frequency/amplitude characteristics, and I would define the perfect loud-speaker as one having a ratio of acoustic output to acoustic input of unity at all amplitudes and at all frequencies and combinations of frequencies. The volume is of considerable importance, as a perfect reproduction of, say, an orchestral piece with a volume, however, of only 1/100th the original would be of little artistic and realistic value. We can produce wireless receiving amplifiers with combinations of radio, detector and audio stages which give very reasonably uniform frequency/amplitude characteristics, and we can do the same for wire telephony with combinations of loaded lines, filters and audio-frequency amplifiers. We can also employ in both cases transmitting apparatus that will very fairly follow the frequency/amplitude characteristics of the applied sounds. But what can we do with the loud-speaking receiver? We can tune out the more prominent harmonics by mechanical modifications of the moving system, by acoustic modification in the air chambers above and below the moving system and in the horn, and, lastly, we can apply electrical tuning to the loud-speaker in the form of rejector circuits and filters. But all these devices, if pushed to the point of producing a true uniform frequency/amplitude characteristic, result in the loud-speaker belying its name; in other words, there is no reasonable audio output, and the devices above referred to can only be used to the extent of effecting slight improvements. In some cases it is reasonable to infer that the use of a receiving amplifier with a uniform output will result, with a particular type of loud-speaker, in considerably more distortion of the blasting form than when a non-uniform audio-frequency amplifier of, say, the transformer-coupled type is utilized. Thus, if a loud-speaker has a prominent resonance point at, say, 2 000 periods, and a non-uniform amplifier with a flat peak at, say, 1 500 periods is used, this might give more articulate output than a uniform-output amplifier, and will certainly give a very considerable sound output. All this indicates the importance of fitting the loud-speaker to the amplifier, and in the very few cases where this is deliberately done the results are of a very high order indeed. Many loud-speaker and amplifier combinations which give fairly uniform output from, say, 500 periods upwards, and therefore are very articulate for speech, give a colourless tonal quality to music in consequence of the rapid falling-off in output at frequencies below 500, and this is a point to which I think serious attention should be drawn. I would suggest as a very fruitful field for experiment the combination of three or four loud-speakers used simultaneously and each tuned to exaggerate slightly a different portion of the audio spectrum. It is obvious that the frequency/amplitude characteristic of loud-speakers, and indeed of any telephonic apparatus, is of fundamental importance, and apparatus for the measurement of this characteristic is becoming essential in the research laboratory. I have brought to this meeting some apparatus which has been developed for this purpose and I shall now describe and demonstrate it. The device consists of a heterodyne oscillator and high-frequency amplifier coupled to a detector, low-pass filter and audio-frequency amplifier. The combination gives a constant output over the audio range of about 50–5 000 periods, and the whole range is obtained by rotating an air condenser through 180°. This condenser is placed in a light-tight box provided with a shutter and has a cylinder, carrying negative paper, attached to it. If the frequency/amplitude characteristic of a loud-speaker, for example, is to be obtained, the loud-speaker is fed from the oscillator and its output recorded on the negative paper by a non-resonating microphone transforming the received sound into current and recording on the negative paper by means of a suitable galvanometer. The rotation of the condenser dial by hand through 180° produces the complete frequency/amplitude characteristic of the apparatus under test. Constant output is obtained by using variable resistance and inductance combinations for coupling the audio-frequency amplifier.

[Captain Cohen then gave the following demonstrations: (1) Output of oscillator and its amplifier to give constant frequency/amplitude characteristics; (2) output of an ordinary form of two-stage transformer-coupled audio-frequency amplifier, with very small output at low and high frequencies; and (3) motional impedance component of a loud-speaker indicated by horn effect and hand effect at resonance points.]

Mr. G. H. Nash: I should like to put forward some practical considerations in connection with a fundamentally important part of any loud-speaker, i.e. the coupling between the vibrating mechanical system and the air. Professor Rankine remarks: "Of horns I will say no more than that they ought, if at all possible, to be dispensed with . . . because of their resonant character." Captain Eckersley, also, has demonstrated a loud-speaker having a large diaphragm and no horn, and has claimed that this receiver brings out the lower tones so often lacking in other loud-speakers. Let us consider the large diaphragm. It is inherently an inefficient arrangement; it has great mechanical impedance directly coupled to small air impedance. It is true that receivers of this type bring out the low frequencies very well, but the diaphragm coupling is actually less efficient at low frequencies than at high frequencies, and a good low-frequency output in practice is achieved by having a low resonance point. Such a receiver therefore possesses as much resonant properties as a horn receiver; in fact, the low frequencies are overdone and the damping is so low that crisp, staccato effects are spoiled. The reproduction of low frequencies is not therefore an intrinsic virtue of the large diaphragm;

in fact, the same result can be secured with a horn if the diaphragm behind the horn is loaded sufficiently to have a low resonance frequency. Something might be done on the principle of the large diaphragm, if it were not inherently inefficient. Experimental work indicates that the wave-forms of speech or music have peaks somewhere between 5 and 10 times the R.M.S. value, and in music there occurs also a wide range of intensity; this means in practice that for the best results the last valve in the amplifier should have fairly low impedance and should be used with about 6 volts on the grid and 100 volts or more on the plate when an efficient loud-speaker is used. The use of an inefficient instrument, such as the large-diaphragm type, requires not only that more valves must be used, but that the last one must be capable of a greater output of undistorted power. Now consider the horn; it is physically a scientific and proper coupling between the

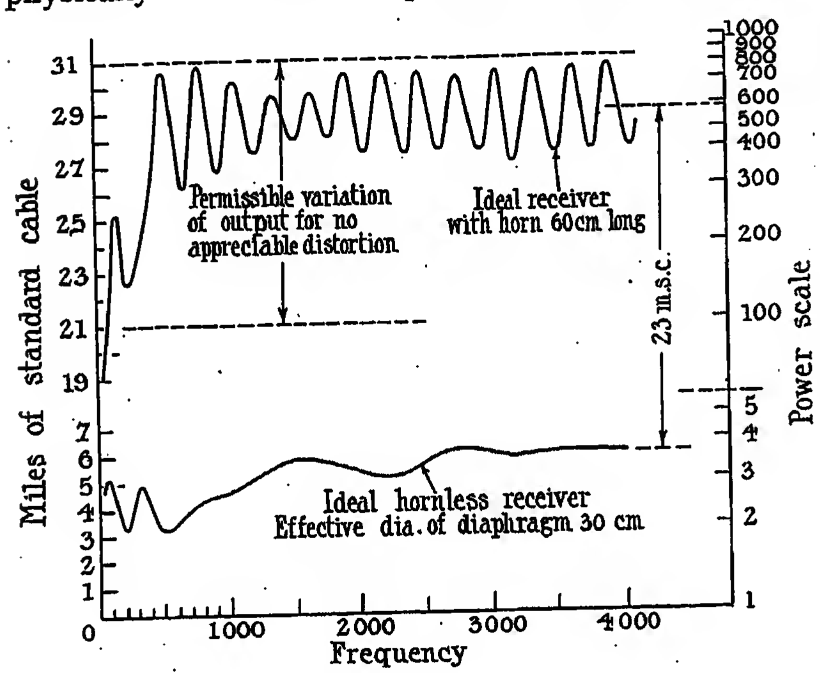

FIG. A.

impedance of the mechanism and the air; its only fault lies in the necessity of compromising between a length that would be ideal and a length that is convenient. Let us see how serious the reputed resonance effects of the horn really are. Fig. A shows the calculated sound-power output from a large weightless diaphragm for varying frequency when a constant force is acting. The upper curve shows the output from a horn of reasonable length, having the same diameter at the large end as the diaphragm and with the same force supposed to be acting at the small end. It will be noticed that the given force produces about 150 times as much power through the horn as it does when applied direct to the diaphragm, and the resonance effects of the horn are really not at all important. It has been well established that distortion within the limits indicated by the dotted lines is quite negligible, and the resonances of the horn are seen to be well within these limits. Further, the resonances can be reduced in amplitude and the output at low frequencies increased by using a longer horn. I contend, therefore, that horns are by no means to be discarded; on the contrary, they *must* be used if good results are to be obtained with a reasonable number of valves of reasonable power, and if a horn is properly designed it does not introduce serious distortion and is not responsible for distortion effects for which it is often blamed.

Captain H. J. Round: If we take any microphone and attempt to magnify the resulting currents, we are very quickly led to recognize the limitations of the amplifying apparatus. A valve amplifier can be stated to have certain peak-voltage limits. Distortion in a valve is generally produced by two effects: the curvature of the plate current characteristic, and the voltage-drop due to the grid current; and in order to exclude these the peak voltages of the microphone current which have to be magnified must not exceed certain values. By increasing the size and power of the valves we can increase this voltage limitation, but there is one place in the system in which this cannot be done economically, and that is the place where the maximum power is used, namely, in the wireless transmitter itself. The consideration of the effect of this is exceedingly complex. The natural sounds which we desire to transmit have all sorts of peak amplitudes, at all sorts of frequencies, but I shall now only consider the question of what basis to adopt for transmitting these different frequencies. The difficulty is this: Suppose we have a microphone which can deliver voltages at the end of our amplifier for all frequencies proportional to air amplitude, or proportional to air pressure, or proportional to some arbitrary scale. What would be the result? It will be admitted that, provided the law were known and moderately simple, we should merely have to apply at the receiving end an inverse to reproduce the original sounds, if no other considerations such as wireless interferences, etc., entered. Unfortunately, however, they do enter: the adjustment of the microphone may be such that the low notes occurring in nature produce 10 volts, whereas the high notes produce 0·1 volt, so that our valve transmitter will be fully used for the low notes and used hardly at all for the high notes. This is very important at the receiving end, for really we are getting 1 kW, say, for middle C and 0·001 kW for the piccolo. Admittedly, given no atmospherics and no valve noises, this difficulty can be overcome, but in general these interferences will be of the same amplitude at all frequencies, and we should have the same ability to hear all the frequencies over the interferences. What exactly does this mean? On the microphones and amplifiers in use now, it is possible to make a very large number of changes in the way the frequencies are represented. Experimentally, I have tried a large variety of sounds such as orchestras, singers, speakers, etc., and I have set the microphone adjustments so that on a variety of ordinary receiving apparatus, such as telephones and loud-speakers, the results are loudest and on an average satisfying, and I have then measured what my microphone is doing. Very approximately equal amplitude of modulation is being given to the transmitter from 200 frequency to 5 000 frequency for sounds of unity audibility, taking as a standard the average of a number of observers. What one might call the tilt of the scale has to be altered a little for various situations, such as different rooms; but in face of other

serious difficulties, which I shall mention, this is a small matter. The sound experts will certainly object to unity audibility, but actually it is at the moment the easiest thing to get without complex apparatus. They will cite the recent work of Fletcher, published in the *Journal of the Franklin Institute*, on the masking effect of low tones on high tones, the meaning of which is really that no complex tones ever sound the same unless the strength remains the same to one's ears. This masking effect is extremely marked and at present prevents any attempt to get a perfect reproduction with a different strength from that of the original. I shall now refer to the use to which we put this. I have a very simple piece of valve apparatus which will deliver pure notes at any frequency and amplitude. I insert these currents into my telephones or loud-speaker and I plot a curve between voltage applied and frequency for just audibility. Curve 1 in Fig. B represents one of these curves for a pair of quite ordinary telephones, and the resulting effect on audibility (neglecting masking effects) is illustrated in curve 2.

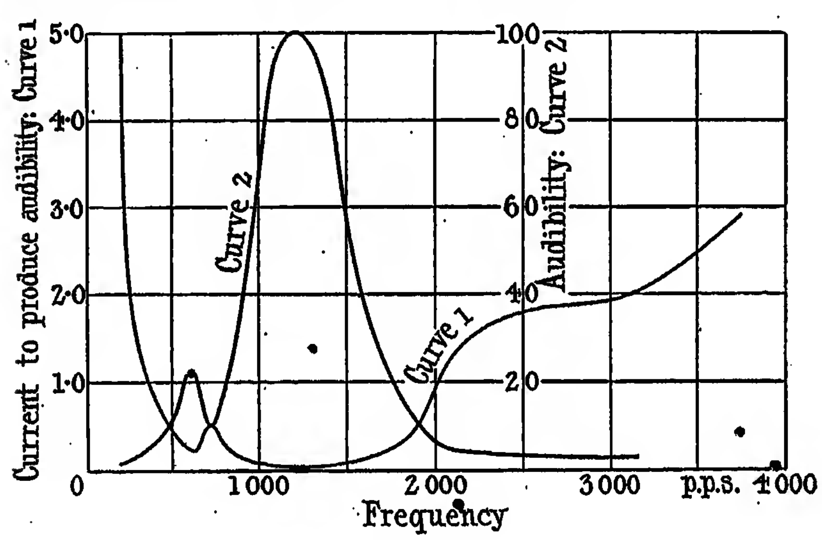

Fig. B.

The meaning of this is as follows: 2LO, received by a receiver in which there is no appreciable electrical distortion, on those telephones would give audibilities for the different frequencies as represented in the curve, instead of equal audibilities. If we try an experiment with that particular pair of telephones and insert in series with them a sufficiently damped rejector circuit so as to flatten out that curve very considerably, although we shall have reduced the total noise we shall quickly understand what fine quality we have missed without it, and we can increase the total sound much more than before without hurting our ears. Moreover, that annoying room echo in some transmissions is considerably reduced. Probably before long it will be possible for the National Physical Laboratory or the British Broadcasting Company to give us a frequency strength standard and then the difficulties of obtaining the audibility curves of our receivers will be less. I have taken up this question of what is being transmitted, and a simple case of its action on a telephone, to show those who are designing telephones and loud-speakers what the input is with which they have to work.

Mr. W. J. Brown: At the last meeting Prof. Fortescue drew attention to the necessity for using in the last stage of an audio-frequency amplifier a valve of considerable output, operating at an anode voltage of the order of 200. From the point of view of the broadcast listener the extra expenditure involved by the use of such high anode voltages is a serious item, while the use of a valve having a large electron emission causes an undesirable drain on the filament batteries. Hence it is of great interest to know exactly how much power a given valve operating at a given anode voltage is capable of delivering to an output circuit such as a loud-speaker without introducing distortion in the valve; this may be termed the "maximum distortionless output." In this connection the orthodox power rating of a valve is extremely misleading; for instance, a so-called 20-watt valve will be found to have a maximum distortionless output of only 0·01 to 0·1 watt, using an anode battery of 120 volts. In course of time, valve manufacturers will probably state the exact amount of power which their valves are capable

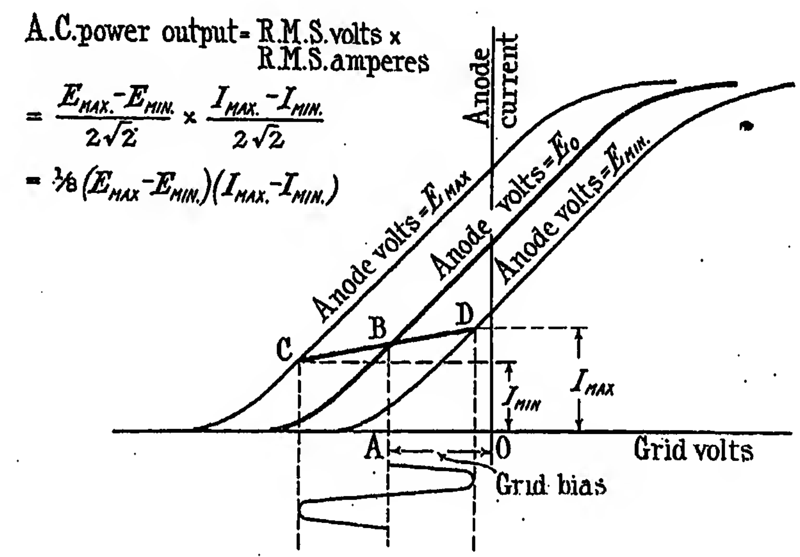

Fig. C.

of handling without distortion when operating at some standard anode voltage, but at present the user of a valve has to make his own calculations and I propose to develop a very simple formula whereby the maximum distortionless output can be calculated. The method has probably been used before, but apparently has not been published. The following assumptions are made: (1) That the output circuit is purely resistive—this, of course, is by no means true, but the case of reactive loads will be considered later. (2) That the waveform is sinusoidal. Though this, strictly, is only applicable to the case of a sustained pure note, the formula will apply equally well for comparative purposes to any wave-form. Suppose that the anode battery voltage is E_0, and that the thick-line curve in Fig. C represents the (anode current)/(grid voltage) characteristic of the valve at this voltage. Choose now a value of grid bias, say, OA. This gives the operating point B on the characteristic. If the a.c. voltage applied to the grid has the magnitude indicated in Fig. C, the operating point will move along some line such as CBD. The anode current will vary from $I_{min.}$ to $I_{max.}$, while the anode voltage will vary from $E_{max.}$ to $E_{min.}$ due to the resistance of the valve. The current

will attain its maximum value at point D at the same moment as the voltage reaches its minimum value. The a.c. power delivered to the resistive output circuit is obviously equal to the product of the R.M.S. anode current and the R.M.S. anode voltage, the alternating

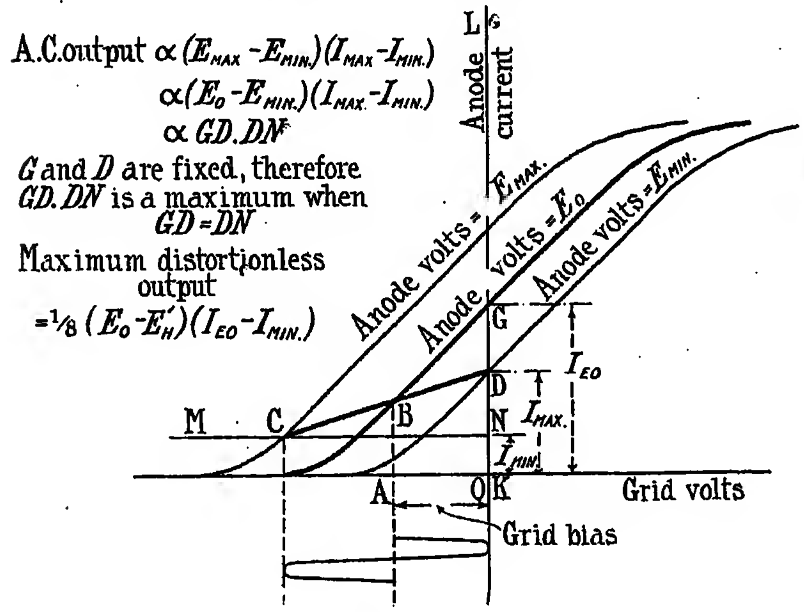

FIG. D.

components only being considered. When the valve is working along the line CBD this power is equal to

$$\frac{E_{max.} - E_{min.}}{2\sqrt{2}} \times \frac{I_{max.} - I_{min.}}{2\sqrt{2}}$$
$$= \tfrac{1}{8}(E_{max.} - E_{min.})(I_{max.} - I_{min.})$$

By increasing the length of the line CBD we can increase the power output. In practice, the length of this line is limited, at the left-hand end on account of curvature of the characteristics, and at the right-hand

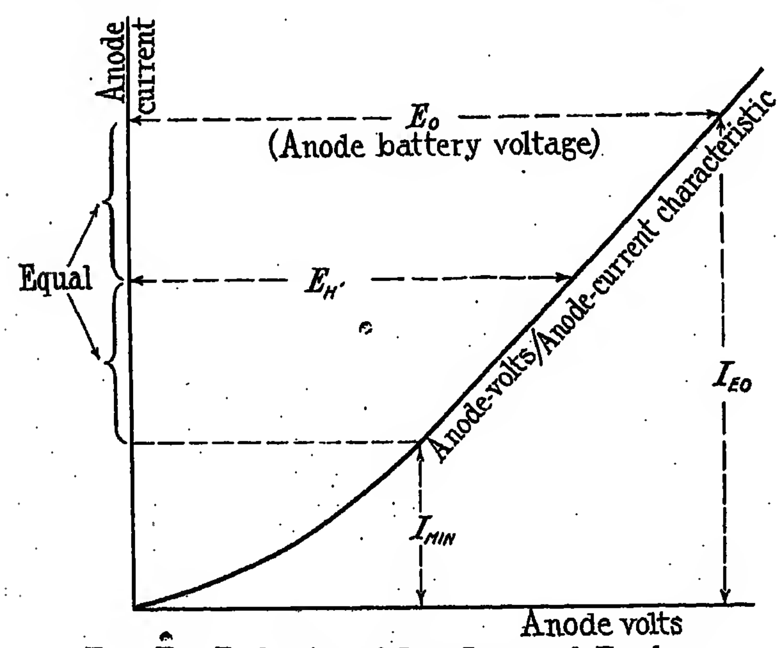

FIG. E.—Deduction of I_{EO}, $I_{min.}$ and $E_{H'}$ from characteristic.

end on account of grid current. In Fig. D the line KL is drawn to indicate the highest grid voltage we may attain without serious grid-current distortion, while the line MN indicates the minimum anode current attainable without curvature distortion. In Fig. D, KL has been drawn through zero grid voltage, while MN has been drawn through the bottom of the substantially straight portion of the characteristic. For maximum distortionless output, the extremities of the line CBD will lie on the lines MN and KL respectively. The problem is to find the conditions for maximum power, and then to calculate the power output under these conditions. As shown before, the power output is proportional to $(I_{max.} - I_{min.})(E_{max.} - E_{min.})$, or otherwise to $(I_{max.} - I_{min.})(E_0 - E_{min.})$. But $(E_0 - E_{min.})$

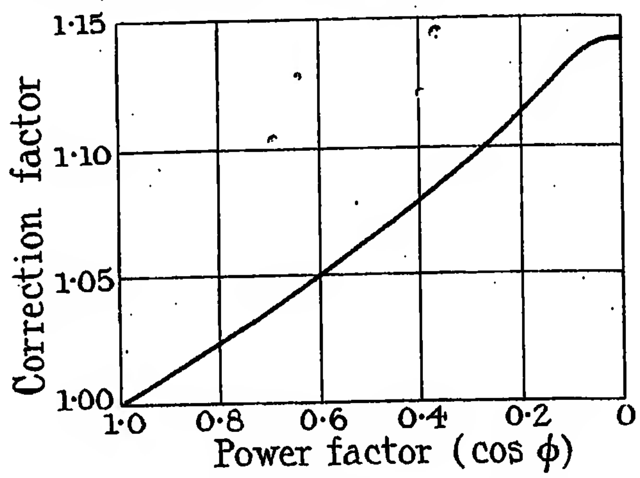

FIG. F.—Correction factor for formula
Max. distortionless output $= \frac{1}{8}(E_O - E_{H'})(I_{EO} - I_{min.}) \cos \phi$.

is proportional to GD in Fig. D, while $I_{max.} - I_{min}$ is equal to DN. Hence the output is proportional to the product of GD and DN. Since the sum of GD and DN is constant, the product, by a well-known theorem, has a maximum value when GD = DN. If a is the differential anode conductance of the valve, then GD on the current scale $= a(E_0 - E_{min.}) = \frac{1}{2}a(E_{max.} - E_{min.})$,

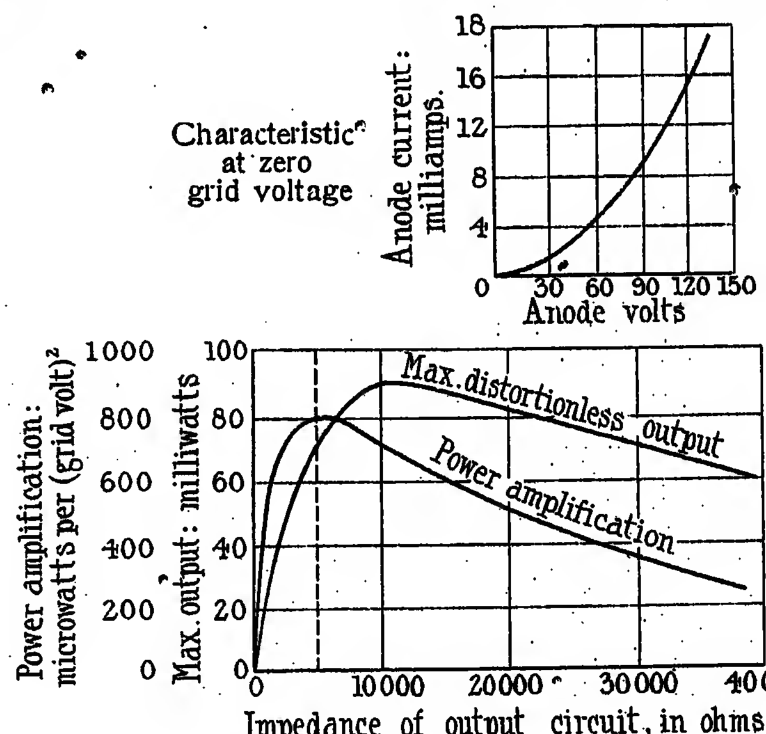

FIG. G.—Output and amplification curves of typcal power valve. Anode battery voltage 120.

while DN $= (I_{max.} - I_{min.})$ to the same scale. The condition for maximum output is therefore

$$I_{max.} - I_{min.} = \tfrac{1}{2}a(E_{max.} - E_{min.})$$

But $(E_{max.} - E_{min.})/(I_{max.} - I_{min.})$ equals the resistance R of the output circuit. Hence $R = \frac{1}{2}a$ is the required condition. In other words, the resistance of the output

circuit must be so adjusted that it is twice the anode resistance of the valve. We will assume that the output resistance is adjusted to this value, and proceed to calculate the maximum distortionless output under these conditions. Returning to Fig. D, let I_{E0} be the anode current at normal anode voltage E_0 and at the limiting positive value of grid voltage (in this case,

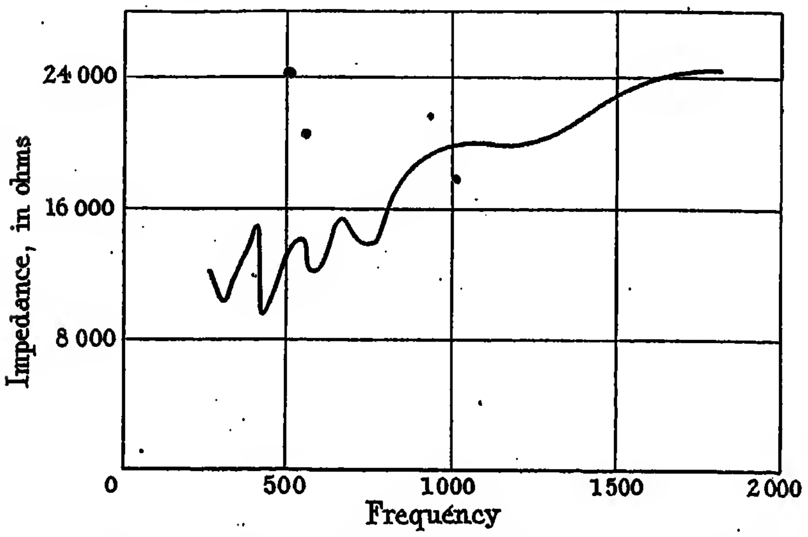

FIG. H.—Impedance/frequency curve of loud-speaker A. Testing current 2·0 mA; resistance 49·25 ohms at 20°C.

zero grid volts). Let $I_{min.}$ be the minimum anode current permissible from curvature considerations. Let E_H be that anode voltage which is required to give an anode current of $\frac{1}{2}(IE_0 + I_{min.})$ working at the limiting grid voltage. This is, in fact, the particular value of $E_{min.}$ which brings the point D midway between

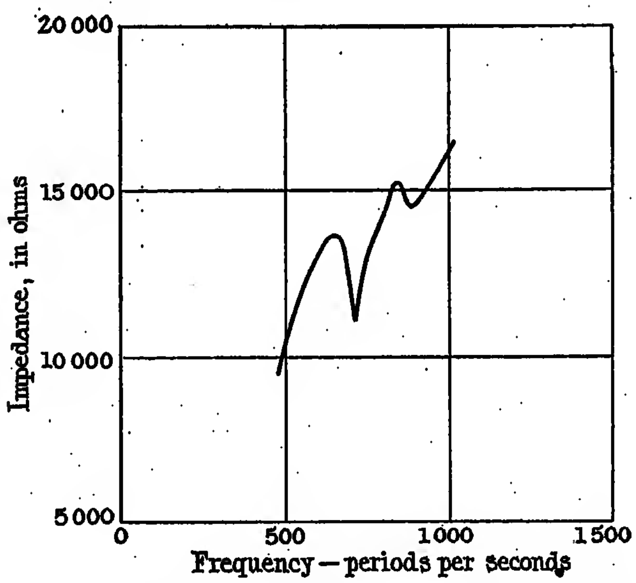

FIG. J.—Impedance/frequency curve of loud-speaker B. Constant current = 2·5 mA.

points G and N. The maximum distortionless output obtainable is then

$$\tfrac{1}{8}(E_{max.} - E_{min.})(I_{max.} - I_{min.}) = \tfrac{1}{4}(E_0 - E_{min.})(I_{max.} - I_{min.})$$

But $(I_{max.} - I_{min.}) = \mathrm{ND} = \frac{1}{2}\mathrm{NG} = \frac{1}{2}(IE_0 - I_{min.})$ and $(E_{min.} = E_H)$. Hence *maximum distortionless output* $= \frac{1}{8}(E_0 - E_H)(I_{E0} - I_{min.})$. Having chosen E_0 the anode battery voltage, the remaining three quantities IE_0, $I_{min.}$ and E_H, may be read directly from the (anode volt)/(anode current) curve, taken at the limiting value of grid voltage, as shown in Fig. E.* We read off I_{E0} directly from the curve, at the point corresponding to E_0, while $I_{min.}$ is selected from curvature considerations. E_H is the length of the abscissa corresponding to the current $\frac{1}{2}(IE_0 + I_{min.})$. No other data are required, so that the method has the advantage of extreme simplicity. The problem of an inductive load is more complicated and there is not time to work it out here. The line CBD of Figs. C and D becomes an ellipse, and we find that the maximum distortionless output is approximately equal to the expression obtained for the resistive case, multiplied by the power factor. The formula thus becomes $\frac{1}{8}(E_0 - E_H)(IE_0 - I_{min.}) \cos\phi$. In other words, the maximum distortionless output expressed in volt-amperes is more or less independent

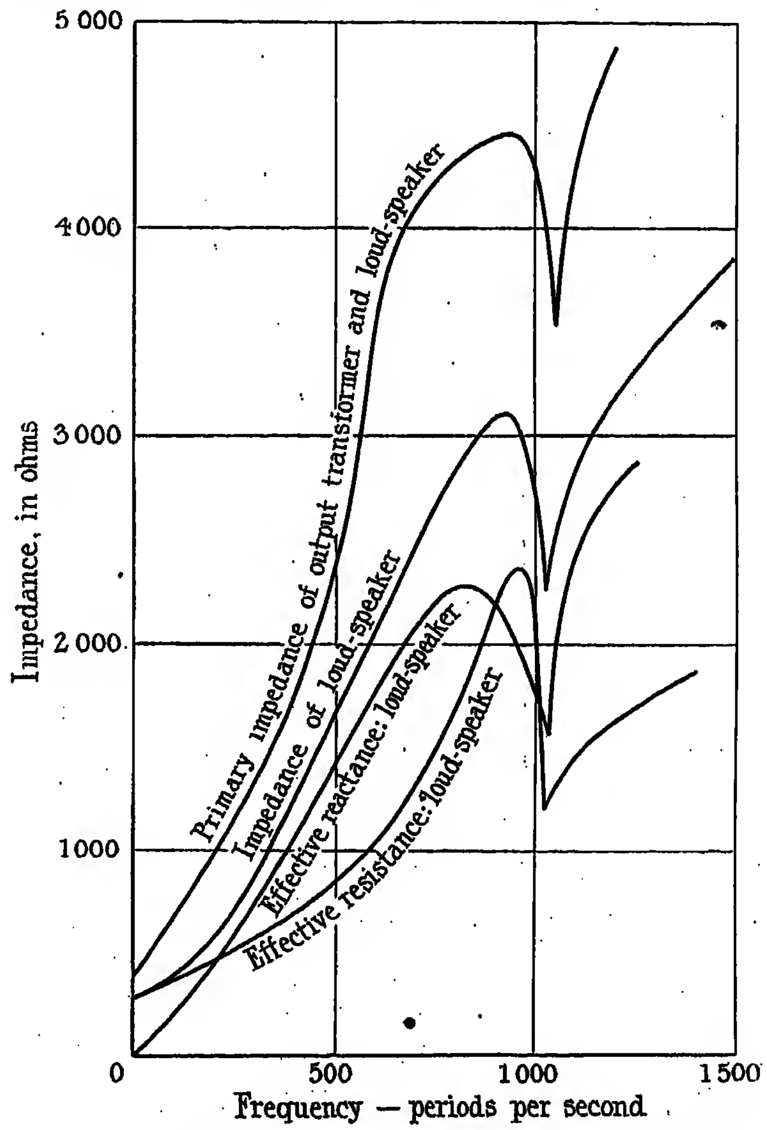

FIG. K.—Impedance/frequency curves of loud-speaker C. Constant current = 5 mA.

of the power factor. Strictly speaking, the figure obtained is rather more favourable for low power factors, and at power factors in the neighbourhood of zero about 14 per cent may be added to it. Fig. F shows the correction factor plotted against power factor. It is interesting to note that the output impedance must be equal to twice the anode resistance in order to obtain maximum distortionless output. On the other hand, the condition for maximum power amplification is met by making the output impedance equal to the anode resistance. Thus we cannot have maximum distortionless output and maximum amplification at the same time. Fortunately, the impedance adjust-

ment is not very critical. Fig. G shows the relative importance of the impedance adjustment for the two cases; this refers to a valve of 5 000 ohms anode resistance. Table A shows the output and amplification obtainable from three typical loud-speaker valves for the two optimum valves of impedance, using an anode battery of 120 volts. The very low value of the output figures will be noted: they vary from 0·27 to 0·086 watt, though the orthodox rating of these valves is of the order of 10 watts. In practice, the adjustment of the impedance of the loud-speaker to suit that of the valve is carried out by using an output transformer of suitable ratio or by suitably adjusting the windings of the loud-speaker. Only a very rough approximation can be made, due to the very wide variation in impedance of the loud-speaker as the frequency is altered. It is thus fortunate that the adjustment of this impedance to suit the valve is not very critical. Figs. H, J and K show impedance/frequency curves of typical loud-speakers and illustrate the amount of variation which may be expected. It will be noticed that these curves have very pronounced peaks, and each peak corresponds closely to a frequency at which the loud-speaker resonates. In fact, this forms a very simple method of detecting the resonant frequencies of a loud-speaker. Returning, in conclusion, to the calculation of the maximum distortionless output of a valve, the formula deduced—and indeed any formula—would depend on the values chosen for the limiting maximum grid voltage and for the limiting minimum anode current. These values can best be found by aural estimation, using a cathode-ray oscillograph for determining the limiting values reached. Prof. Fortescue has shown some cathode-ray oscillograms representing amplifier distortion. It would be interesting to hear whether he has investigated the amount of distortion, particularly of the grid current and of the curvature varieties, which may be introduced into an amplifier without detection by the human ear.

Mr. A. H. Davis: Given physical measurements of the output of loud-speakers, it remains for us to interpret the meaning of the results in terms of the effect on the human ear. Unfortunately, sufficient data for this are not available. It is, however, desirable to consider some of the acoustic determinations which enable us to appreciate the range of the ear and the way it behaves, and especially to consider those which throw light upon any side of the question of distortion. In normal conversational speech the pressure amplitude in the sound waves at 1 ft. from the mouth appears to be about 1 000 times as great as the minimum necessary for audition, and about 1/1 000th of the maximum that can be reached before tickling sensations and pain supervene in the ear. The total range of audible amplitudes is thus about a million-fold. It assists in appreciating these figures to note that persons not ordinarily called deaf may require up to 100 times the normal "threshold" value, and those who need a further hundred-fold increase are sufficiently deaf to require an ear trumpet. With respect to the capacity of the ear for detecting differences of loudness, it just discriminates between two successive notes of the same pitch when the amplitudes of vibration differ by 5 per cent. Thus equal increments of sensation result from equal increments in the logarithm of the stimulus. It is thus useful to plot intensities logarithmically. The figure of 5 per cent is, however, increased for faint sounds. It is found from these data that the million-fold auditory range can be covered in not more than 270 steps of increasing loudness, each one just perceptibly louder than the former. A two-fold amplitude change is equivalent to about 14 such steps, a hundred-fold to 94. The loudness of speech has some bearing on its distinctness, which is best for the medium level (1 dyne/cm^2) of normal conversation. Ten-fold increase or decrease in amplitude is almost without effect, but decrease to 1/100th reduces articulation by about 50 per cent. We find that consonants are more seriously affected than vowels by reduction of speech intensity. As stated by Sir Richard Paget, some of them are carried by very high frequencies, and in ordinary conversation 50 per cent of mistakes of interpretation can be traced to three of them alone. In these circumstances, and seeing that

TABLE A.

Maximum Distortionless Output in Milliwatts, and Power Amplification Factor in Microwatts per (Crest Grid Volt)^2.

(1) With output circuit impedance adjusted for maximum amplification, ($Z = 1/a$).
(2) With output circuit impedance adjusted for maximum distortionless output, ($Z = 2/a$).

Valve	$Z = 1/a$			$Z = 2/a$		
	Z	Amplification	Output	Z	Amplification	Output
	ohms	μW/V²	mW	ohms	μW/V²	mW
A	4 720	802	58	9 440	713	86
B	8 350	488	39	16 700	434	44
C	10 300	392	27	20 600	348·5	30

experience leads public speakers actually to emphasize their consonants, it is surely unfortunate that loud-speakers become weak at high frequencies. It must surely limit their use in acoustically difficult conditions unless the electrical system is designed to effect some compensation. With further reference to speech, the falling off of loud-speaker efficiency at frequencies less than 300 should have little effect on distinctness, but some change of character or raising of the pitch is to be expected. The normal male voice has a very pronounced low-pitched constituent of frequency about 120, and the female voice has one about an octave higher. To reproduce speech and to preserve all its characteristic qualities, frequencies from 100 to above 5 000 must be delivered with approximately the same efficiency. The amount of distortion permissible in reproduction of speech or of music will naturally depend upon circumstances, and no accepted criteria seem to be available. However, judging from threshold values —and there is some evidence to indicate that we may do so—there are certain imperfections in individual ears which probably set a limit beyond which accuracy of reproduction need not be carried. It is found that, although the average of several normal ears has fairly smooth sensitivity over the frequency range, the threshold sensitivity of a normal individual ear is not uniform, but exhibits maxima and minima at various frequencies peculiar to that particular ear. In a typical case, from two-fold to six-fold variations occur as the frequency range is covered. Different individuals have quite different characteristics, so that, apparently, music does not sound the same to different persons. Consequently, while the effect of distortion within, say, a two-fold limit might be detected, probably there would be divergencies of opinion as to whether improvement in quality had been effected. The *minor* peaks and resonances exhibited by the best loud-speaker curves appear to fall very near to the minimum thus indicated as the least distortion that normal individual ears could fully appreciate.

Mr. A. J. Aldridge : I wish to give some quantitative information in regard to the orders of magnitude occurring in loud-speakers, and to draw attention to a fundamental error which appears in many commercial instruments. Fig. L shows the diaphragm motions of a number of commercial loud-speakers operated with different inputs. The first point to be noticed is the very small extent of the motion. An average of about 0·05 watt in most loud-speakers will give sufficient volume comfortably to fill a normal private dwelling room, though this does not mean that this figure may not be considerably increased on individual notes. The corresponding diaphragm motion is usually less than ½ mil. Curves (*a*), (*d*) and (*e*) are for instruments constructed on the lines of an ordinary receiver, i.e. with a plain iron diaphragm. It will be noticed that the inwards motion considerably exceeds the outward for the same input [in the case of (*e*) by 30 per cent, with an input of 0·05 watt]. This means that very serious distortion, producing harmonics, will occur, and would appear definitely to bar this type of instrument for accurate reproduction for any but small inputs. Curve (*b*) is for a moving-coil instrument, and curve (*c*) for one with a balanced armature. The apparent greater efficiency of this latter model is probably due to the method of test. Direct current was used, and this makes no allowance for unavoidable losses due to slight slackness in the linkages used in this type of instrument. I have intentionally omitted any mention of resonance, which is dealt with by other speakers, but in selecting a loud-speaker it must, of course, be considered. Resonance is undoubtedly serious, but can be corrected, whereas the fault to which I have referred would appear to be only capable of correction by the use of a larger diaphragm and smaller motion, or the use of a larger air-gap, with corresponding increase of power. I think that insufficient attention has been paid to irregular diaphragm motion, which

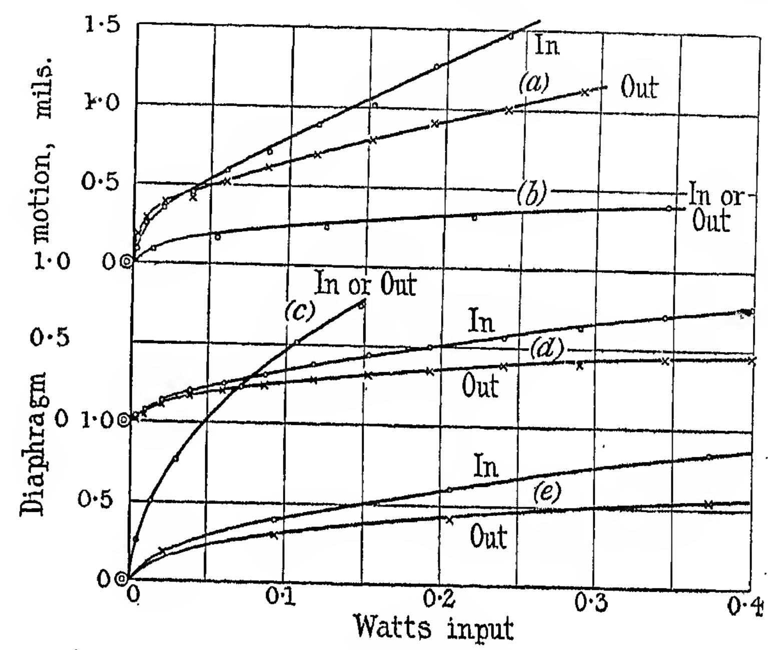

FIG. L.—Diaphragm movements in loud-speakers.

probably accounts for much of the faulty reproduction and poor tone appearing over the whole gamut of frequency unless very small amplitudes are dealt with.

Captain N. Lea : Prof. Rankine draws attention to the danger of reaction complications when a forced vibration begins to influence the form of the forcing vibration. The possibility of this happening in the mechanical parts of the system has probably been less obvious to those engaged in wireless research than that it should occur, for example, in the last stage of a thermionic amplifier. Prof. Rankine points out in his concluding remarks that in testing results it is not much use to attempt to obtain simultaneous visible records of the sound source and sound image (if one may use such an expression), because of the difficulties of attaining exact results and interpreting them in their audible equivalents. Nevertheless, in view of the fact that, as we approach more and more to fidelity of reproduction, audition becomes an increasingly difficult test to apply, I think that the process of feeding sensibly pure sine oscillations into the apparatus under test, and of watching the results by instrumental means as the frequency of the oscillations is varied, must always be followed. Prof. Fortescue has described some of the difficulties of amplifier design, but he has not exaggerated them because he has taken no account of the limitations imposed upon any design intended

to cater for the domestic user. It is, for example, impossible to expect the music-lover to fill his house with high-voltage batteries, and it is taking some time to persuade people to use an adequate number of valves which are large enough to ensure good results. In discussing the horn, which forms part of the conventional loud-speaker, no one seems to have referred to the polar distribution of radiated sound energy at various frequencies. I do not know whether other observers have noticed, as I have done on frequent occasions, that even if the frequency balance is good when the ear is in a line with the horn opening, it may happen that a large percentage of the upper part of the sound spectrum is missing when the ear is moved to one side of this line. It may be of interest to describe an arrangement which I have employed with rather pleasing results. The device may perhaps best be described as a spectroscope for audible frequencies. It consists of two main portions, first a rotating spindle for the purpose of controlling the frequency of the oscillations imposed upon the apparatus under test, in such a manner that it sweeps over the whole audible scale during the revolution of the spindle. The spindle has mounted on it a variable condenser of the semi-circular vane type which is connected to one of two high-frequency oscillators employed for the production of beats, which latter, when rectified, are used as a variable-frequency source for testing apparatus within the audible scale. The second part of the device consists of a cathode-ray oscillograph with its auxiliary apparatus. By this means it is possible to cover a very large frequency range without altering the constants of the oscillating circuits by more than a very small percentage, and hence one may be reasonably certain that the amplitude of the beats produced does not vary with their frequency. There is, of course, the risk that this method of setting up a variable-frequency source may give trouble owing to interaction between the two oscillators and also to the departure from sine wave-form of the beats when rectified. It is also necessary to employ a fairly high decrement in the high-frequency circuit attached to the rectifier, in order to prevent a change of amplitude in the induced current when the frequency of one of the oscillators is changed. The application of the beat frequency of the apparatus under test gives rise to an E.M.F. on the output side which can be applied to one pair of deflecting plates in the cathode-ray oscillograph. A rotary potentiometer is mounted on the same spindle as the variable condenser already referred to, and this furnishes an E.M.F. which can be applied to the other pair of deflecting plates for the purpose of spreading out the output indications at various frequencies and thus giving a spectrum band. The potentiometer merely separates the various frequencies in the same way as a prism does in an optical spectroscope. A commutator is also mounted on the spindle in order to prevent a second image being obtained when the condenser is passing through the second half of its revolution, and when, in consequence, the frequency band is traversed in the inverse direction. The spectrum produced consists of an illuminated band, the width of which at any point is a measure of the response experienced at the corresponding frequency. By mere inspection it is possible not only to discover faults in the distribution of response, but also instantly to observe the effect of any steps taken to improve the results. Some speakers have raised the question of the relation between the sensitiveness of the human ear and the frequency impressed upon it. Surely it would be wrong to introduce such a function into the design of a loud-speaker, because it is only by making the output a copy of the original that we can hope to deceive the listener into believing that he is, in fact, listening to the original. Any device for the correction of ear-frequency balance would (like spectacles) have to be a personal matter, and unless the arrangement could be attached to the head it would seem necessary to put the sub-normal listener with his special loud-speaker in a room by himself.

Mr. G. C. Marris: I cannot agree with all that seems to be inferred from the facts given in this discussion. As each speaker has presented his own particular problem, the general effect is that nothing can be done. Perhaps this is true so long as we make no clear decision as to whether we will have more quality or more volume. In other words, ought we not to develop two distinct types of loud-speaker, or perhaps three? These would be, first, a general-purpose instrument, as most of the instruments on the market seem to be. They give plenty of sound for a large private room or for the entertainment of a small private party. They reproduce speech very clearly and give music which is pleasant to listen to for a short time. Only a comparatively small valve is necessary for their operation. The second class would be the new one, and would be a type of instrument working off the largest output valve practicable in a private house, suitable only for use in a small room or by persons sitting close to the instrument, with resonance of every kind suppressed to the lowest limit at the expense of volume and designed to cover a wider range of frequencies. The third class exists already in the instrument used for large halls and audiences. Since a fairly wide range in the matter of power supply is permissible with this type, the problems of design should be simpler, or perhaps it is more correct to say, less obvious. With these possibilities, more particularly Class 2, in mind, I should like to comment on the remarks of some of the previous speakers. Several have suggested that the horn is the ideal form of coupling between the electrical system and the room. It is indeed to be hoped that this is not the case. I have listened a good deal to loud-speakers, and in all cases have become very tired of the horn resonance. That it is horn and not diaphragm resonance is easily proved by removing the horn. If we are to make an electrical analogy it must be to a resonance transformer or a very short transmission line, neither of which is a good coupling device. Further, there is the fact that the actual musical instruments with wider frequency-ranges, such as the violin and piano, have no horn. The other point is in connection with valves. Having had to urge the use of valves of large output, I am very pleased to read Prof. Fortescue's summary of the various forms of amplifier distortion. I should

like to corroborate his remarks in regard to the distortion due to the valve itself. Measuring the characteristics of a valve with a power output of about the maximum practicable for a private set, I found that for about 1 volt (peak) on the grid the second harmonic was 0·4 per cent of the fundamental, while for 5 volts (R.M.S.) on the grid the second harmonic was 1 per cent of the fundamental. If, however, one attempts to obtain under the same conditions so much power out of, say, an R valve, the higher harmonics would be of the order of 50 per cent. of the fundamental. It seems to me, however, that Prof. Fortescue's remarks on page 272 on the output required should be qualified, as otherwise we should have to condemn, I think, unnecessarily a large proportion of existing loud-speaker outfits. Using the ordinary loud-speaker which makes use of horn resonance, an ordinary room can be pleasantly filled with speech or music if a valve having a maximum distortionless output of, say, 5 milliwatts is used. I believe that this power covers 90 per cent of the loud-speakers in use. Here, it seems to me, is the great opportunity for the quieter, better-quality type of loud-speaker referred to above as Class 2. Let us make use of the larger-output valves capable of giving 50 to 100 milliwatts of power with reasonable voltages, but direct this power to the improvement of quality, not of volume. It seems quite practicable to design valves with still larger distortionless outputs at reasonable voltages, but at present there is no loud-speaker which is capable of making good use of such power in a small room. In connection with the formulæ given to-night for output, there is a very simple way of getting the figure from the constants of the valve, pointed out by my colleague, Mr. A. C. Bartlett. If v be the length of the straight part of the valve characteristic on the negative side of zero, at the particular anode voltage applied, then the R.M.S. grid voltage which can be applied to the valve without causing distortion is nearly $\frac{1}{2}v$, and the distortionless power output is therefore approximately $(m^2 v^2)/16R$, where m is the amplification factor and R the anode filament resistance, usually known as the internal resistance of the valve. It is useful to note that $\frac{3}{4}v$ is also the optimum value of the direct-current negative voltage at which to work the grid.

Mr. W. E. Burnand: From what has already been said and demonstrated it is very obvious that there are many other factors connected with loud-speaker reproduction than the loud-speaker itself, and that many faults which are blamed to the loud-speaker may be traced to something else. The extra output on certain notes—similar to what is called the "wolf" note in some violins—can often be traced to the amplifier. One can imagine an amplifier with a tendency to oscillate, working near that point. When a signal comes through of the same frequency the two together will give rise to this "wolf" note. It may be the loud-speaker, but the fact remains that, in many cases, by altering connections or applied potentials it can be got rid of, thus showing that the amplifier and not the loud-speaker is at fault. There still remains the trumpet tone and the various other resonances. Apart from these, I think sufficient prominence has not been given to the effect of harmonics and overtones. All the experiments or curves connecting output with input which have been shown are with pure tones. I think that the overtones and harmonics are of equal importance, even beyond the audible range, in the effect produced by the speaker, since these form beats within the audible range. I was led to suspect this by running two loud-speakers in series, a large Brown and a large Western, about 6 ft. apart, and standing 8 ft. away from them. The input to each was exactly the same, and yet, listening for a period, it was curious how the sound appeared to emanate first from the one and then the other, and how at other times the outputs of the two were approximately the same. It does not mean that one loud-speaker takes charge of the high notes and the other takes charge of the low notes. It seems to be a matter of the timbre quite as much as of the high or low notes, and the timbre is of course due to the various frequencies and harmonics. For instance, the sound of a flute would appear to come from one instrument, and the announcer would appear to speak through the other. The explanation that this might be due to the standing waves is I think also done away with by the fact that one appeared

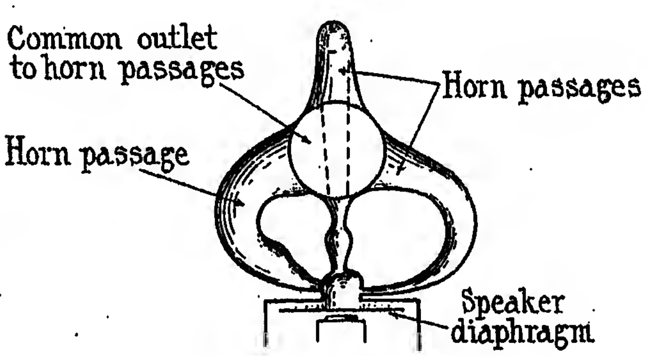

Fig. M.

to take charge for a matter of some seconds, during which a considerable number of notes were sounded, and the position of those standing waves would vary with the note. I think, therefore, that one horn or one air passage cannot be the best thing for all classes of music or all tones, and that it is possible to get a much better result by having either a number of horns or a number of air passages, which might be combined in one outlet. This is shown in rough diagrammatic form in Fig. M, several horn passages of different length and configuration branching out from the sound box and meeting again at a common outlet. I was interested in the demonstration showing the modes of vibration of a diaphragm, but I cannot think that those apply even approximately to a diaphragm such as is used in the Brown instrument with a conical diaphragm, or to the Western with the concentric corrugations, or to the loud-speaker with the radial corrugation shown by Captain Eckersley. Having designed transformers for 30 years and personally evolved some 9 000 different windings, some of which are, of course, now obsolete, I must say that the average transformer put in a wireless amplifier on the low-frequency side is very much worse than might be expected from the firms who, one would imagine,

should know better. On the question of the open circuit compared with the closed magnetic circuit transformer, they both have their defects. For the amplifier a transformer with characteristics lying somewhere between those of the series and the ordinary shunt transformer is required, i.e. both the magnetic and current densities vary, and also there is a d.c. component. With a closed magnetic circuit, that component shifts the flux to one side of the neutral position. Therefore the alternating component of an average of 1 000 frequency must give a distorted output. Going to the other extreme, there is the open-circuit transformer used with a straight core, which, as is well known, requires quite a large magnetizing current. Many papers have been written to show that the output does not then match the input, especially under the conditions used in an amplifier, where the amplitude varies with inductive and capacity reactance as well as resistance. I think, therefore, that for good results something between the two is necessary, i.e. a transformer with a nearly closed magnetic circuit, with an air-gap (a few thicknesses of paper will give sufficient spacing) of 1 or 2 per cent of the length of the magnetic circuit. The old Edison "electro-chemical" telephone was, I believe, the first of the loud-speakers in which the diaphragm vibration was augmented by varying the friction on a revolving element. According to an old book,* this consists of a flat spring, attached to a 4-inch mica diaphragm at one end, pressed by a rubber pad on to the surface of a revolving cylinder of moist gypsum impregnated with potash and mercuric acetate. The spring is made negative. Used with a contact point on the end of the spring touching the cylinder, this is also employed as a transmitter.

Dr. H. M. Barlow: I should like to say one or two words about a novel type of telephone which I am now

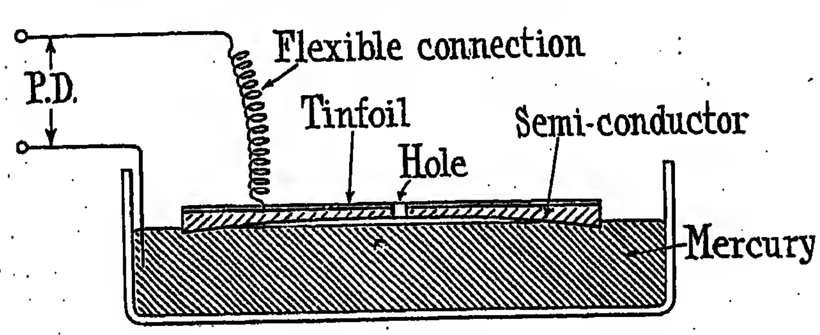

FIG. N.

engaged in developing, and which Fig. N will help to explain. The so-called Johnsen-Rahbek effect, involving the electro-adhesion set up between a solid metal and a semi-conductor which are in contact and have a potential difference between them, is well known, but I do not think it is generally known that the same effect is obtained with a semi-conductor in contact with a liquid metal such as mercury. I made this observation myself some time ago,† and I have applied it to a telephone, among other instruments. Take, for example, a piece of semi-conductor such as lithographic stone or slate, in the form of a thin disc, and make the underside of it concave or convex, so that when floated on a pool of mercury the surfaces do not make contact over the whole area. Cement a piece of tinfoil to the upper surface of the disc, and apply a varying P.D. between it and the mercury. The semi-conductor will then oscillate on the surface of the mercury, due to the variation in the electrostatic forces operating across the interface. If a telephonic voice current is employed, speech is reproduced. An alternative method of producing sound is to bore a small hole through the centre of the disc so that, when it is pulled down, the air is squeezed out of the confined space between it and the mercury. The arrangement has given very good results with a 2-valve receiving set working on 2LO.

Mr. P. G. A. H. Voigt: So far only one or two speakers have said anything in favour of the present-day loud-speaker. One of the accusations which is generally levelled against it is that of chronic inefficiency. I do not believe that the peak of efficiency is much more than 10 times the average efficiency, and I shall now show one experiment to prove that the loud-speaker's efficiency is more than the fraction of 1 per cent with which it is generally credited. It is an experiment which has been known to telephone engineers for many years. It is a kind of Hopkinson test. The power from the loud-speaker, acting as a microphone (quite a good microphone too), is fed through a telephone transformer to the input circuit of an ordinary single-valve note magnifier. The output goes through another telephone transformer to the other loud-speaker, and the sound output is sufficient to maintain an oscillation. If we take the extreme theoretical case of an efficiency for that stage of note magnification of 75 (transformer 5 : 1, valve amplification factor 15), then the efficiency of our loud-speakers is the reciprocal of the square root of that figure, i.e. between $\frac{1}{8}$th and $\frac{1}{9}$th of 100 per cent, say 12 per cent at the most efficient frequencies. If we take a more reasonable figure of 25 for the stage of note magnification, we get a peak efficiency of 20 per cent, which is very far removed from 1 per cent. It can quite easily be shown that it will oscillate on several notes, but there are definite gaps. [Demonstration.] I think those gaps explain the reason why with two different loud-speakers in series the sound apparently wanders from one to the other. There is another efficient point among the lower notes. I expect that one is the air-column resonance of the air in the horn and the first is the mechanism resonance, and I believe that the greater part of the loud-speaker distortion, when the loud-speaker is responsible for it, is due not to the horn but to the mechanism. We have been told that the resonance in a telephone can be compensated for very easily by a suitable, tuned circuit, and we have also been told on good authority on previous occasions that the present-day loud-speaker which is fairly well evened up cannot be so compensated. Recently I listened through my loud-speaker to the opera, and at the end of it I concluded that although the results were very good, they were not quite natural, and I remembered a circuit which I had drawn out in

* "Electricity in the Service of Man" (Cassell and Co.); also see H. M. Barlow: "An Investigation of the Friction between Sliding Surfaces," *Journal I.E.E.*, 1924, vol. 62, p. 183.

† *Journal I.E.E.*, 1924, vol. 62, pp. 143 and 156–158.

May 1922 but had not yet tried. In that arrangement a loaded telephone and a closed telephone—that is, one with the front covered up—were used in a Wheatstone bridge, and instead of having a galvanometer at the junction points I had the primary of a transformer which fed back the difference into the grid circuit, thus attempting to even up the output by balancing the loaded against the unloaded telephone. I tried that arrangement with loud-speakers, but the difference between the two is so slight that it is necessary to feed back several stages to get any change at all, and the result even then is only howling at various frequencies. But with a slight modification; i.e. disconnecting the closed loud-speaker from its transformer and reducing the impedence of that transformer, an arrangement is obtained which I think gives results a little more natural than the usual circuits. [Demonstration.] The effect is best shown when there is a full orchestra, or preferably the opera, in which all the instruments are present. In the 2LO orchestra I understand that the bass instruments are omitted for the simple reason that they do not reproduce. Therefore a loud-speaker which would reproduce them if they were there cannot properly prove its superiority. I can switch over from the compensating arrangement to the other, but that can only give an indication of the change. If it is

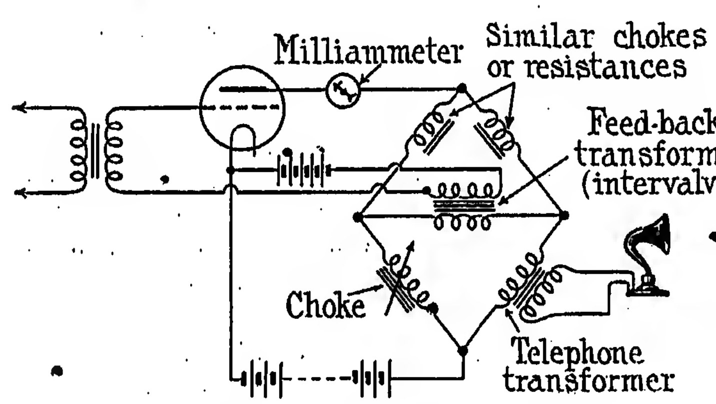

FIG. O.—Compensating circuit.

desired to find out what the difference really is, the characteristics of the loud-speaker must be well known. People ignorant of any change have remarked on the difference although they had not heard the instrument at work for several days. Actually the change-over on the switch does not seem to indicate anything like this difference. I should like to point out that the efficiency is only slightly reduced, and when several people are speaking together the voices appear to come out separately instead of all together. Further, the lower, and sometimes the higher, notes come out better, while the middle notes are suppressed or muffled. The compensating circuit is shown in Fig. O. The musical scale with its harmonics covers 10 or 11 octaves. The ordinary loud-speaker is fairly efficient over the two octaves which are most used (say 300 to 1 200 cycles per sec.). The resulting distortion is most noticeable with a piano. The human voice sounds high-pitched; an orchestra sounds as though the instruments were differently distributed; and most solo instruments sound like similar instruments of different tone. Because of this, the perfect loud-speaker, or a perfectly compensated loud-speaker, will not seem much more natural than those we have at present, unless the reproduced music can be directly compared with the original. After knowing a certain loud-speaker for a long time, however, the ear becomes very sensitive to its imperfections, and notices any improvement at once, although, to a stranger, both reproductions may sound equally perfect. The question of transformer distortion has been raised. I find that with reasonably good transformers the distortion is hardly perceptible even with a compensated loud-speaker. One great difference between a resistance-coupled and a transformer-coupled amplifier is that if we attempt to overload the valves of a resistance-coupled amplifier it shuts down, whilst the corresponding transformer-coupled amplifier distorts. Instead of the operator, it is the transformer or loud-speaker that is blamed. In conclusion, I greatly regret that many firms are now incorporating the parallel condenser in their loud-speakers. This condenser, by reducing the efficiency at the highest frequencies, not only spoils the reproduction but by masking valve distortion encourages users to overload their valves and spoil the reproduction still further.

Mr. C. M. R. Balbi (*communicated*): Professor Fortescue's work on the power amplifier has shown that distortion is not due to the amplifier if the apparatus is properly designed, while others put the blame directly on the diaphragm of the loud-speaking device. The sound pictures of Professors MacGregor-Morris and Mallett are very convincing in this respect, and one feels obliged to agree with Mr. Pocock when he remarks that "Present-day electromagnetic loud-speakers are without exception a compromise between relatively good efficiency and good quality." The main line of attack towards better articulation is to obtain an improved form of diaphragm. One or two practical suggestions have been made to overcome this defect, but those responsible for them seem to admit that they are still a long way from the correct solution. In an attempt to solve this problem I have devised a system in which the inherent inertia and the natural frequency of the diaphragm have been completely eliminated. This is accomplished by vibrating the diaphragm continuously at a slightly supersonic frequency by electrical means, and then producing the required articulation either by modulating the energizing source or by varying the friction between two rubbing contacts to obtain the same result, as in the case of the Brown "Frenophone" or the Johnsen-Rahbek loud-speaker. The active part of the diaphragm of this apparatus may be as much as 8 or 10 inches in diameter. Among the advantages of this system is the fact that a very much larger volume of sound can be controlled by a single unit than has hitherto been possible.

Mr. F. E. Smith (*communicated*): Professor Rankine has suggested that it ought to be possible to make a direct comparison between the original and the reproduced sounds. Such a comparison is possible and can easily be made by means of an oscillograph if the latter enables two records to be made simultaneously. In practice the speaker (or source of sound) and the receiver should be housed in the same building, an easy matter

to arrange in the 2LO station. In addition to the oscillograph, two telephone receivers, as identical as possible, would be needed; these receivers should be connected to the oscillograph and when a sound is made in front of them the two traces should be practically identical. Distance and echoes must, of course, be taken into account. In an experiment with speech the speaker would broadcast as usual, but one of the telephone receivers would be placed near the transmitting microphone, and the other would be acted on by the reproduced speech from the loud-speaker. Two oscillographic records would thus be obtained, one corresponding to the original and the other to the reproduced sound. The difference between the two records would be due to the distortion produced in the link, made up of microphone, amplifier, transmitting set, receiving set and loud-speaker. Such an experiment has not to my knowledge been made, but it presents no great difficulty. I have taken many speech records with oscillographs and obtained excellent results. Records of speech would not be very useful. A good plan would be to have fairly pure tones from tuning forks varying in frequency from 50 to 5 000. At first, single tones should be transmitted, but afterwards it would be well to transmit two notes simultaneously. Differences in amplification should not be difficult to detect by analysis of the resultant curves.

Mr. L. W. Wild (*communicated*): I desire to discuss in some detail a cause of tone distortion which is very generally met with and which I consider has not yet received adequate attention. It is common practice to operate a loud-speaker by means of two low-frequency valves. It is the distortion occasioned by the valve coupling that is in my opinion the worst offender in receiver design. This coupling is generally effected by means of an iron-cored transformer with a moderate step-up ratio. The standard pattern of transformer has a primary inductive impedance of about 10 000 ohms on 260 periods (middle C). The valve preceding the transformer has an internal impedance round about 100 000 ohms. An unloaded transformer working below its resonance frequency (about 1 500 periods) may be considered to be a simple inductance. The valve impedance may be considered to be simply a resistance. We thus have a resistance in series with an impedance, the former being the predominant partner at all frequencies below resonance. An inductance has the property that its current and E.M.F. waves are different in form, unless both are pure sine waves. Every harmonic present in the current wave is intensified in the E.M.F. wave. For example, a third harmonic in the current wave comes out exactly three times as strong in the E.M.F. wave. It follows from the foregoing that on all fundamental frequencies except for about one octave near the resonance point, the harmonics in the current wave will be substantially the same as in the E.M.F. wave impressed upon the grid of the first valve and, in consequence, the harmonics in the E.M.F. wave impressed upon the transformer and passed on to the grid of the second valve will be greatly intensified, thus causing tone distortion. Could, however, the inductive impedance of the transformer be greatly increased so that throughout the musical scale it was several times the impedance of the preceding valve, we should have an E.M.F. wave impressed upon the grid of the second valve substantially similar to that impressed upon the grid of the first valve, with practically no tone alteration. I have worked out a design for a transformer having an even ratio and an inductive impedance of 2 megohms on 260 periods, or about 20 times the impedance of an average valve. The weight of this transformer would be 40 lb., and I am afraid that it would not be considered an ornament in the drawing-room. But why use a transformer at all? A simple inductance constructed on the same lines but without a secondary winding can be made having the desired impedance and not weighing more than 5 lb., which is, I think, within the limits of size, weight and cost requisite to meet with approval. I have made several of these inductances and have distributed them amongst my friends, all of whom report that by substituting these for their former transformers they have effected a marked improvement in tone reproduction besides obtaining an increase in volume of sound. The increase in volume is no doubt due to the fact that full advantage is taken of the amplification factor of the first valve, which is not the case with a transformer, and is not compensated for by the step-up ratio. These inductances have an inductive impedance of 2 megohms and a capacitative impedance of rather over 4 megohms on 260 periods. Their impedance is therefore several times that of the preceding valve over the whole range of the piano scale. The same tone reproduction can be obtained with the well-known but little used resistance coupling, but under the best conditions the amplification realized with this form of coupling cannot exceed half that obtained with inductive coupling if the same number of high-tension cells are used. Because I condemn the employment of transformers for valve coupling it does not follow that I cannot find a place for them in some part of a receiver. A potential transformer following a crystal and preceding a valve is a perfectly legitimate appliance to use, provided that no high-frequency amplification is employed. A treated galena crystal has an impedance of only about 400 ohms, and if the transformer has a low primary resistance, an impedance of about 10 000 ohms on 260 periods and not too much self-capacity, there should be practically no tone distortion. To design a potential transformer free from tone distortion for employment in this position is not difficult. What is more difficult is so to adapt the design as to obtain the maximum volume of sound, and, for this purpose, consideration has to be given to the oscillating circuit from which all power must be drawn. Most of our present transformers are fairly efficient in this respect but could probably be improved somewhat by about trebling their weight.

[The replies of the authors of the introductory papers will be published later.]

INSTITUTION NOTES.

Faraday Medal.

At the Ordinary Meeting held on the 31st January, 1924, the President announced that the third award of the above Medal had been made to Dr. S. Z. de Ferranti, a Past President of the Institution.

George Montefiore Prize.

The 1923 award of the above prize has been postponed to 1925, the last date for the receipt of papers being 30th April, 1925. Full particulars of the prize, the value of which on this occasion will be 22 500 francs, can be obtained from the Secretary, Association des Ingénieurs Électriciens sortis de L'Institut Électrotechnique Montefiore, 31 Rue Saint Gilles, Liège.

The Benevolent Fund.

The following Donations and Annual Subscriptions were received during the period 26 January–25 February, 1924 (excluding those paid direct to the Institution bankers which will be published later) :—

THEORETICAL AND EXPERIMENTAL STUDY OF THE ELECTRIC FIELD IN AN ELECTROLYTIC CELL.*

By ABDEL AZIZ AHMED, Ph.D., M.Sc.(Eng.), Associate Member.

(*Paper first received 11th September, and in final form 7th November, 1923.*)

SUMMARY.

The paper has for its principal object the theoretical and experimental investigation of the electric field produced when a current flows in an electrolytic cell having plane parallel electrodes.

On the theoretical side a general expression for the electrolytic conductance is derived in terms of the stream flux and the potential difference between the electrodes, and is applied to special problems of complex transformations. The distribution of the electric stress along the surface of parallel plane electrodes is also determined mathematically (see Section 1).

The experimental work has been planned with two objects in view: (1) To verify the theoretical results by means of experiments in which the mathematical conditions are represented with sufficient and reasonable accuracy (see Sections 2 and 3); and (2) to apply the theoretical results for the solution of certain practical questions, and to investigate experimentally how far such applications agree with test results (see Section 4). Both objects have been in some measure satisfactorily attained.

On the side of electro-physics the validity of Ohm's law is proved for any elemental current in the electrolyte by a direct experiment devised for this purpose (see Section 3). The significance of this result lies first in its providing tangible evidence of the coincidence of stream lines with lines of force everywhere in the electrolytic medium, and secondly, in its proving that under certain conditions an electrolyte may be taken to represent a perfect homogeneous dielectric with something approaching mathematical precision. As an example of the practical application of this theorem, a method is derived for calculating the conductance of such apparatus as metal-refining and simple electro-deposition tanks, and certain types of liquid rheostats. A practical chart which is provided for this purpose may prove useful to the designers of such apparatus (see Section 4).

Furthermore, the results obtained may find a field of application in the measurement of electrical and magnetic phenomena where the distribution of energy is analogous to that shown to exist in the electrolytic cell, as, for example, the capacity of an irregular system of conductors or the reluctance of a magnetic circuit.

TABLE OF CONTENTS.

TABLE OF CONTENTS—*continued.*

1. MATHEMATICAL STUDY OF THE ELECTRIC FIELD IN AN ELECTROLYTIC CELL.

Consider an electrolyte* in which a steady flow of current is maintained by the application of a potential difference between two conducting electrodes immersed in it. Various points in the electrolyte will in general be at different potentials. There will be a system of equipotential surfaces which are intercepted orthogonally by tubes of flow, indicating by their orientation the direction of the current at any point in the electrolyte. The representation of current distribution is analogous to that of an electrostatic field, and in what follows we shall begin by assuming that the tubes of flow coincide with Faraday tubes in the electrostatic field which would be produced in an analogous dielectric medium.†

Experiment shows that Ohm's law applies to electrolytes as precisely as to metallic conductors. Consider an element of a tube of flow passing through a given point P in the electrolyte. Let its length be ds and its cross-section a. Let i be the current density at P, and k the conductivity of the electrolyte. Then if dV be the potential drop in the elemental tube we have

$$dV = \frac{1}{k} \times \frac{ds}{a} ia$$

or

$$\frac{dV}{ds} = \frac{i}{k} \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad (1)$$

where dV/ds is the potential gradient at P.

We shall now investigate more fully the analogy

* The Papers Committee invite written communications (with a view to publication in the *Journal* if approved by the Committee) on papers published in the *Journal* without being read at a meeting. Communications should reach the Secretary of the Institution not later than one month after publication of the paper to which they relate.

* The present discussion deals in particular with an electrolytic medium, but the same method of reasoning holds good for any conducting medium.

† The question as to whether stream lines follow the lines of force or whether they may be deviated by electromagnetic action has received attention. The results show that there is no electromagnetic effect (see R. HEILBRUN, *Annalen der Physik*, 1904, vol. 15, p. 988). The magnetic effect of electrolytic current was investigated by S. SHELDON and G. M. DOWNING (*Physical Review*, 1898, vol. 7, p. 122), where it was shown that an electrolyte contained in a rubber spiral produced the same electromagnetic effect as a metallic conductor having the same number of ampere-turns.

between the electrostatic and the current fields in the electrolyte, and for simplicity we shall assume that:

(1) The electrolyte is of infinite dimensions and that current flows between two electrodes immersed therein.
(2) The electrolyte is homogeneous and has constant conductivity throughout.
(3) The flow of current is steady.

Let V_1 and V_2 be the potentials of the electrodes, so that their potential difference is $V_1 - V_2$. Suppose the electrolyte to be replaced by air, and let each electrode receive an equal and opposite charge until the potential difference becomes equal to that in the current problem. The potential of the electrodes, however, may or may not be equal to that in the current problem. Let E_1 and E_2 be the new potentials of the electrodes. We have

$$V_1 - V_2 = E_1 - E_2$$

Let $E = V + C$.

Then we get

$$\frac{dE}{dr} = \frac{dV}{dr} \quad . \quad . \quad . \quad . \quad . \quad . \quad (2)$$

where dr is the outward-drawn normal at a given point on the electrode surface.

From Equation (1) the current flowing in the direction dr per unit area of the electrode surface is given by

$$i = k\frac{dV}{dr}$$

and the total flow of current from the electrode is

$$I = k\iint\frac{dV}{dr}dS$$

where dS is an element of the surface of the electrode. From (2) we also have

$$I = k\iint\frac{dE}{dr}dS$$

If Q be the quantity of electricity on each electrode, in the electrostatic problem we have by Gauss's theorem

$$\iint\frac{dE}{dr}dS = 4\pi Q = \psi$$

where ψ is the total electrostatic or dielectric flux emanating from each electrode.

Hence $$I = k\psi$$

If V be the potential difference (equal to $V_1 - V_2$) and K the conductance of the electrolyte so that

$$I = KV$$

then K will be given by

$$K = k\frac{\psi}{V} \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad (3)$$

The expression ψ/V represents the surface integral of stream lines per unit potential difference, and may be called the "geometric conductance"* of the medium, i.e. the conductance corresponding to unit conductivity, and we shall denote it by K' so that

$$K' = \frac{\psi}{V} \quad . \quad . \quad . \quad . \quad . \quad . \quad (4)$$

Similarly to (3) the resistance will be given by

$$R = \rho\frac{V}{\psi}$$

where ρ is the resistivity, and the "geometric resistance" by

$$R' = \frac{V}{\psi} \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad (5)$$

Equation (4) is of practical importance, as it enables us to express the conductance of an electrolyte as a function of the potential difference between the electrodes and the flux issuing from them. The conductance thus expressed will be measured in the same unit as k.

Steady Flow in Two Dimensions.

When tubes of flow are the same in all planes parallel to that of xy, and there is no current parallel to the axis of z, we may regard the flow of current as being two-dimensional and consider only the circumstances in the plane xy.

Considering now two plane parallel electrodes immersed in an electrolyte, we may regard the flow of current between them in a normal plane sufficiently remote from their upper and lower edges as being two-dimensional. Let ds be an element of tube, and i the current density along ds as before. Let u and v be the components of i along the axes x and y, and l and m the direction cosines of u and v.

We have
$$u = li$$
$$= lk\frac{dV}{ds} \text{ from Equation (1)}$$

Hence
$$u = k\frac{dV}{dx}$$

and similarly
$$v = k\frac{dV}{dy}$$

Now for a steady motion the equation of continuity is given by

$$\frac{du}{dx} + \frac{dv}{dy} = 0$$

By substituting in this equation the values of u and v obtained above, we get

$$\frac{d^2V}{dx^2} + \frac{d^2V}{dy^2} = 0$$

which is Laplace's equation for the potential function in two dimensions. This equation is satisfied by a solution of the form

$$\psi + jV = \chi(x + jy) \quad . \quad . \quad . \quad . \quad . \quad (6)$$

where $j = \sqrt{(-1)}$.

The relation between ψ and V can be found by

* The term "geometric conductance" is analogous to "geometric permeance" as used by Karapetoff (see "The Magnetic Circuit," chap. 5, p. 93).

differentiating Equation (6) with respect to x and y. Thus we get

$$\frac{d\psi}{dx} + j\frac{dV}{dx} = \chi'(x + jy)$$

$$\frac{d\psi}{dy} + j\frac{dV}{dy} = j\chi'(x + jy)$$

whence

$$j\frac{d\psi}{dx} - \frac{dV}{dx} = \frac{d\psi}{dy} + j\frac{dV}{dy}$$

or

$$\frac{d\psi}{dx} = \frac{dV}{dy}, \quad \text{and} \quad \frac{d\psi}{dy} = -\frac{dV}{dx}$$

Functions satisfying these relations are called conjugate functions.

It is evident that the families of curves given by $\psi =$ constant and $V =$ constant intersect orthogonally at every point. In other words the curves $\psi =$ constant are stream lines, while the curves $V =$ constant are the equipotentials.

If stream lines and equipotentials are drawn for a series of equal infinitesimal increments of V and ψ they will divide the plane into infinitesimal squares. For if dx be the distance between two consecutive stream lines, and dy that between two consecutive equipotential lines, the current may be expressed by $d\psi/dx$ or dV/dy. Hence if $d\psi = dV$ then $dy = dx$.

Consider now more fully Equation (6) and let us write

$$z = x + jy$$

and

$$w = \psi + jV$$

so that

$$w = \chi(z)$$

If we represent values of z in one Argand diagram and values of w in another, it can be shown that corresponding infinitesimal parts of the two diagrams are similar, and Equation (6) is therefore said to transform a diagram in the z plane "conformally" into the w plane. Such transformations have been successfully applied for the solution of certain physical problems, especially in hydrodynamics and electricity, which are otherwise incapable of solution.

The condition that the potential over a conductor is constant may be represented in the w plane by straight lines parallel to the real axis, and since stream lines cut equipotentials orthogonally it follows that conductors in the z plane can be transformed conformally into rectangles in the w plane, provided the proper function χ in Equation (6) is found in each case. In other words, Equation (6) will transform an irregular conductor in the z plane into a rectangle in the w plane bound by straight lines $\psi =$ constant and $V =$ constant. These conductors will be electrically equivalent since the transformation is conformal, i.e. the mutual relationship between equipotentials and stream lines bounding corresponding infinitesimal parts is preserved in both conductors.

We shall now illustrate the use of the above method of transformation by simple examples.

Take the function

$$\psi + jV = (x + jy)^2$$
$$= x^2 - y^2 + 2jxy$$

so that $\psi = x^2 - y^2$; and $V = 2xy$.

The stream lines are rectangular hyperbolas with the axes of co-ordinates as axes, and the equipotential lines are also rectangular hyperbolas with the axes of co-ordinates as asymptotes. We can make use of this transformation to find the resistance of a conductor bounded by these lines, such as the shaded diagram in Fig. 1, where APB and A′QB′ are the stream-line boundaries, and AA′ and BB′ are the equipotential boundaries of the diagram in question.

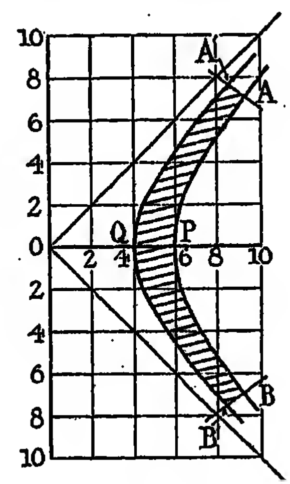

FIG. 1.

From Equation (5) the required resistance is given by

$$\frac{V}{\psi} = \frac{V_A - V_B}{\psi_P - \psi_Q} = \frac{2x_Ay_A - 2x_By_B}{(x_P^2 - y_P^2) - (x_Q^2 - y_Q^2)}$$
$$= \frac{2 \times 8 \times 8 - 2 \times 8 \times (-8)}{(6^2 - 0) - (4^2 - 0)} = 12 \cdot 8$$

Thus the irregular conductor APBB′QA′ is transformed into an equivalent rectangle whose boundaries are $V_A = 128$; $V_B = -128$; and $\psi_P = 36$, $\psi_Q = 16$.

Another simple example is given by the following transformation:

$$\psi + jV = \log(x + jy)$$
$$= \log re^{j\theta}$$

where r is the radius vector, and θ the argument in polar co-ordinates, or

$$\psi + jV = \log r + j\theta$$

Hence we have $\psi = \log r$, and $V = \theta$.

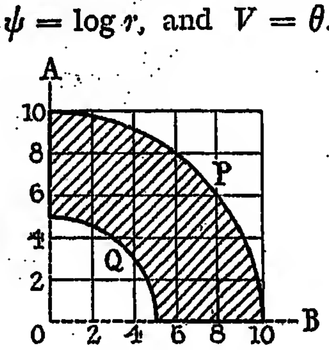

FIG. 2.

Thus the stream lines are a system of concentric circles, and the equipotentials radii diverging from their common centre. We can use this function to find the resistance of any figure bounded by these lines. Take as a special case the shaded portion of Fig. 2.

The equipotential boundaries are $V = 0$ and $V = \pi/2$, and the stream-line boundaries are $r = 10$ and $r = 5$. From Equation (5) the geometric resistance is given by

$$R' = \frac{V}{\psi} = \frac{V_A - V_B}{\psi_P - \psi_Q} = \frac{\frac{1}{2}\pi - 0}{\log r_P/r_Q} = \frac{\frac{1}{2}\pi}{\log (10/5)} = 2\cdot 27$$

The transformation illustrated by the above examples has been made directly from the z plane to the w plane. Such direct transformation, however, is not always possible, and in general it is effected through the intermediation of a third diagram, which is taken, for convenience, in the real axis of a semi-infinite plane.

If $t = \xi + j\eta$ represent a point in the semi-infinite plane, let

$$z = f(t) \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad (7)$$

and

$$w = F(t) \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad (8)$$

Equation (7) will transform a conductor in the z plane conformally into an equivalent diagram in the t plane, and Equation (8) will transform this again into the t plane.

The method of transformation discussed above has its limitations. The purely mathematical difficulties are such as to make it applicable only in a comparatively few simple cases.

The transformation of a rectangular polygon into the real axis of a half plane can be effected by means of a general theorem due to Christoffel and Schwarz, which states that

$$\frac{dz}{dt} = C(t - t_1)^{(\alpha_1/\pi)-1}(t - t_2)^{(\alpha_2/\pi)-1} \ldots (t - t_n)^{(\alpha_n/\pi)-1} \quad (9)$$

where α_1, α_2, α_n are the internal angles of the polygonal conductor in the z plane, and t_1, t_2, t_n are the co-ordinates of points in the t plane corresponding to the angular points of the polygon. Three of these co-ordinates are arbitrary and the rest are determined from the configuration of the polygon.*

We shall now proceed to apply this theorem for the solution of the problem with which we started, viz. the case of plane parallel electrodes immersed in an infinite electrolyte.

The plane equidistant and parallel to the electrodes is an equipotential and can be replaced by a conducting lamina without disturbing the configuration of equipotential and stream lines. The problem the solution of which is required can now be put in the following form, to which the Schwarzian transformation readily applies.

Imagine a semi-infinite plate CD (Fig. 3) at potential V placed at a distance h above and parallel to an infinite plate AB at zero potential; it is required to map out the distribution of electric stress or potential gradient at the electrode surface.

The polygonal conductor ABCDEA (traced by the dotted line) will first be transformed into an equivalent conductor having a straight-line boundary in the real axis of the t plane, and then transformed again by the same theorem into a rectangle in the w plane, bounded by equipotentials and straight lines. In order to transform the polygon to the t plane we assume three arbitrary values of t. Take $t = -\infty$ at the point A, $t = -1$ at the point (B, C) and $t = 0$ at D, then we shall have $t = \infty$ at E. The angles of this polygon are $\alpha = 0$ at (B, C) and $\alpha = 2\pi$ at D.

Hence we have by Schwarz's theorem

$$z = C\int \frac{t}{t-1} = C\,[t - \log (t + 1) + D] \quad . \quad . \quad (9)$$

where C and D are the constants of integration and may be determined from the boundary conditions of the plates. These, as assumed above, are at $y = 0$ and $y = h$. Hence we have

$$z = x + jy = \frac{h}{\pi}[t - \log (t + 1) + j\pi] \quad . \quad . \quad (10)$$

The diagram in the w plane consists of two parallel straight lines, KL and MN. The internal angle at (L, M)

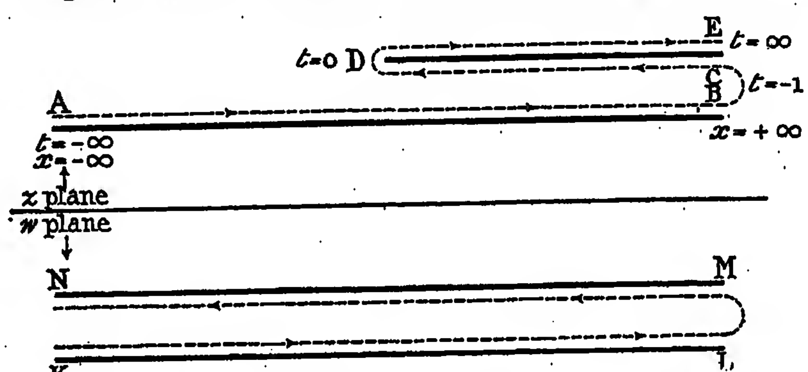

FIG. 3.—Diagram illustrating Schwarz's transformation.

corresponding to the point $t = -1$ is zero. This diagram is transformed to the t plane thus :—

$$\frac{dw}{dt} = A\frac{1}{t+1}$$

or

$$w = A \log t + B$$

A and B can be found from the condition that the two planes are, as previously assumed, at $V = 0$ and $V = V$; whence we have

$$w = \psi + jV = \frac{V}{\pi}(\log t - j\pi) \quad . \quad . \quad (11)$$

Equations (10) and (11) give the general solution of stream-line distribution for both plates.* Thus for the side DC we equate real quantities and obtain

$$x = \frac{h}{\pi}\{t - \log (t + 1)\} \quad . \quad . \quad . \quad . \quad (12)$$

and

$$\psi = \frac{V}{\pi}\log (t + 1) \quad . \quad . \quad . \quad . \quad . \quad . \quad (13)$$

where t varies from 0 to -1.

Also from (12) and (13) we obtain the density of stream lines thus :—

$$\frac{d\psi}{dx} = \frac{d\psi}{dt} \times \frac{dt}{dx} = \frac{V}{h} \times \frac{1}{t}$$

DOUGLAS: "The Reluctance of Some Irregular Magnetic Fields," *Transactions of the American Institute of Electrical Engineers*, 1915, vol. 34, p. 1067, which contains useful references to original papers.

* Equations (10) and (11) are identical with those given by Sir J. J. Thomson in "Recent Researches," *loc. cit.*, to which the reader is referred for further explanation of the method of solution.

and from the conjugate property of ψ and V we get the electric stress

$$\frac{dV}{dy} = \frac{d\psi}{dx} = \frac{V}{h} \times \frac{1}{t} \quad . \quad . \quad . \quad . \quad . \quad (14)$$

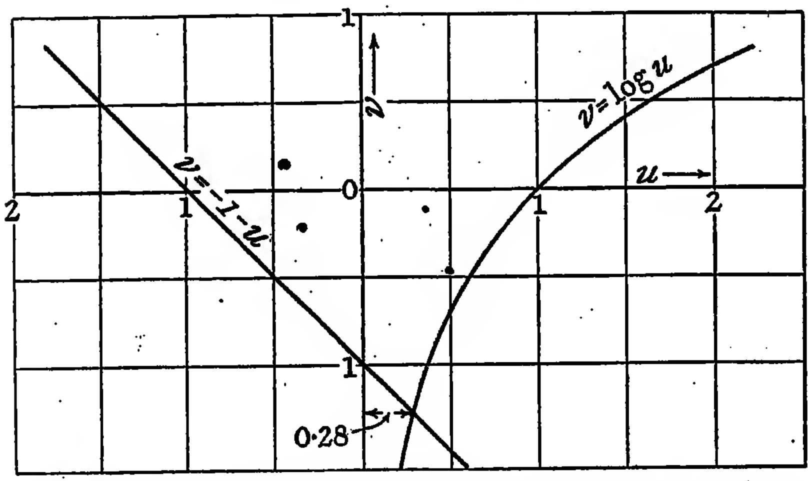

FIG. 4.—Graphical solution for determining t on the lower plate, corresponding to the extremity of the upper plate.

Similar expressions can be obtained for the side AB by putting $y = 0$ in (10) and (11); thus we get

$$x = \frac{h}{\pi}\{t - \log(-1 - t)\} \quad . \quad . \quad . \quad . \quad (15)$$

and

$$\psi = \frac{V}{\pi}\log(-1 - t) \quad . \quad . \quad . \quad . \quad (16)$$

Hence

$$\frac{d\psi}{dx} = \frac{dV}{dy} = \frac{V}{h} \times \frac{1}{t} \quad . \quad . \quad . \quad . \quad (17)$$

In this case t varies from -1 to $-\infty$.

Put $(-1 - t) = u$, and write the equation thus :—

$$\log u = -u - 1$$

This equation is best solved graphically by taking

$$v = \log u\,; \quad \text{and} \quad v = -u - 1$$

The corresponding graphs are shown in Fig. 4, where they intersect at the point $u = 0{\cdot}28$, which gives $t = -1{\cdot}28$.

Similarly we can find the point from which ψ is to be measured on the lower plate AB. We have from (16)

$$0 = \frac{V}{\pi}\log(-1 - t),$$

whence $t = -2$, which gives the corresponding value of x as $-0{\cdot}637$.

Thus for the lower plate AB, x is to be measured from the point $t = -1{\cdot}28$, and ψ from the point $t = -2$.

Fig. 5 shows the relative distribution of potential gradient on one electrode and the neutral plane, being calculated for an electrode 10 cm wide placed at a distance 10 cm from another identical electrode. The curves shown in this figure give also to a certain scale the current density near the electrode surface in a current problem, and to another scale the charge density in an electrostatic problem.

2. Experimental Work.

(A) *General plan.*—The experimental work has been planned with two objects in view: (1) To verify the mathematical results obtained in Section 1 on the distribution of electric stress near the electrode surface,

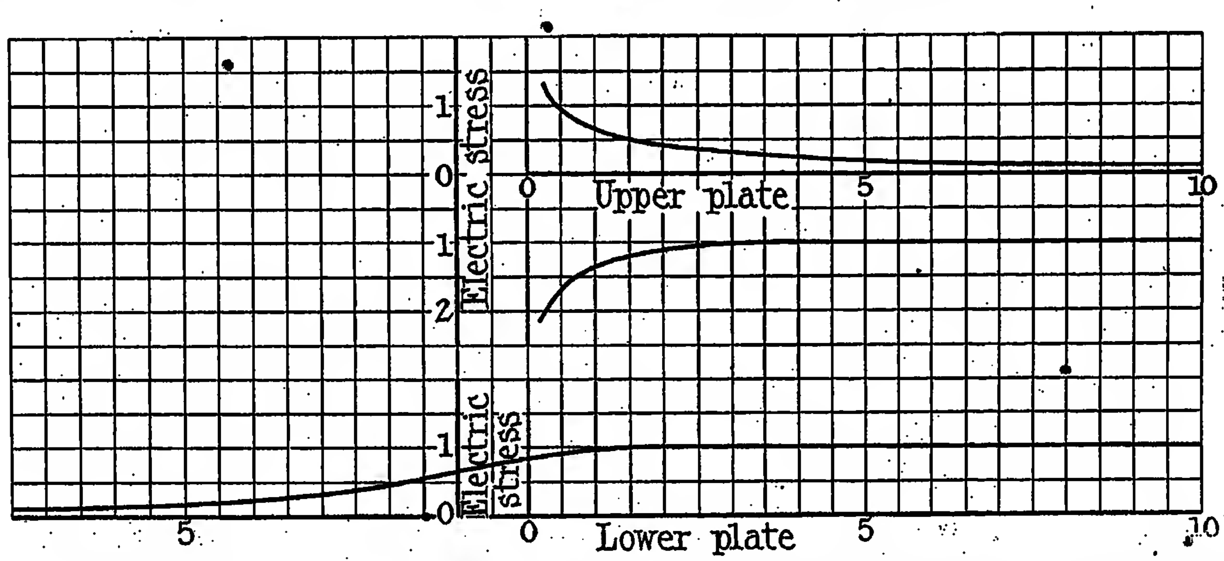

FIG. 5.—Relative distribution of electric stress on the upper and lower plates shown in Fig. 3.

Now for the side CD both x and ψ are to be measured from the point D, where $t = 0$ and $x = 0$. For convenience we shall measure x on the lower plate AB from the foot of the perpendicular let fall from D on AB, and in order to find the corresponding value of t we have, from (15),

$$0 = \frac{h}{\pi}[t - \log(-1 - t)]$$

or

$$t = \log(-1 - t)$$

by means of experiments in which the mathematical conditions are represented with sufficient and reasonable accuracy, and (2) to apply these results for the solution of certain practical questions, or rather to find out problems to which these results are applicable, and to investigate experimentally how far such applications agree with test results.

The principle which has been previously stated, viz. that tubes of flow are identical with tubes of force, enables us to replace a dielectric medium by a conducting

medium, and for this purpose an electrolytic cell is admirably suited.

The conjugate character of stream lines and equipotentials suggests the possibility of transposing the roles of equipotentials and stream lines, so that the electric field can be completely determined by mapping out either system. It appears, however, that experimental investigation on these lines has been confined to the tracing of equipotentials, and thus only a qualitative representation of the manner in which the electric stresses are distributed in a given field has been obtained.* In the experimental work to be described, measurement of potential gradient and also, in some tests, of elemental current have been taken in chosen planes of observation. These measurements also represent to another scale the electric stresses in an analogous electrostatic field, and in this manner the stress distribution is determined quantitatively as well as qualitatively.

(B) *Account of apparatus and method.*—The apparatus consists of two rectangular plane copper plates immersed in a solution of copper sulphate and contained in a large glass vessel (Fig. 6). The suspension of the electrodes is arranged on ball bearings operating in an oil bath so as to ensure that the electrodes are vertical as well as rigid. Each electrode with its suspension system can travel so as to give within the limits of the apparatus any required spacing between them. The spacing is measured on two scales fixed on either side of the vessel. The potential gradient at any point in the electrolyte is measured by means of two thin copper wires, insulated throughout with wax except near their extremities, thus acting as exploring points leading to a quadrant electrometer* as shown in Fig. 7. The exploring electrodes are held firmly in an ebonite block fastened to a glass tube in which the electrometer leads are housed. This tube is securely held in a sliding carrier capable of movement along a transverse scale,

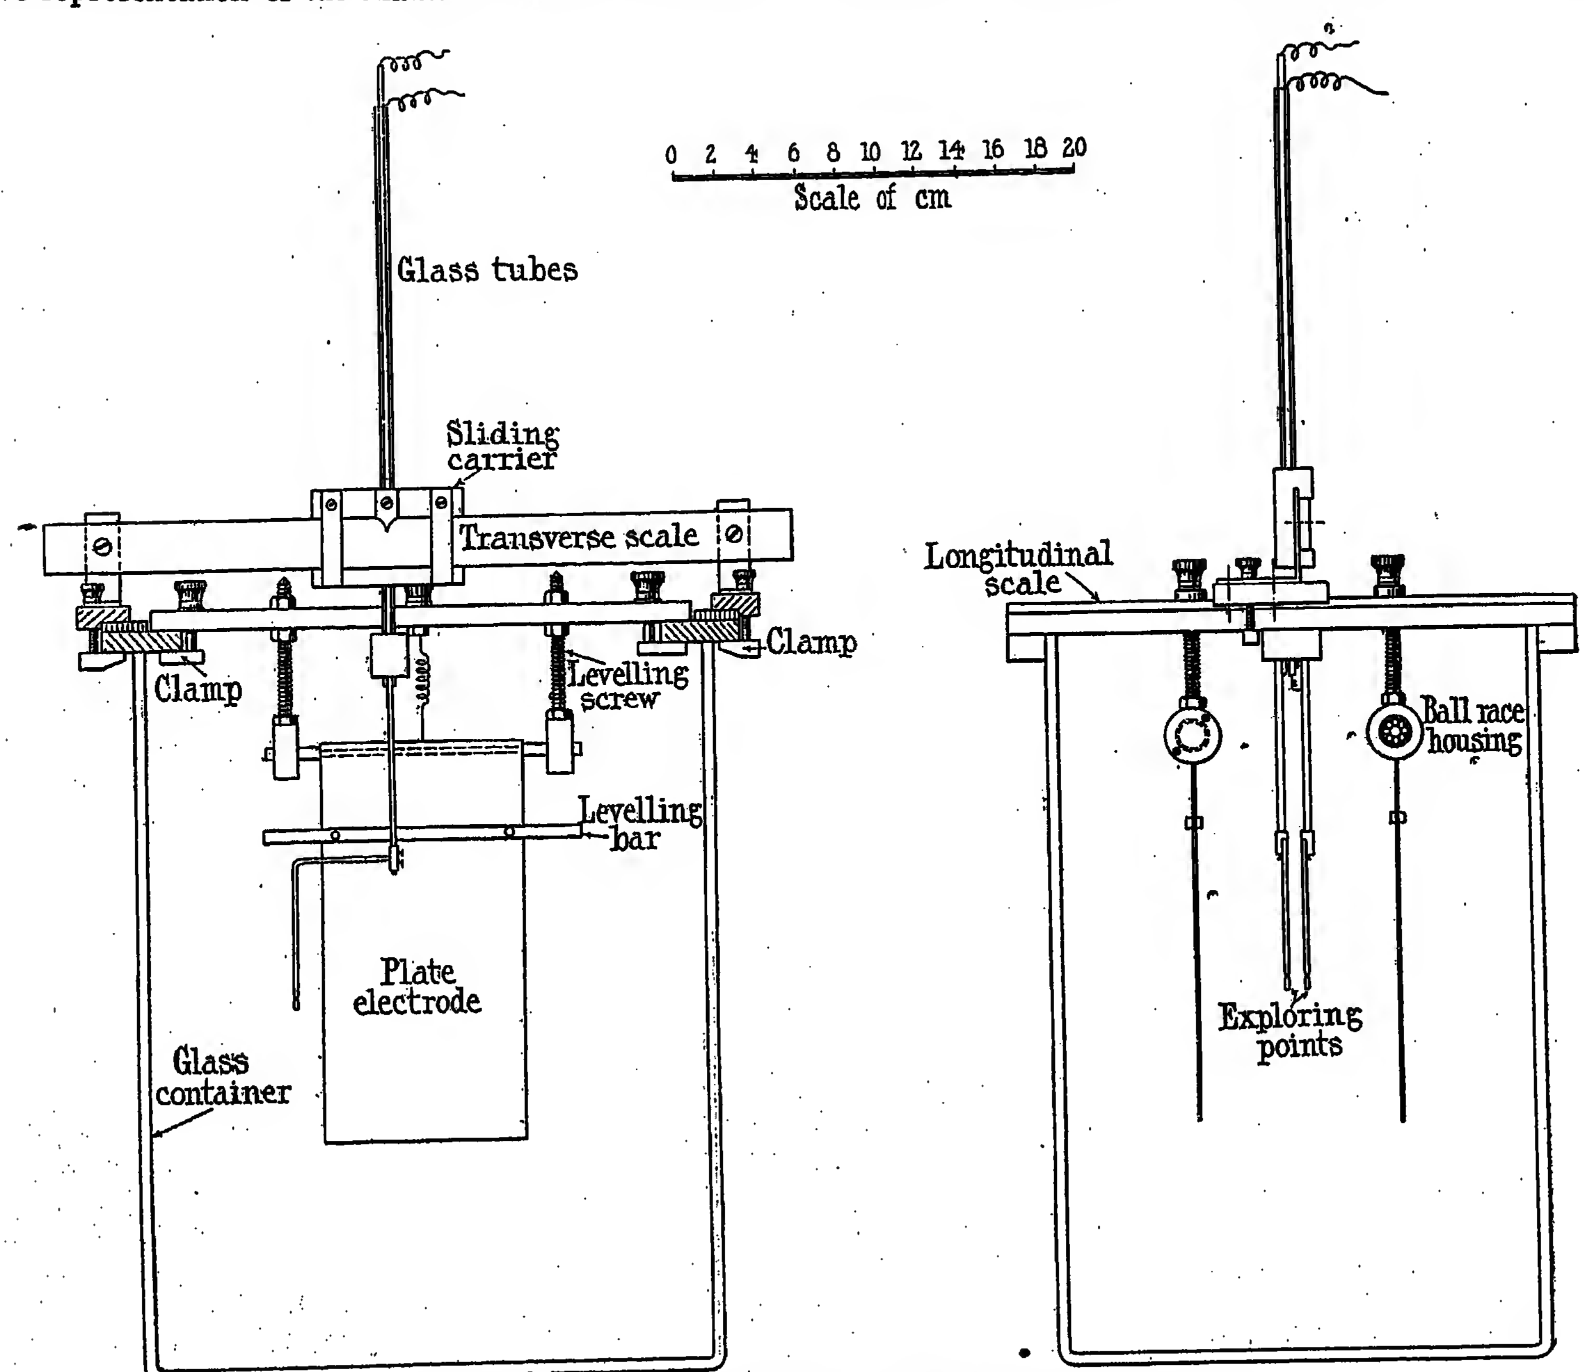

FIG. 6.—Diagram of apparatus for use with electrolytic cell.

* Such investigation has recently been carried out by C. L. FORTESCUE and S. W. FARNWORTH, *Transactions of the American Institute of Electrical Engineers*, 1913, vol. 32, pt. 1, p. 895.

* The electrometer is of the Dolezalek type, the needle being charged to 120 volts.

which in turn can travel with the sliding carrier along the two longitudinal scales fixed at the side of the vessel. In this manner the exact position of the exploring points can be read in rectangular co-ordinates.

In order to represent the mathematical conditions with sufficient accuracy, care has been taken to set the electrodes exactly symmetrical with each other, with reference to the neutral plane in which the exploring points have been previously adjusted to travel, so that each electrode coincides with the reflection of the other. For this purpose levelling bars are fixed to the electrodes above the water-level, at precisely the same distance from their lower edges and projecting sideways, so as to act as supports for a spirit-level and in general to act as a datum line from which all measurements are to be taken.

In order to secure the correct alignment the bearing housings are held by means of adjustable screws, which enable the movement of the electrodes to be effected in a vertical plane, while their motion in a horizontal direction is attained by sliding the bearings in their

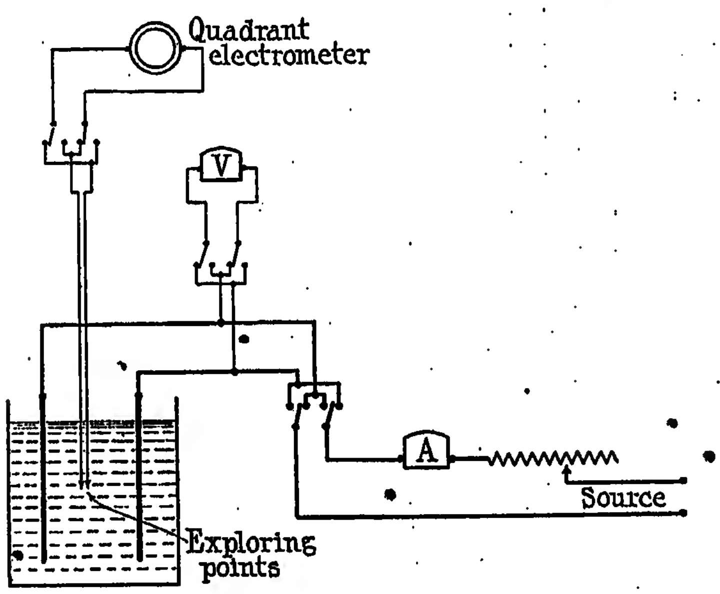

FIG. 7.—Diagram of connections.

housings. The spacing in the various tests could thus be adjusted to the nearest 0·25 mm.

(C) *Choice of elements of electrolytic cell.*—It is well known that when current from an external source is circulated through an electrolytic cell a counter E.M.F. is set up in the cell, which tends to diminish the current and is generally known as the polarization E.M.F. Principally it is the decomposition voltage which is responsible for the chemical work done in the cell. It is a physical constant for any particular cell, being independent of the magnitude of the current and varying according to the elements which compose the cell. Any increase in the rate of decomposition comes only from the current component of the power. It may therefore be deduced that in electrolytic cells where the flow of current does not produce definite chemical changes there would be no potential drop of decomposition. This is practically the case in electro-deposition cells, or in general in any cell where the electrodes are so chosen that the electrolyte is exactly reconstituted by the use of a soluble anode of the same nature as the cations which are being deposited; the sum total of the mass of metal remains the same, and the electrolyte undergoes practically no change. The chemical energy consumed in tearing the particles of deposit from the anode is recovered when these articles enter into chemical combination with the cathode, so that the algebraic sum of the energy consumed is zero and theoretically no work is done in the process of deposition.

In the cell described above, the electrodes were therefore chosen of pure copper and the electrolyte of a solution of copper sulphate.

In an electrolytic cell there is usually a certain quantity of gas evolved by electrolysis and adhering to one or both electrodes. The quantity of gas thus formed varies according to the material of the electrodes and is generally greater with inactive electrodes than with soluble ones.* The presence of gas bubbles has the effect of mechanically interrupting the flow of current at the points of the electrode surface to which they adhere, thus causing a diminution of the effective surface of the electrode and, consequently, local increase of current density. Now when current flows from one conductor to another there is generally some perceptible evidence of potential drop occurring at the surface of contact. In solids, contact is more or less perfect according to the nature and the state of the surfaces of contact, and for mechancial reasons an absolutely perfect contact is practically impossible. When a conductor is immersed in a liquid the conditions are more favourable for obtaining good contact, but as electrolysis begins the gas liberated increases the contact resistance. The potential drop due to contact resistance increases with current density, and hence it is evident that the effect of the gas bubbles would be to increase the potential drop at the surface of contact by increasing the current density. The author has carried out extensive tests for the purpose of ascertaining the magnitude of the potential drop occurring at the electrode surface in the particular cell described. These have been omitted from the paper for want of space, and only the results are given below:—

(*a*) No polarization E.M.F. could be detected in the cell.

(*b*) The contact resistance is from 4 to 6 per cent of the cell resistance, and varies with the current and the nature of the electrode surface, being greater with smooth than with rough surfaces. This may be due to the fact that a spongy surface which has been roughened by deposition presents a larger surface per unit area of electrode.

(D) *General comparison of the electrostatic and current problems.*—In the mathematical treatment the electrolyte is assumed to be homogeneous, and the potential difference maintained at the conducting plates is therefore a continuous function of the distance separating them. Neither of these conditions is strictly true for an electrolytic medium. In the first place, local changes of density occur in the neighbourhood of the electrodes, the electrolyte near the cathode becoming denser, and that near the anode weaker than the

* See LE BLANC: "A Text-book of Electro-Chemistry," p. 296.

rest, which practically maintains its original density. Secondly, there is generally an abrupt drop of potential at the surface of contact between the electrolyte and either electrode, which forms a discontinuity in the potential function. If the P.D. between one electrode and a point close to its surface be measured by an electrometer, the reading will give the fall of potential due to the resistance of the electrolyte which fills the space separating the point from the electrode surface, plus the P.D. occurring at the surface of contact.

It is evident, therefore, that the neighbourhood of the electrodes does not provide a suitable position for the verification of the mathematical expressions, and in order to attain this object with reliable and accurate results it is necessary to take measurements of potential gradient at a distance from material objects which are likely to disturb the homogeneity of the electrolyte and either side, and therefore may be regarded as being equivalent to the shifting of the boundaries of the electrolytic medium from the metal conductors to the adjacent equipotential surfaces, which may, as a first approximation, be assumed to be planes parallel to the electrodes. This corresponds to a reduction of spacing of the electrodes by an insignificant amount equal to the thickness of the gas film formed at the electrodes.

Incidentally there is another point which is uniquely possessed by the neutral plane as a suitable field for observation. Small lengths of tubes of flow in this region such as are intercepted by the exploring points are practically straight lines normal to the neutral plane. Thus when the transverse scale is adjusted so that the exploring points travel astride the neutral plane, readings of potential gradient can be taken for any point in the plane without altering either the setting of the transverse scale or

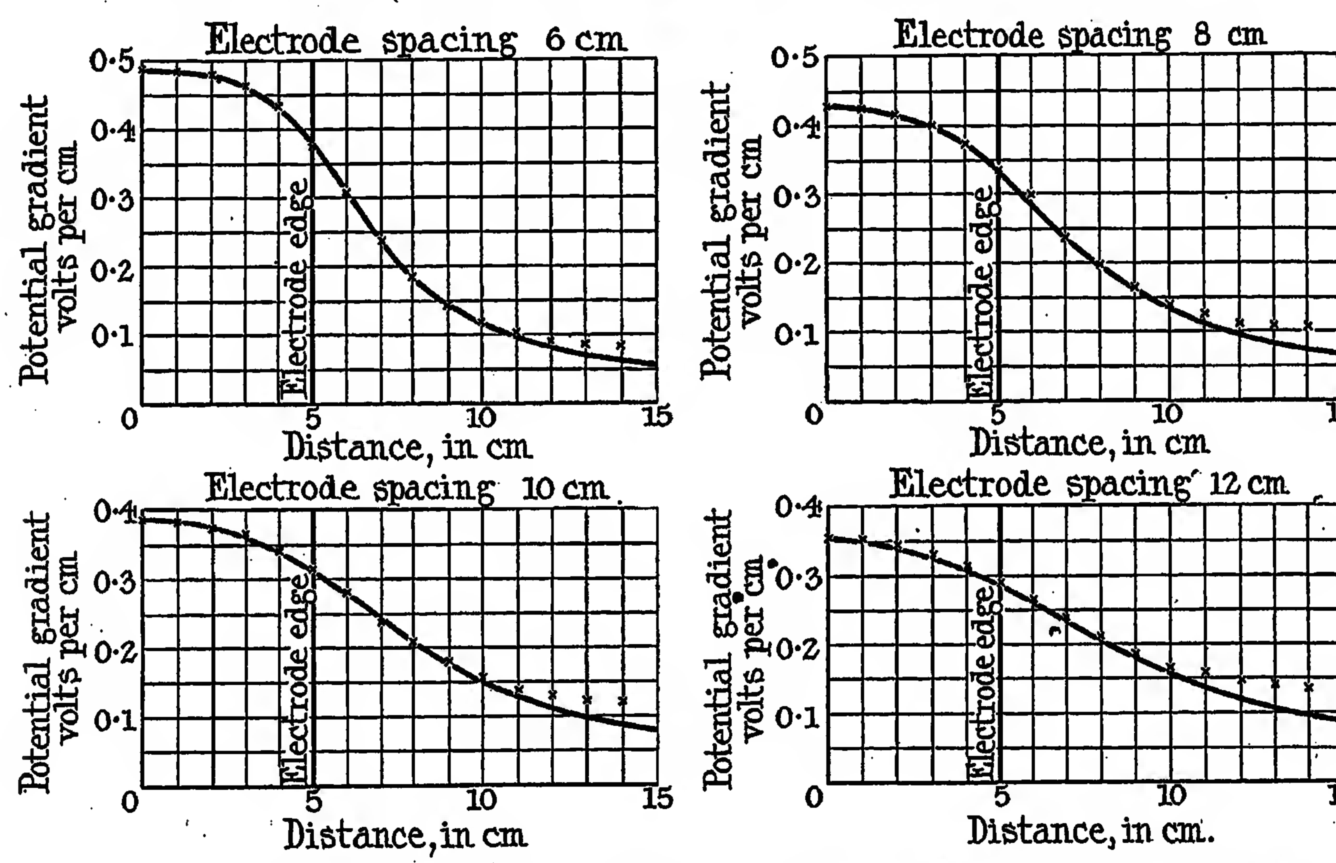

FIG. 8.—Comparison of theoretical and experimental results. Main current = 2 amperes.

introduce other uncertain factors. In this respect the neutral plane, i.e. the plane equidistant between, and parallel to, the electrodes, appears to be a suitable field of observation. It provides a hypothetical conductor which may be taken to represent the infinite plate in the mathematical problem (Fig. 3), while either electrode may be taken as the semi-infinite plate.

We shall now proceed to show that neither the local changes of density nor the contact drop at the electrode surface will materially affect the relative measurements of potential gradient in the neutral plane. For since the change of density is equal and opposite at the two electrodes, and therefore extends over the same distance from each electrode, it follows that in a space diagram the position of the neutral plane remains unchanged. The effect of the potential drop occurring at the surface of each electrode will be simply to reduce the applied pressure by an equal amount at the orientation of the exploring points. In any other plane or equipotential, however, the exploring points would have to be turned through an angle for each different reading so as to lie tangentially to the tube of flow passing through any particular point. This position can be found by trial, and corresponds to a maximum deflection of the electrometer for any given point in the electrolyte. The choice of the neutral plane for observation is amply justified by the general consistence of the numerous results obtained. Practically all the tests made in this plane show remarkable agreement between calculated and observed values of potential gradient. A few typical tests are given below.

(E) *Experimental results.*—In the following tests measurements of potential gradient have been taken at various points 1 cm apart along the neutral plane. The range of readings extended from the central line of the electrodes to the boundary of the glass container,

this operation being repeated for different electrode spacings.

Test 1.—The current was kept constant at 2 amperes for the various spacings 12, 10, 8 and 6 cm. The results are shown in Fig. 8, where the full-line curve gives the theoretical distribution of potential gradient, and the crosses are actual readings.

are shown in Fig. 10, the spacing being 10 cm. It will be shown in Section 3 that current density is proportional to potential gradient, so that Fig. 10 also represents the relative distribution of current on the front and back sides of the electrode.

(F) *Discussion of results.*—Examination of Figs. 8 and 9 shows, in general, good agreement between

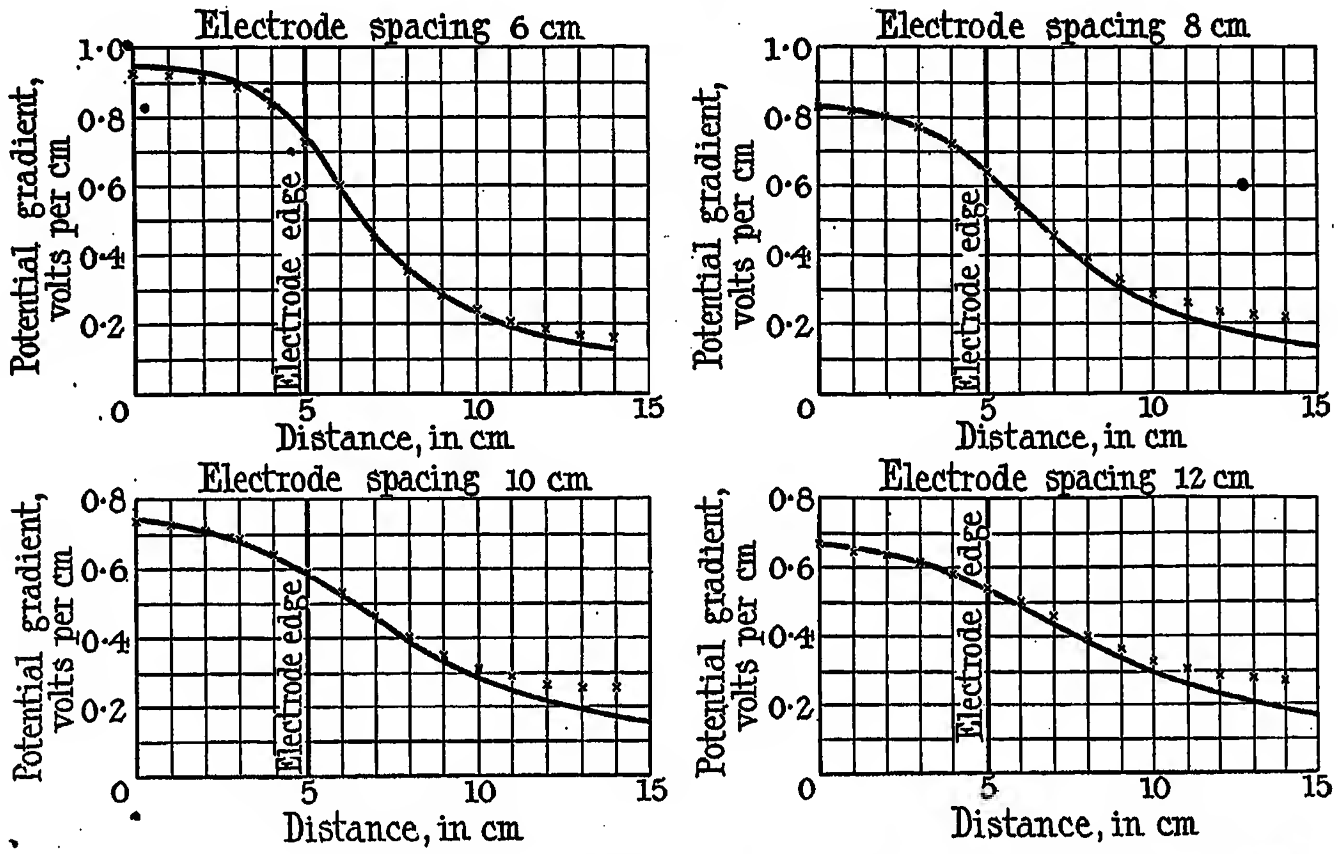

FIG. 9.—Comparison of theoretical and experimental results. Main current = 4 amperes.

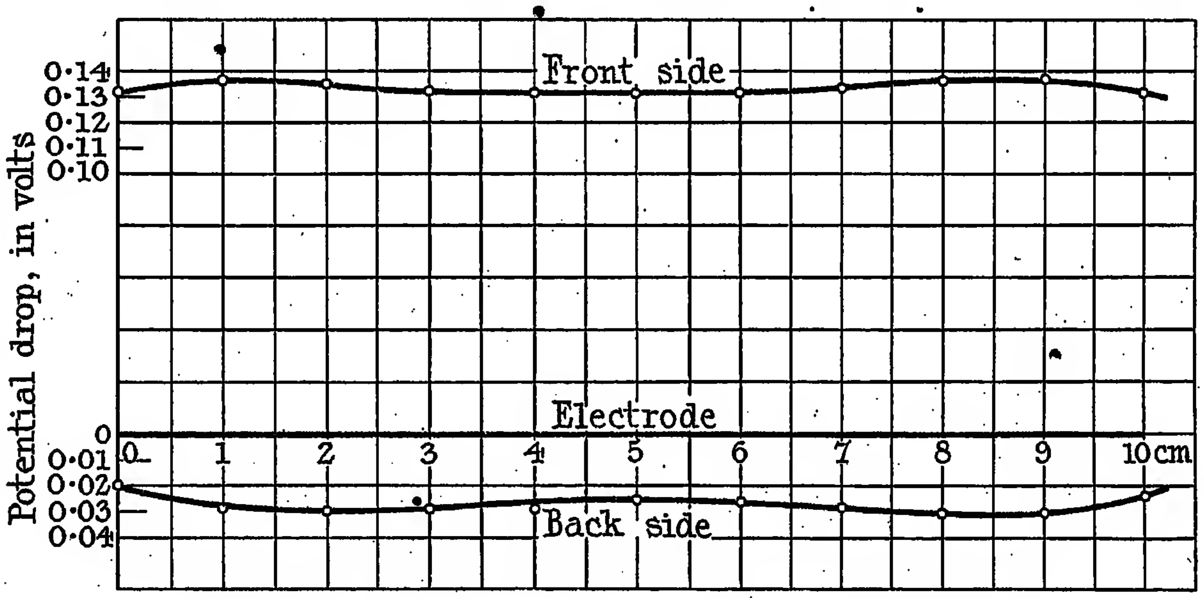

FIG. 10.—Potential-drop near front and back sides of electrode.

Test 2.—Is similar to Test 1 with the exception that the current was kept constant at 4 amperes. The corresponding curves are shown in Fig. 9.

Test 3.—In this test, readings of potential gradient were taken at a distance 1·5 cm from the electrode so as to eliminate local disturbances taking place in the proximity of the electrode. The object of this test was to give a picture of the relative distribution of potential gradient near the electrode surfaces, and the results

calculated and observed values of potential gradient in the neutral plane, except at the lower parts of the curves, i.e. near the boundary of the glass container, where the experimental values are slightly higher than those obtained by calculation. This is common to all the curves, and is principally due to the restrictive influence of the non-conducting boundary on the direction and density of stream lines in that neighbourhood. It will be remembered that in the mathematical

treatment of the problem the medium was assumed to be of infinite dimensions, so as to eliminate the restrictive effect of the boundary on the free flow of stream lines in order to simplify the problem. The same condition would be fulfilled if the fixed boundaries of the conducting medium were so shaped as to follow in each case the direction of a given stream line. In such a case there would be no component of current normal to the boundary, as is evident from the definition of a

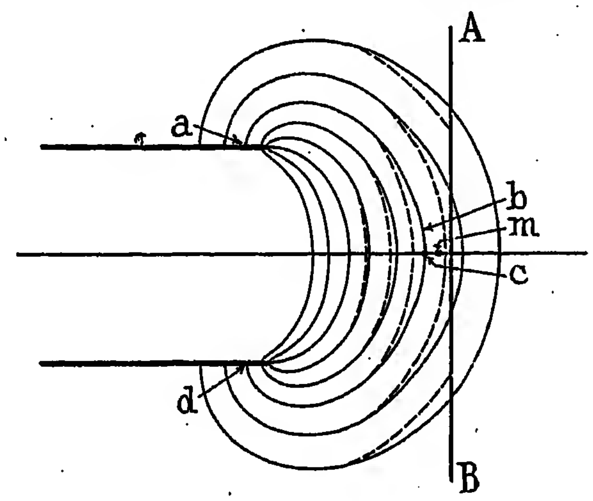

FIG. 11.

stream line. If the position of the boundary does not follow a stream line there would be always a restricted flow of current normal to its surface, and this would create a local disturbance. This is actually the case in the present experiments.

Suppose that the field of stream lines is already established between two electrodes immersed in an electrolyte of infinite dimensions. Let now a boundary surface approach the field, coming from a distance until it occupies the position AB in Fig. 11. Let abcd

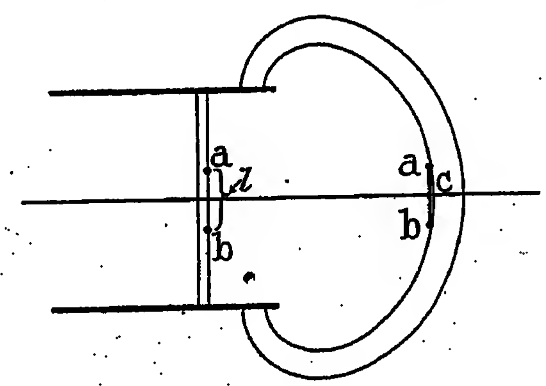

FIG. 12.

represent a stream line and assume first that its position remains the same as before the insertion of the boundary surface. The stream lines to the left of abcd will obviously remain as before in their original respective positions. Those to the right of abcd, impinging on the non-conducting boundary surface and thus being diverted from their natural course, will concentrate in the space enclosed between that boundary and the stream line, abcd, giving rise to increased current density. The potential gradient, say, at a point m in that narrow space will therefore rise to correspond and would assume a higher value than that at c. Since, however, the fall of potential must take place in a progressive manner from the electrodes outwards, it follows that the line abcd must readjust itself by moving to the left in order to occupy such a position that c will have a higher potential gradient than m. Adjacent stream lines will rearrange themselves in a similar manner and follow the dotted lines shown in Fig. 11, with the result that the potential gradient of points near the boundary become higher than their corresponding values if there were no boundary, i.e. higher than the values obtained mathematically.

This explanation accounts for the rise of observed values of potential gradient at the lowest parts of the curves of potential gradient, i.e. in the proximity of the boundary. It will be noticed, however, particularly in the curves taken for large spacing, that the deviation of observed from calculated values starts soon after leaving the inter-electrodal space, indicating that the boundary is not solely responsible for the rise of observed readings over the calculated values.

Let a and b be the exploring points, and l the distance between them (Fig. 12). In the inter-electrodal space stream lines run more or less normally to the neutral plane, and so the line ab, having been previously adjusted perpendicular to the neutral plane, coincides more or less closely with the direction of stream lines, the smaller the spacing the better the normality of stream lines and the closer the coincidence of the line ab with the stream line passing through any particular point.

If V be the P.D. measured across the exploring points, then the potential gradient dV/dl will be given approximately by V/l. Outside the space enclosed between the electrodes, however, stream lines begin to assume curved shapes, so that ab will now bridge an arc acb, which may be appreciably greater than l. If s be the length of the intercepted arc then the approximate potential gradient should be given by V/s and not by V/l. Thus the observed reading of potential gradient may be higher than the true value as calculated mathematically, the discrepancy being greater the more curved are the stream lines, i.e. the wider the electrode spacings.

3. A METHOD OF MEASURING THE CURRENT DENSITY AT ANY POINT IN THE INTERIOR OF AN ELECTROLYTIC MEDIUM.

The principle of the method lies in circulating current from an external source between the exploring electrodes while lying in a given position inside the electrolyte, through which current is already flowing between the main electrodes. The direction of the exploring electrodes is such that the line joining them follows the path of stream lines in the given position. The current impressed on the exploring points is of opposite direction to that of the main current in the electrolyte, and of such a magnitude as to reduce the potential difference of the exploring points to zero. The diagram of connections is given in Fig. 13. When this condition is fulfilled the impressed current exactly neutralizes the main current localized at that particular position where the exploring points are inserted. This is shown when a galvanometer connected across the exploring points gives no deflection. The balancing current (indicated on a milliammeter placed in the

circuit of the independent source) is a measure of the current density at that particular point.

The potential gradient may be read on the electrometer before the impressed current is switched on, and so the relation between the potential gradient and the current flowing in any position of the exploring points may be determined.

Theory of the method.—Consider first the case when the main current through the cell is interrupted, and that

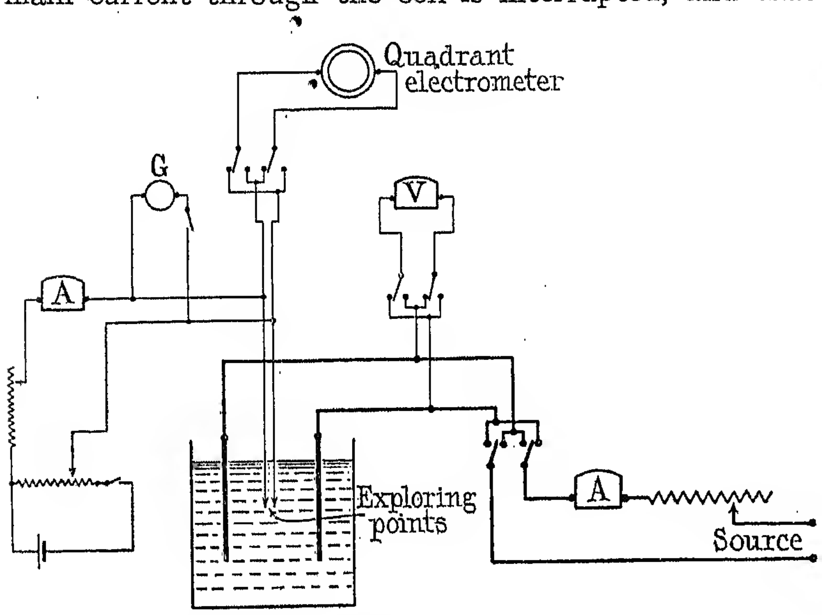

FIG. 13.—Diagram of connections.

only a current I supplied by the external source is impressed on the exploring points while lying in a given position in the electrolyte. We shall now proceed to find the resistance between these electrodes.

Take the transformation

$$w = \log \frac{z - c}{z + c}$$

where w and z have the same significance as before, so that we have

$$V + j\psi = \log \frac{x + jy - c}{x + jy + c}$$

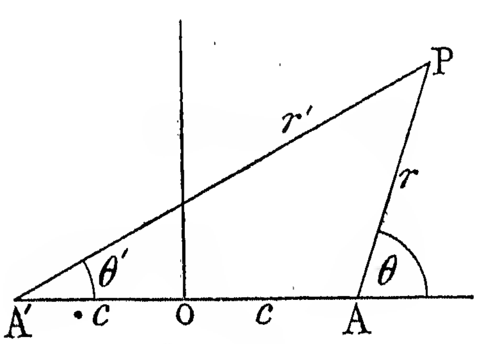

FIG. 14.

In Fig. 14 let OA = OA′ = c, and let P be a point $x + jy$.

It is clear from the figure that (vectorially)

$$\text{AP} = x - c + jy$$

and $$\text{A'P} = x + c + jy$$

Let $$x + jy - c = r\epsilon^{j\theta}$$

and $$x + jy + c = r'\epsilon^{j\theta'}$$

We obtain

$$V + j\psi = \log \frac{r\epsilon^{j\theta}}{r'\epsilon^{j\theta'}} = \log \frac{r}{r'} + j(\theta - \theta')$$

so that $$V = \log \frac{r}{r'}; \quad \text{and} \quad \psi = \theta - \theta'$$

It is obvious that the stream lines are circles passing through A and A′, and the equipotentials are an orthogonal family of circles. The solution therefore represents flow from a fictitious " source " placed at A to an equal negative source or " sink " placed at A′ (see Fig. 15).

Applying these functions to find the resistance between two cylindrical electrodes immersed in an electrolyte, we may regard one electrode as a " source " of current and the other as a " sink."

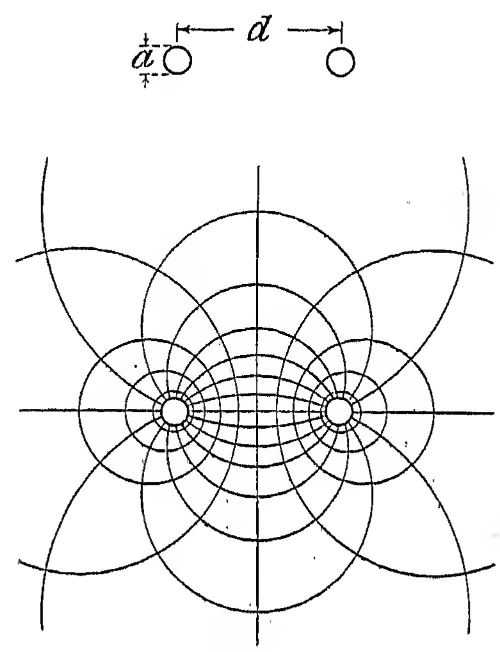

FIG. 15.

Let a be the radius of each electrode, and d the distance between their centres, assumed to be great compared with a. The equipotential boundaries of the medium the resistance of which is required are the traces of the electrodes, and its stream-line boundaries are given by $(\theta - \theta') = 0$ and $(\theta - \theta') = 2\pi$.

The two-dimensional geometric resistance can be found by applying Equation (5) thus:—

$$R' = \frac{V}{\psi} = \frac{\log (r/r')}{\theta - \theta'}$$

where r varies from $r = a$ to $r = (d - a)$, and r' from $r' = (d - a)$ to $r' = a$; while $(\theta - \theta')$ varies from $(\theta - \theta') = 0$ to $(\theta - \theta') = 2\pi$. Hence we have

$$R' = \frac{V - V'}{\psi - \psi'} = \left\{ \Big[\log r\Big]_a^{d-a} - \Big[\log r'\Big]_{d-a}^{a} \right\} \times \left[\frac{1}{\theta - \theta'}\right]_0^{2\pi}$$

$$= \frac{1}{2\pi} \log \frac{(d-a)^2}{a^2} = \frac{1}{\pi} \log \frac{d-a}{a} \qquad (18)$$

This equation gives the geometric resistance between the exploring electrodes in two dimensions, i.e. the resistance between their traces in a plane perpendicular to their length. If l be the depth of the uninsulated

part of either electrode,* their resistance will be given [from Equation (18)] by

$$R' = \frac{1}{l\pi} \log \frac{d-a}{a} \quad . \quad . \quad . \quad . \quad (19)$$

Let now a current be sent through the cell of such a value as to produce a current density i in the position occupied by the exploring points, and of opposite direction to the impressed current I. Since the line joining the exploring points follows the stream-line direction, i may be taken as being constant along that line. Hence the potential difference between the equipotentials passing through the exploring points due to a current density i is obviously $i\rho d$, where ρ is the resistivity of the electrolyte and d, as before, the distance between the exploring points. Let the impressed current I be so adjusted that the potential difference between the exploring electrode is zero. Hence we have

$$i\rho d = I\rho R'$$

whence

$$i = \frac{R'}{d} I = cI$$

This equation gives the current density i in terms of the balancing current I, which is read on the milliammeter, c being the constant of proportionality given by

$$c = \frac{R'}{d} = \frac{1}{dl\pi} \log \frac{d-a}{a}$$

In the following experiment various readings of elemental current were taken in the neutral plane by the method just described, while the main current through the cell was kept constant at 2 amperes; corresponding readings of potential gradient were also taken on the electrometer. The results are shown in Fig. 16. The effective resistance between the exploring points has been calculated from the ratio of corresponding ordinates of both the potential gradient and current curves. The resistance graph is shown to be a straight line parallel to the x axis, i.e. the resistance is constant.

This result proves the validity of Ohm's law for any elemental current in the electrolyte. Furthermore, it shows that the potential gradient at any point can be replaced by the current. The latter result is instructive, as it provides an experimental proof of the conjugate property of stream and equipotential lines, so that we have

$$i = \frac{dI}{dx} = \frac{1}{\rho} \times \frac{dV}{dy} = \frac{1}{\rho} \times \frac{d\psi}{dx}$$

or

$$I = \frac{\psi}{\rho} = k\psi$$

which is identical with the expression given on page 302.

We can now calculate the geometric resistance between the exploring electrodes by applying Equation (19) and substituting the actual dimensions of these electrodes. Thus we have

$$R' = \frac{1}{l\pi} \log \frac{d-a}{a}$$

* The exploring electrodes used were insulated all over with paraffin wax with the exception of a length of 5 mm near their extremities which was left uninsulated. The extremities themselves were also wax-insulated so that the end effect was thereby eliminated.

In the present test the measured dimensions were:

$$d = 1 \text{ cm}$$
$$l = 0\cdot5 \text{ cm}$$
$$2a = 0\cdot2 \text{ cm}$$

Hence

$$R' = \frac{1}{0\cdot5\pi} \log 9 = 0\cdot637 \times 2\cdot197 = 1\cdot4$$

Now we have from the resistance graph (Fig. 16) $R = 70\cdot5$ ohms, hence the resistivity of the electrolyte can be deduced thus:—

$$\frac{R}{R'} = \frac{70\cdot5}{1\cdot4} = 50\cdot3 \text{ ohms/cm}^3$$

and the conductivity is therefore given by

$$k = 0\cdot0199 \text{ mho/cm}^3$$

Confirmation of results.—It is evident from the above discussion that the ordinate of the current curve shown in Fig. 16 when multiplied by c gives the current density in the neutral plane. Since the total current emanating from the front and back sides of the electrodes passes through the neutral plane, it follows that the line integral of the current density in this plane gives the current flowing in a horizontal slice of the electrolytic cell 1 cm deep. This can be obtained by taking the area of the current curve and multiplying it by c. The total current in the cell can then be calculated from the dimensions of the electrodes and the lateral and bottom margins as follows:—

Numerical calculations.—Electrode dimensions (immersed surface) = $13\cdot6 \times 10$ cm^2, and bottom margin = $11\cdot1$ cm. The current curve (Fig. 16) extends from the central line of the electrodes to the walls of the glass vessel, so that the lateral margin (which is the same on either side of the electrode) is included in the current curve. Hence the area of this curve multiplied by c gives half the current sheet flowing in a slice 1 cm deep taken horizontally through the cell.

The current area for the bottom margin can be estimated by producing the current curve (Fig. 16) to a point $11\cdot1$ cm from the electrode edge, which is the length of the bottom margin, and taking the corresponding area from this curve. Hence we have:—

Area of current curve (Fig. 16) from the electrode centre to the vessel wall	=	42·35 mA-cm
Current area for a horizontal slice 1 cm deep = 2 × 42·35	=	84·7 mA-cm
Current area per cm length of bottom margin	=	24·0 mA-cm
We therefore have		
Current volume in the inter-electrodal and lateral space = 84·7 × 13·6	=	1 150 mA-cm^2
Current volume in the bottom marginal space = 24·0 × 10	=	240 mA-cm^2
		1 390 mA-cm^2
	=	1·39 A-cm^2

Hence total current through the cell = $1\cdot39c = 1\cdot39 \times 1\cdot4$ = 1·95 amperes

Actually the current in the cell was kept constant in the above test at 2 amperes, so that the discrepancy is about 2·5 per cent. It will be noticed, however, that the centage of the total current and would probably account for the above discrepancy.

An important conclusion which may be drawn from

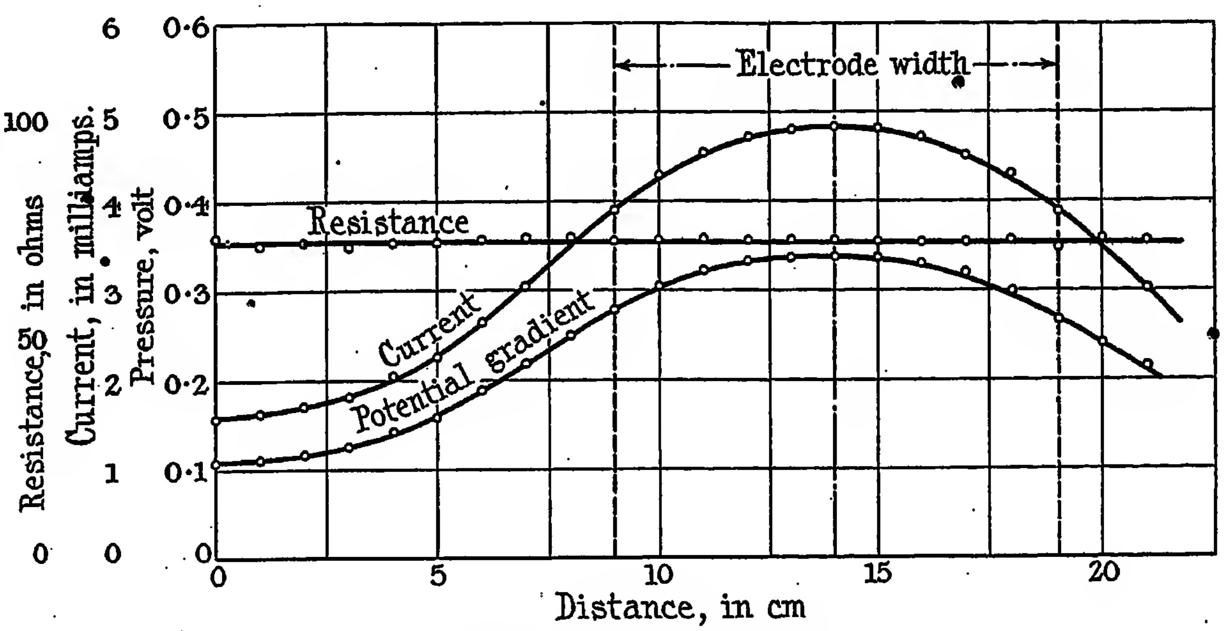

FIG. 16.—Distribution of potential gradient and current in the neutral plane.

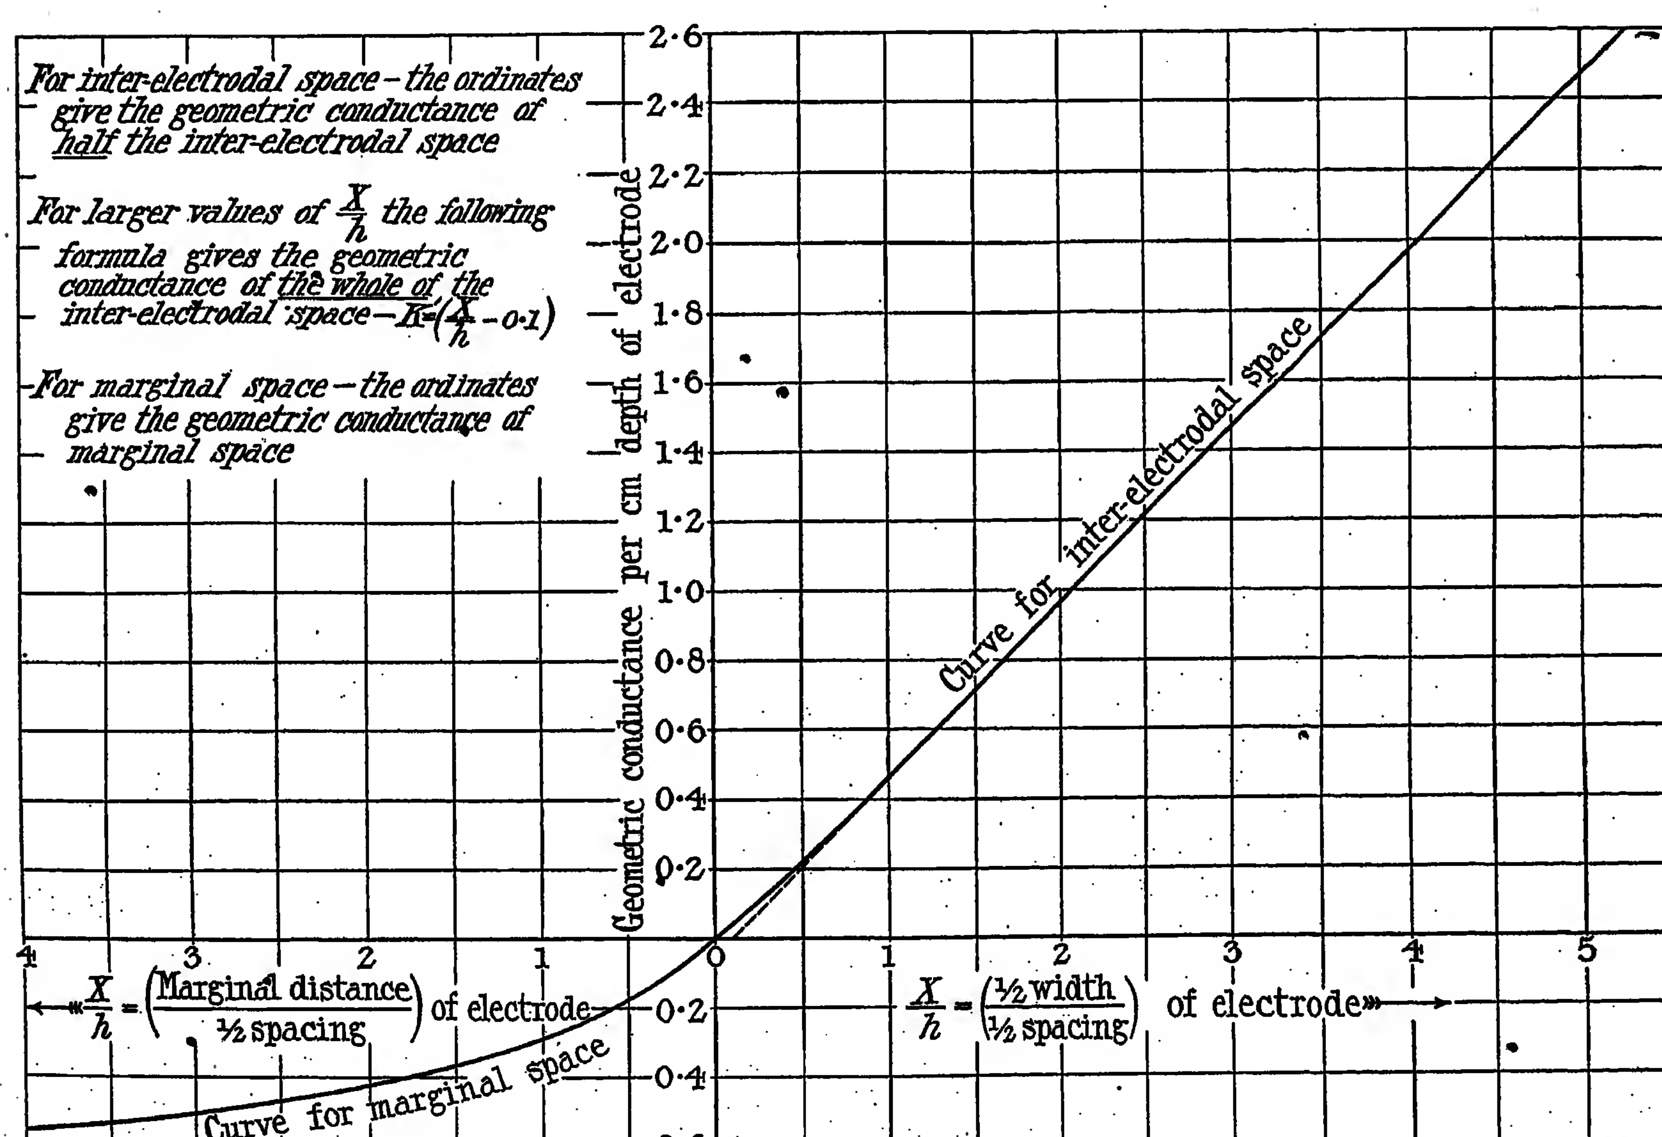

FIG. 17.—Chart for finding the geometric conductance of an electrolytic cell with plane parallel electrodes.

current issuing from the corner points of the electrodes is not taken into account in the above calculation, as the flow from these points is no longer two-dimensional. It is conceivable that this current is only a small per-

the above experimental results is that at any point in the electrolyte stream lines rigidly follow the direction of electric stress, so that an electrolyte may be taken to represent a perfect homogeneous medium with something

approaching mathematical precision. Thus a homogeneous dielectric such as air may be represented by an electrolyte in which the measurement of current would give to a certain scale the dielectric flux, which is otherwise impossible of measurement by direct experiment.

The importance of this result lies in its application to the practical measurement of such electric quantities as may be determinable by the measurement of the dielectric flux involved, e.g. the capacity of an irregular system of conductors. The method of procedure would be to take an electrolytic analogue of the dielectric circuit and measure its conductance, then to take another simple system whose capacity can be calculated mathematically (such as two parallel wires) and measure its conductance in the same electrolyte. The required capacity can then be found from the ratio of the two conductances and the known capacity of the two wires.

4. Calculation of the Geometric Conductance of an Electrolytic Cell having Plane Parallel Electrodes.

Consider first the case of two plane parallel electrodes such as those shown in Fig. 3. The geometric conductance in two dimensions is given by the line integral of the stream lines issuing from either electrode per unit potential difference, or by Equation (4)

$$K' = \frac{\psi}{V}$$

In order to evaluate ψ in this equation the simpler way is to take the stream flux on the lower plate AB in Fig. 3, as this represents the sum of stream lines emanating from the front and back sides of the upper plate CD. This flux is given by Equation (16), viz.

$$\psi = \frac{V}{\pi}\log(-1-t)$$

and hence
$$K' = \frac{\psi}{V} = \frac{1}{\pi}\log(-1-t) \quad . \quad . \quad . \quad (20)$$

Equation (20) thus enables us to find in the case under consideration the geometric conductance of the electrolyte between any assigned boundary values of t, where t varies from -1 to $-\infty$.

In order to express the dimensions on the electrolytic cell in terms of t we have from Equation (15)

$$\frac{x}{h} = \frac{1}{\pi}\{t - \log(-1-t)\} \quad . \quad . \quad . \quad . \quad (21)$$

Hence Equation (20) gives

$$K' = f(t) = f(x/h) \quad \text{[by Eqn. (21)]}$$

so that the geometric conductance for the above case can now be calculated by means of Equations (20) and (21).

We shall now proceed to deduce similar expressions for the geometric conductance between two parallel plane electrodes placed opposite to each other in an electrolytic cell.

Imagine a lamina placed in the neutral plane so as to divide the cell into two equal sections symmetrically situated about the neutral plane. Each section will then be analogous to the case considered above. The introduction of such a lamina does not affect the original distribution of current in the cell, as it coincides with an equipotential surface, viz. the neutral plane. Since the two halves into which the cell is thus divided are in series with each other, the resultant conductance is obviously half of each and is therefore given from Equation (20) by

$$K' = \frac{1}{2\pi}\log(-1-t) \quad . \quad . \quad . \quad . \quad (22)$$

Thus Equation (22) gives the geometric conductance of the cell in two dimensions, i.e. the geometric conductance of a slice of unit depth taken through the cell normal to the electrode planes.

Construction of a Chart for Finding the Geometric Conductance of an Electrolytic Cell with Plane Parallel Electrodes.

We can now construct a chart for finding the geometric conductance of an electrolytic cell or any portion

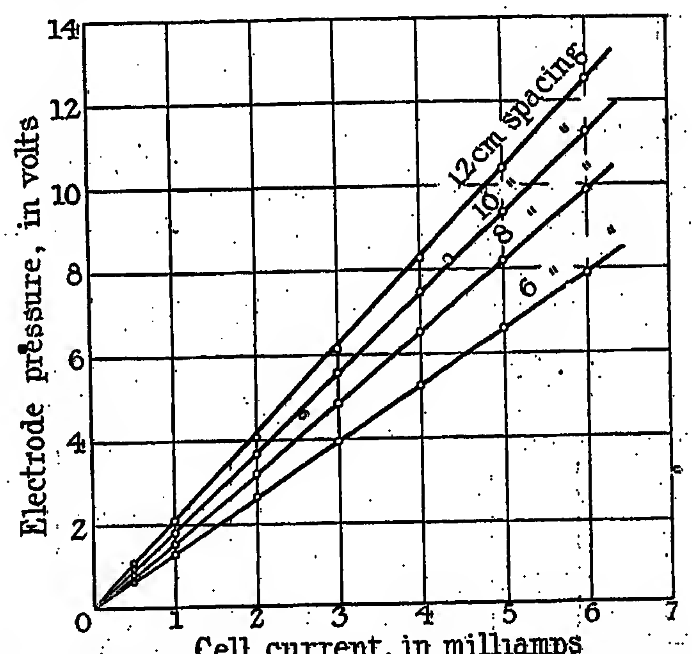

Fig. 18.—Measurement of the conductance of an electrolytic cell.

of the electrolytic circuit between two assigned limits, by taking various values of t in Equations (21) and (22). Such a chart, shown in Fig. 17, gives the geometric conductance in terms of x/h, where h is half the electrode spacing and x the distance measured from the electrode edge, and has the following significance:

(a) For the inter-electrodal space, x is to be taken equal to one-half the width of the electrode, and x/h is taken in the chart along the positive side of the x axis. The corresponding ordinate of the curve gives the geometric conductance of half the inter-electrodal space.

(b) For the lateral space or the marginal space beneath the electrodes, x is equal to the distance from the electrode edge to the boundary wall of the containing vessel, and x/h is taken in the chart on the negative side of the x axis. The corresponding ordinate of the curve gives

the geometric conductance of that portion of the cell to which x refers.

In order to illustrate the use of the chart we shall take the following simple example:

To find the geometric conductance per unit depth of an electrolytic cell having the following dimensions:—

Electrode width = 20 cm
Lateral margins = 6 cm each
Spacing = 10 cm

(*a*) *For the inter-electrodal space*

$$\frac{x}{h} = \frac{\frac{1}{2}\,(\text{Electrode width})}{\frac{1}{2}\,(\text{Electrode spacing})} = \frac{10}{5} = 2$$

From the chart (Fig. 17) the conductance K' of half the inter-electrodal space = 0·965

(*b*) *For one marginal space*

$$\frac{x}{h} = \frac{\text{Marginal distance}}{\frac{1}{2}\,(\text{Electrode spacing})} = \frac{6}{5} = 1\cdot 2$$

From the chart the conductance K' of marginal space .. .. .. = 0·315

Hence the geometric conductance of one-half of the cell per unit depth = 0·965 + 0·315 = 1·28

and the geometric conductance of the cell per unit depth is therefore .. = 2·56

It may be observed from Fig. 17 that for large values of x/h the geometric conductance curve is practically a straight line, which, when produced, cuts the x axis at the point $x/h = 0\cdot 1$. A formula can therefore be deduced which gives the geometric conductance for values of x/h beyond the range shown in the chart. Let α be the angle which the straight line part of the curve produced makes with the x axis. Then we have

$$K' = [(x/h) - 0\cdot 1] \tan \alpha$$

where $\tan \alpha = 0\cdot 5$ (approximately).*

Therefore $$K' = \frac{1}{2}[(x/h) - 0\cdot 1]$$

This formula gives the geometric conductance of half the inter-electrodal space, so that for the whole of that space we get

$$K' = (x/h) - 0\cdot 1$$

The same chart can be used for cases where the electrodes are of unequal dimensions, e.g. the case shown in Fig 3, discussed at the beginning of this section. Here h is to be taken as the total electrode spacing, and x will have the same significance as explained above. The geometric conductance, however, will be twice that given by the chart for any particular value of x/h.

The total geometric conductance of the cell (in three dimensions) can now be easily calculated from the electrode and marginal dimensions of the cell, as shown in the table.*

Confirmation of Results.

In the table on page 316 the geometric conductance of the electrolytic cell experimented with was calculated for different electrode spacings by the use of the chart (Fig. 17). The actual conductance of the cell was measured experimentally for the same spacings, and the results are shown in Fig. 18. The conductivity of the electrolyte was then deduced from the ratio of the measured conductance to the corresponding geometric conductance obtained by calculation. The average value works out as 0·0191 mho/cm^3.

In order to verify the results thus obtained the conductivity of the actual electrolyte was determined in a separate experiment arranged specially for the purpose. A description of the apparatus and the method used is given in Appendix 2. The value obtained for the conductivity was 0·02 mho/cm^3.

Conclusion.

Inspection of the previous table shows that the values of conductance calculated by the use of the chart (Fig. 17) are in fair agreement with those obtained experimentally.

The proportionality of geometric conductance to conductance is obvious from the table. The average conductivity obtained by calculation works out at 0·0191, against 0·02 obtained by direct experiment (see Appendix 2), with a difference of 4 per cent, which may be permissible in a calculation of this description. This result also compares favourably with the value of the conductivity obtained in Section 4, where its calculation by a different method gives 0·0199 mho/cm^3.

Some Practical Remarks.

Some interesting deductions may be made from the previous discussion, which may be of use to the designer of ordinary metal-refining tanks and liquid rheostats.

It will be observed from Fig. 17 that the value of the margin in contributing to the conductance of the cell per unit of its length decreases as we recede from the electrode edge. The most useful part of the margin in this respect appears to extend from the electrode edge to a point $x/h = 2$. Any increase of margin beyond this point adds comparatively little to the conductance of the cell. The rate of increase of conductance approaches zero as a limit.

It may be added that for a given size of electrode the relative contribution of the margin to the conductance increases with electrode spacing, and conversely. An economical limit can be determined by consideration of the relative size of tank and electrodes to give a specified conductance.

A practical illustration of the use of the above results is afforded where graphite or some similar expensive

* The ultimate value of $\tan \alpha$ is $\frac{1}{2}$ at a distance sufficiently remote from the edge so that the field becomes uniform. For if x be the width of a portion of the inter-electrodal space lying in such a uniform field, and $2h$ its length (electrode spacing), the geometric conductance, i.e. the conductance for unit conductivity, is $\frac{1}{2}\,x/h$.

* Electrochemists use the term "cell constant" to denote what we have called the "geometric conductance" of the cell. It is determined experimentally for any particular cell of given configuration by using an electrolyte of known conductivity and measuring the conductance of the cell by the well-known Kohlrauch or similar method whence the cell constant is deduced.

substance is employed as one of the electrodes. The question arises in this case as to how far a diminution of the electrode area can be compensated for by the lateral conductance of the electrolyte.

The results are probably equally important to the electrical engineer in the design of equalizing bars and heavy busbars of short length. They show the importance of making contact over the whole end of a heavy bar in order to utilize fully the metal of the bar.

In conclusion the author wishes to express his cordial thanks to Professor W. Cramp, D.Sc., for his helpful advice during the course of the present investigation as well as for reading the paper in manuscript. The whole of the work has been carried out at the University of Birmingham.

(3) The concentration of the electrolyte was kept constant throughout the various tests, and a constant level was maintained in the cell. The solution contained 100 grammes of copper-sulphate crystal per litre.

(4) It was noted that when the current was first switched on, the first set of readings were sometimes erratic and inconsistent with subsequent tests. It appears as though this was due to want of uniformity in the ionization of the electrolyte at the start. It was therefore arranged to allow about 15 minutes before taking any readings. It is significant that such an allowance was not necessary after a reversal of current, but only at the beginning of each working day.

(5) As a rule, when the current was kept constant in any particular test the P.D. across the electrodes also

APPENDIX 1.

Some Remarks on the Method of Procedure in the Experimental Work.

(1) In order to equalize the deposit on both electrodes as much as possible, the current was reversed in the cell roughly every 30 minutes, which was about the duration of each test.

(2) The temperature of the electrolyte was observed at the beginning and end of each test. Owing to the large volume of liquid used, the actual rise of temperature was not more than 3 degrees C.

remained constant, but in some tests, especially with higher values of current, slight variations of P.D. or current were apt to take place in such a manner that their ratio was no longer constant, indicating a variation in the conductance of the cell. Since the temperature-rise was small and the concentration was kept constant, it was considered unlikely that such fluctuations would arise from changes of the resistivity of the electrolyte, but rather from variations of contact resistance at the electrode surface, caused chiefly by the formation of gas bubbles. It was therefore decided to keep the current rigorously constant, in order to maintain a constant potential difference at the boundaries of the

electrolyte, which is essential for the purpose of comparing observations with mathematical results, and to note the variations of P.D. as they occurred.

(6) If tests taken at different times be compared, a slight difference may be observed in the results. This is due to alteration of the surface condition of the electrode by electro-deposition, which has the effect of altering, sometimes appreciably, the conductance of the cell.

APPENDIX 2.

Determination of the Conductivity of the Electrolyte.

The apparatus employed is somewhat similar to one used by S. W. J. Smith * and H. Moss for the same purpose. It consists of two bottles connected near their bottoms by a horizontal tube (see Fig. 19). The bottles and connecting tube contain the electrolyte whose conductivity is to be measured. Current is sent through the electrolyte by means of electrodes placed in the bottles. Two auxiliary electrodes are inserted in the tube near its ends and connected to an electrometer by means of leads which pass through two mouths having rubber stoppers in the tube. The fall of potential across the electrolyte in the tube is measured on the electrometer and the reading compared with that across a known resistance; in this way the required resistance is found.

* *Proceedings of the Physical Society of London*, 1913, vol. 25, p. 133.

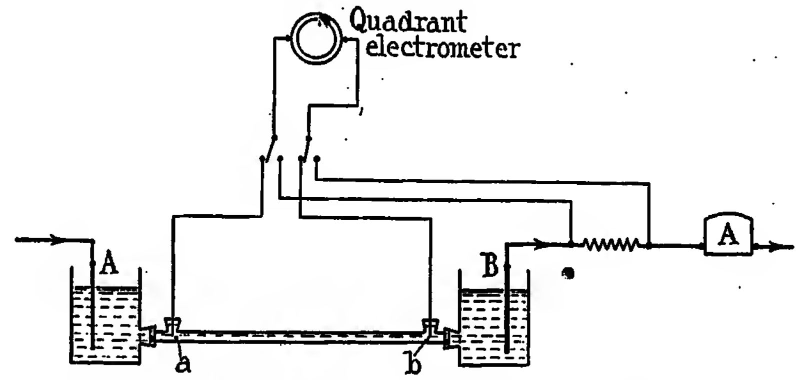

Fig. 19.—Apparatus for measuring the conductivity of an electrolyte.

The internal cross-sectional area of the tube is determined from the mass of distilled water which would fill a measured length of the tube.

Various readings were taken for different currents, giving consistent values of the resistance of the electrolyte. The conductivity works out at 0·0202 mho/cm^3.

RAILWAY ELECTRIFICATION IN FOREIGN COUNTRIES.

By Stanley Parker Smith, D.Sc., Member.

(Abstract *of a Lecture delivered before* The Institution *3rd January, before the* Western Centre *7th January, before the* North Midland Centre *22nd January, before the* South Midland Centre *16th January, and before the* Scottish Centre *12th February*, 1924.)

As I wish to treat the subject of railway electrification as objectively as possible, I propose to deal with the various countries in alphabetical order. It will be noticed from the title that I propose to consider only what has been done in foreign countries; in fact there is nothing to say about the electrification of long-distance railways in Great Britain.

Austria.

I wish to give some idea of the work that has been going on largely since the war. Before the war Austria had already had experience with electric railways, and just prior to hostilities the line known as the Mittenwald railway, which runs from Innsbruck to the German frontier, then into Bavaria, back again into Austria and so on to Reutte, was built as an electric railway and equipped on the single-phase system. The frequency was raised from 15 to 16⅔ cycles, in accordance with the common practice of Germanic countries. This is a privately-owned railway. The power is obtained from the station at Rutzbach, which is now also supplying the power for the Arlberg Railway. Another railway which was running before the war was the pilgrim and tourist line from St. Pölten to Maria Zell. Originally this was a steam line. It was converted to electric working in order to increase the traffic facilities, and it has been a success ever since it was opened. There are several water-power stations, and at St. Pölten there is a Diesel engine station run from Galician crude oil. Another railway which was opened just before the war—also a private line—runs from Vienna to Pressburg in Hungary. This line is a direct-current line at the termini, while single-phase locomotives haul the trains in the open country.

The position of Austria after the war was a very serious one, and it was therefore important to utilize

her water power in order to reduce coal imports. The country is very mountainous, and water power is fairly plentiful. The worst problem the Austrians had to face was the Arlberg line which connects the route from Lake Constance to the capital through Innsbruck —the main east and west route through Austria. The Arlberg Tunnel gave considerable difficulties in the old dual monarchy, but for various reasons, particularly strategic, nothing was done in the way of general electrification. This line was commenced first. The hydro-electric station at Spullersee is fed from a large storage lake, which can be drawn on during peak loads, frosty weather and droughts, and serves also as a general reserve. This station will work in parallel with the Rutzbach station.

In July 1920 the National Convention decided on a general electrification scheme and made a five years' programme for the conversion of the Arlberg, West, Tauern and Salzkammergut lines. In July of last year (1923), the Innsbruck end of the Arlberg line was opened for electric working. It is interesting to mention that the 55 000-volt supply cables, instead of being taken through the tunnels, are led over the Arlberg and Korntauern passes. These passes are often inaccessible in winter so that the construction has to be very rigid.

The system which the Austrians chose was the single-phase system with 15 000 volts at the contact wire, and a frequency of $16\frac{2}{3}$ cycles. They had had previous experience with that system, and were accustomed to the manufacture of the machinery. They also found that for various reasons it would be the most economical one. The power is to be supplied mainly by railway generating stations, though in the south power may be bought from private companies. Generally speaking, however, the Federal railways are equipping their own stations.

France.

The scheme commenced by the French since the war is probably of much greater extent than that of any other country. Their experience of coal shortage and the need for using the natural resources have probably had considerable influence in urging their decision to make rapid progress with railway electrification. Before the war a certain amount of work on the single-phase system had been done by the Midi group, chiefly on lines running into the Pyrenees. This was successful, but in accordance with the decision which was ratified by the French Government, that work has now been converted into the national system, which is direct current at 1 500 volts. This system is to be used for the Midi, the Orleans, and the Paris, Lyons and Mediterranean Railways. The power for these railways is to be obtained from a national three-phase, 50-cycle, 150 000-volt network. Water power will be utilized wherever possible. There is a great deal of power available in the Pyrenees, in the Massif Central (Central Plateau) and in the Alps. In addition to this immense water power resource, there are large steam stations at Paris, Gennevilliers (which has been recently opened) and other stations in the course of construction. Where the distances are shorter, transmission voltages lower than 150 kV will be used. The pressure will be transformed down and converted either by means of 1 500-volt, 50-cycle rotary converters, by mercury rectifiers, or by the older method of using two 750-volt rotary converters in series. As these matters have been recently described before the Institution,* it is not necessary for me to dwell very long on France. It may be well to say that the scheme is simply enormous in extent. Each of these railways is contemplating something like 2 000 to 3 000 km of route electrification, so that the 20 years' programme which they have arranged is perhaps something that no other country has hitherto attempted.

As regards the work already done, the Paris–Orleans route is now electrified for a considerable distance. The Midi is probably further ahead than any. On the P.L.M. very little has been done as yet. The Culoz–Modane line has been chosen as the experimental section, and it is hoped next to get on with work round Nice, and on the Côte d'Azur.

With regard to the locomotives, the goods engines are pretty well standardized, mainly on the American model, while for the express locomotives the French are building a large number of types for experimental purposes.

With regard to the mode of collection, it is not the object of this lecture to open up or continue any of the academic discussions which we have from time to time; but one question of perennial interest, in common with the choice of system and whether power should be generated by the railway companies or obtained from supply authorities, is whether the current should be collected from a third rail or from an overhead wire. With a d.c. pressure of 1 500 volts it is exceedingly difficult to decide which is the better method. The French therefore decided that all the rolling stock should be made available for collecting the current either from an overhead wire or from a third rail. The result is that many of the lines are using both methods; but some of the lines appear as much prejudiced in favour of the overhead system as other lines are prejudiced in favour of the third-rail system. I mention this to show that just on the border-line of 1 500 volts d.c. it is almost impossible to know what to do; one can get as many divisions of opinion on that as on any other sharply divided subject.

Germany.

Before the war Germany had already started in Prussia, in Bavaria and in Baden to experiment on electric traction, using the single-phase system. In 1920 the German railways, which were previously State railways, were federalized. The Reich immediately set on foot an inquiry into what system should be adopted for the electrification of the railways, because the condition of the coal supply was not much easier in Germany than it was in her neighbouring countries. The result of the inquiry was to confirm the use of the single-phase system. That system had been adopted already and they found it would be best to continue with it, except for the Berlin railways. It was originally intended to make Berlin part of the general scheme in order to utilize

* *Journal I.E.E.*, 1924, vol. 62, p. 213.

existing rolling stock, but that scheme was found to be unsuitable owing to the enormous post-war increase of traffic, which made it necessary to use motor coaches. In view of this it was found more desirable to use direct than alternating current, as the service could be made denser and more in accordance with suburban needs. Further, the equipment for motor coaches was cheaper with direct than with alternating current. It was therefore decided to equip the urban, suburban and ring lines of Berlin with 800 volts (d.c.), third rail. The rest of the system is to be single-phase throughout. It is not easy to state to what extent Germany's decision to use the single-phase system led France to use a different system, but it would be reasonable to assume that the two countries would not adopt the same system.

As so much has been said in connection with interference with communication circuits, it is rather interesting to note that in France it was given as one of the decisive factors that direct current causes less disturbance to communication circuits than does alternating current. In Germany disturbances had, of course, been caused by alternating current, but here the argument was that in any case it is unsound practice to have a high-tension overhead wire near a communication circuit. In other words, the Germans consider that the right procedure is to remove the communication circuits from the track. When once the telephone wires are removed it does not matter, of course, which system is used, from this point of view. Thus one country gets over the interference trouble by using direct current, and the other by removing the communication circuits from the track. In trying to determine which system is really the better financially (both systems are technically sound), a great deal depends on such subsidiary questions as how much it will cost to remove the communication circuits when alternating current is used, and how much the prevention of electrolytic troubles with direct current will cost.

Coming to the Prussian lines, the Silesian mountain railways are worked from the steam station at Mittelsteine, and have been extended considerably since the war. In Saxony there is the experimental track Leipsic–Halle, etc., in an important industrial district. Power is supplied from Muldenstein—a station worked with lignite fuel too poor for steam locomotives.

The Wiesental line in Baden has been working for some years. It is really a small valley line electrified for experimental purposes, and is fed from a hydro-electric station at Augst Wyhlen on the Rhine.

In Bavaria an enormous 100-kV ring main encircling the country from Munich to Nuremberg is being erected. Power will be mainly obtained from a large hydro-electric station at Walchensee and from stations on the Middle Isar River. These stations will all be linked up. When this scheme was under consideration, the railways obtained rights to put down their own pipe lines and their own generators in the stations then being built for the Bavarian ring main. These stations are therefore divided into two distinct portions, a traction part (single-phase) and the general network part (three-phase). It was more economical to obtain traction power in that way than to build separate stations: otherwise the systems are independent. The traction energy is generated in the form of single-phase current at $16\frac{2}{3}$ cycles, so that for the track it only needs to be transformed down in the substations to 15 000 volts.

About 10 or 15 years ago gears were very little used in locomotives; in fact they were then in but a semi-developed state. Germany tried almost every conceivable arrangement with side rods and cranks. The methods that were used in America did not seem to be very popular in Europe. Now there is, as we have seen, much greater freedom. In France gearless locomotives are used with the armatures on the axle, and the geared quill drives are also becoming very popular. Later, gears with side-rod systems began to be used in Germany, while the Austrian types are very similar. Germany has now more or less standardized her drives, and only one of the six standard locomotives is without gears. This gearless locomotive has proved very satisfactory, and is being kept for express work; but for all the other cases it is cheaper to have a geared locomotive. We have to remember, however, that gearing was not altogether feasible some years ago. Attention may be drawn to the individual-axle drive, due to Buchli, which was developed in Switzerland, where it appears to have been a success. It is now being tried both in Germany and in France, sometimes with alternating and sometimes with direct current. This drive has proved very attractive: it overcomes in a very practical manner the difficulty of transmitting the power from a spring-borne motor to a non-spring-borne wheel.

HOLLAND.

It was originally intended here to use single phase—indeed a short single-phase line has been working for some years from Scheveningen to Rotterdam; but on further consideration the Dutch decided that as they wanted to utilize the existing power stations and as the distances were relatively short (Holland being a small country) it would be better for their purpose to use 1 500 volts d.c. One of the decisive reasons was that in Holland the railways are extensively used for telegraph and telephone circuits, and it would be a matter of some difficulty to remove them. They have decided, therefore, when they proceed, to use the d.c. system. The first line that they hope to electrify when necessary is from Rotterdam to Amsterdam.

HUNGARY.

This country has practically no water power and very little coal resources. It has no locomotive coal, and yet it must do something to make itself independent of imports. The scheme that is being put forward is to have a national three-phase, 50-cycle network, obtaining the power from fuel stations fired with brown coal (lignite) or peat. The power for the railways would then be obtained by taking separate phases along the various routes so as to equalize the load as reasonably as possible. The standard a.c. commutator motor for traction work at the present time is that known as

the "neutralized-series" motor, but for successful working a low frequency is necessary and it would not be suitable for use on such a 50-cycle system. I think that one reason why some countries in Europe have been so successful with alternating current is because a lower frequency has been adopted. For instance, $16\frac{2}{3}$ instead of 25 cycles is used on the Continent. Hungary, however, wishes to use 50 cycles, and for that purpose the a.c. commutator motor is not a success as a traction machine. It is hoped, therefore, to overcome the difficulty by using what is known in America as the "split-phase" system. On the locomotive a phase converter is to be used to supply the three-phase induction motors used for driving the locomotive. The system is in successful use in America.

Italy.

This country is really the cradle of railway electrification in Europe: the Valtellina railway was about the first example of European main-line electrification. At that time the three-phase system was practically the only system available. The d.c. arrangement then was in its infancy for main-line work, and the single-phase system had not yet proved a success. The three-phase system entails a double overhead conductor, but when this is said its worst disadvantage has been mentioned. A frequency of 15 cycles was adopted for two reasons. The inductive drop was small, but perhaps the more important matter was that the speed of the motors was more suitable. Gears were not used on locomotives at that time; they were a later development, so that in the early years of this century when Italy began to electrify her railways there was good reason for adopting a low frequency of 15 cycles in order to get a suitable speed for her gearless locomotives. This conversion proved a success, and in 1909 and subsequently the railways known as the Giovi lines were electrified. These have the heaviest train-movement in Italy. There is an enormous traffic from Milan to the port, and in crossing the Apennines there are many tunnels. The Giovi tunnel had a very bad reputation for foulness, and electrification has solved that problem completely. The line from Savona to Ceva, on the way to Turin where the railway crosses the Apennines, was also electrified. The Mont-Cenis line was next tackled and for some years now the tunnel has been worked with three-phase locomotives. There has thus been a tremendous amount of work done with three-phase electrification in Italy. It is easy to criticize this system now that we have other systems which are perhaps simpler and, as we may think, better, but we are trying to look at the matter as objectively as possible, and I think he would be a bold man who would say that Italy had not done well with her three-phase system. It has solved practically all her difficulties. The earlier motors, it is true, ran at only two speeds, but there are now locomotives that will run at three or even four speeds and which appear to fulfil the conditions of the service admirably. It is true that, with the double overhead wire, the voltage has hitherto been kept rather low (about 3 000 volts), but nevertheless I think the greatest credit has to be given to the Italian engineers for their pioneer work in developing a system which up to this day has not had to be replaced.

Future work will extend into the Peninsula. In the Rome district the standard frequency will be 45 cycles and the power will be taken from the existing networks. A higher voltage will be used on the track. Thus it is intended to try the three-phase system at 45 cycles and 10 000 volts with geared locomotives.

Scandinavia.

This is a Germanic country and we must not be surprised to find alternating current used again. The Riksgränsen line has been worked electrically for some years. It is the most northerly railway in the world and lies practically within the Arctic Circle.

This Lapland railway was built for transporting the rich minerals mined at Kiruna and Gellivare. There is a considerable heavy traffic down to the port of Lulea on the Gulf of Bothnia and to Narvik on the Arctic Ocean. The power is obtained from a hydro-electric station at Porjus. The electrification is now being extended through the Norwegian part from Riksgränsen to Narvik by what is known as the Ofoten railway, so that soon the whole railway will be electrified.

The Swedes have also been working a good deal at the electrification problem of the Stockholm–Gothenburg line, and have decided that the best system for their country is a single-phase overhead $16\frac{2}{3}$-cycle, 15 000-volt one. The power will be obtained from stations which are used for general industrial work.

In Norway a little has been done. The Drammen railway was electrified at the same time as the gauge was altered, so that at that time there was a good deal of complication. Two light railways also are electrified, while the extension of the Riksgränsen Railway to Narvik has already been mentioned.

The original Riksgränsen locomotive had no gears, developed about 1 700 h.p. and weighed about 138 tons, while the new geared locomotives give 2 900 h.p. and are about 10 tons lighter than the original.

Switzerland.

Of all countries probably Switzerland has done relatively the most with regard to her electrification schemes. In fact she is going ahead with it so rapidly that recently, when the unemployment question became so acute and it was necessary to do something to keep her works busy, she hastened the programme by 5 years, so that the work which was to have been completed by 1933 has now to be completed by 1928. This will entail the electrification of about 200 km of route per annum instead of about half that amount. Years ago they commenced experiments in Switzerland and, as in other countries, the privately-owned railways were well to the fore. One of the oldest electrifications is the Burgdorf–Thun line, which was electrified on the three-phase system. Next came the Simplon Tunnel, which was equipped with the three-phase system for practical reasons, three-phase power being available from the tunnel workings. They were also able to take a couple of locomotives which were being built for the Valtellina railway.

During the war, conditions were very serious, owing to coal shortage in Switzerland, and they therefore pushed forward the three-phase electrification as far as Sion in the Rhone Valley. The Loetschberg line was electrified from the outset. It was built to connect Berne with Italy, and was equipped on the single-phase system.

The group of privately-owned lines, known as the Rhaetian Railways, is now completely electrified on the single-phase system, power being bought from local supply authorities.

As regards the Federal Railways, the matter has been subject to a good deal of consideration by a special Investigatory Committee, and it was ultimately decided to recommend the single-phase system with a high-voltage overhead contact wire and a low frequency. There was a good deal of argument for a long time, and when, during the war, they really had to begin to electrify the St. Gothard route they still did not decide on what they were going to do until the works at the Ritom power-house were so far advanced as to make a decision imperative; and then it was decided in favour of the single-phase system. Successful results were being obtained on the Loetschberg railway and on the Rhaetian group: in addition, their manufacturers were accustomed to the system, so that they could go ahead without hindrance. The whole of the St. Gothard line is now worked on the single-phase system, the supply being taken from the Ritom and Amsteg stations.

With regard to new work, there is the Rhone Valley line, including the conversion from the three-phase to the single-phase system, and the new station at Barberine.

An immense variety of locomotives have been tried in Switzerland. Some of these have been provided with regenerative equipment, but without very good results. The place where one needs regenerative control—on the suburban lines—is just where it is so difficult to get it. On Swiss lines so little energy is returned that it is almost better to use rheostatic braking, considering its greater simplicity.

A few remarks as to the method by which the Swiss intend to equalize the load, i.e. to get a regular supply of power, may be of interest. The station at Ritom is on the southern side of the St. Gothard Tunnel. There is a lake which collects water in summer. This is drawn on in winter and during peak loads. The other station at Amsteg is fed from the river Reuss on the nothern side of the St. Gothard Tunnel. The water is taken five miles through a pressure tunnel in the hillside, and then goes down a pipe line to Amsteg. In the winter there is not much water in the river, so that this station is mainly for summer traffic. Until the line is electrified up to Basle, these stations will not be fully loaded, so that in the meantime the Federal authorities are installing three-phase generators which will work on the neighbouring general supply networks. Generally speaking, however, the idea is to use their own stations for the railways, and as the railway load develops, the single-phase generators will take the place of the three-phase machines. The stations will then be used for traction solely, and will belong to the Federal authorities.

UNITED STATES OF AMERICA.

In the west there is the Chicago, Milwaukee and St. Paul Railway which was opened for electric working during the war. There is no need to say much about this line as a description illustrated by cinematograph films was given here last year by Mr. Welbourn (see vol. 61, p. 800), and I do not suppose that any line has been more widely advertised. It is the longest electrified railway in the world, and it was originally unique in so far as it uses direct current at 3 000 volts. Previously the highest d.c. voltage had been on the Butte-Anaconda line (2 400 volts), for taking the copper ore from Butte to the smelting works at Anaconda. The C. M. & St. P. Railway is a trans-continental route from Chicago to Puget Sound. Starting at Harlowton, the electrified portion crosses five ranges of mountains. Already the two heavy-grade sections from Harlowton to Avery and from Othello to the Puget Sound termini have been electrified, 650 miles in all. Ultimately nearly 900 miles will be electrified. It is a single track with very few trains per day, but these are very heavy. The locomotives are of about 3 000 to 4 000 h.p. and weigh 200 to 300 tons. The power is bought from supply authorities owning hydro-electric stations, the peak load being definitely limited. This is a fine and interesting experiment with high-voltage direct current, and it had an enormous influence on the French in their decision to use direct current, though they decided to use half the voltage.

In the west there is also the Cascade Tunnel electrification—the only three-phase case in the States—and the single-phase railway at Spokane.

Coming to the eastern portion of the States, there are various tunnel electrifications. Where the tunnel is not a terminus the electric locomotive is simply hitched on to the steam locomotive and pulls the whole train through. At termini the steam locomotive is replaced by an electric locomotive to haul the train through the tunnel.

The Norfolk and Western Railway is a heavy mineral line. In addition, there is the neighbouring Virginian Railway which they have now decided to electrify. It is practically the only electrification started in the States since the war, but it is a very large scheme involving a contract of 15 million dollars. The Virginian Railway, like the Norfolk and Western Railway, is to be electrified on the split-phase system. Coal trains up to 9 000 tons will be hauled by locomotives giving 12 000 h.p.

The electrified lines in the east are chiefly centred about New York and Philadelphia. Some of these railways are very much like the suburban railways round London, with very dense traffic, and operate at 650 volts d.c. The New York, New Haven and Hartford line works on the single-phase system at 11 000 volts and 25 cycles. Probably more single-phase development work has been done on this than on any other line. The locomotives work under the disadvantage that they have to enter New York along the New York Central tracks, so that the single-phase motors have to be adapted to work on direct current also. The result is a compromise, for a single-phase motor cannot be made to

work at its best on direct current, any more than a d.c. motor can be made to work at its best on alternating current. The Pennsylvania Railway has electrified some d.c. lines and also some a.c. lines. There is a scheme ultimately to extend the a.c. system to New York and to Washington.

Passing now to the locomotives, the individual-axle drives are the best known. One gearless type employs the nose or tram suspension for the motors, even for the very largest locomotives. In another arrangement a motor armature is mounted on every driving axle. A further type employs a quill round the driving axle, and the motors may be either gearless or geared. Twin motors have become very popular in the geared drive, the two motors being connected in series in order that double the voltage may be used. Side rods are, or will be, used on locomotives on the Pennsylvania, the Norfolk and Western and the Virginian lines.

On the split-phase locomotives there is a phase converter which converts the single-phase current into three-phase current for the three-phase induction motors which drive the axles through gearing.

Conclusion.

I feel that we ought to know as much about railway electrification as possible, because it is a matter that may affect us very seriously in this country.

We have seen enormous developments in the employment of hydro-electric power. I think that this may affect us in two ways. It may in years to come decrease our coal exports, which is of course a matter of national concern, and on the other hand it shows us that there is an enormous amount of electrical development going on throughout the world in connection with both hydro-electric and railway equipment. I do not think that it matters much what the system is, but my feeling is that, whatever the work may be, our firms ought to see what they can do to take part in this great development. For this reason, they should be given facilities for obtaining experience on home railways—e.g. on single-phase equipment, by extending the electrification to Brighton; and on direct current by proceeding with the scheme on the North-Eastern Section of the London and North-Eastern Railway.

Discussion before The Institution, 3 January, 1924.

Lieut.-Colonel F. A. Cortez Leigh: The author mentions that in France it has been decided to electrify the railways on the d.c. system at 1 500 volts, and that the overhead system has been adopted for the greater part of the work, although the third-rail system is to be used in certain sections. Can he tell us why the overhead system was not continued throughout, as I understand that most of the work has been done in conjunction with the Government? The majority of recent main-line railway electrification schemes have been carried out in countries where water power is available, and this would point to the fact that the availability of ample water power has been the determining factor. I should be glad if the author would confirm this view. What is the proportion of passenger traffic working to freight working in those countries, and what is the actual kilowatt-hour consumption for the two classes of traffic? Another point on which the author's views would be most interesting is as to the reason why the unusual frequency of 45 cycles has been adopted in Italy, instead of that in use in neighbouring countries.

Mr. G. W. Partridge: I am of the opinion that the principal factor which will determine what particular system shall be used for electric traction is not so much what will be the interference effect or the watts per ton-mile, or even the efficiency, but what is the cheapest system which will transmit the energy from the point where it is generated to the draw-bar of the train. Can the author say what is the distance between the a.c. substations in Austria and in Germany? I should also be glad if he would say if it is possible to design a motor which will work reasonably well with both single-phase and direct current. I have seen small motors working satisfactorily and I should like to know whether in the future it will not be possible to have larger motors which will work on the two systems and give reasonably efficient results.

Mr. T. Stevens: Twelve years ago I was asked to go to a foreign country to lay out the electrification of a railway from water power. I came to the conclusion that there was very much more profitable use for all available water power than was obtainable from the railway. I recommended that the railway should still be operated by steam and that all the output of water-power plant should be sold in near-by towns. I cite this case because the electrification of railways is, as just mentioned by Mr. Partridge, a question of economics. If, as was shown in one case in the discussion on Mr. Bachellery's paper, 24 per cent per annum on the capital outlay for electrification can be saved thereby, it is worth while investing that capital. Where only 5 per cent can be saved, as was also then shown in connection with another railway, electrification should not be undertaken unless there are other substantial reasons to warrant that expenditure of capital.

Mr. W. E. Highfield (*communicated*): Quite apart from the economic advantages to the railways, there is an important reason why main-line electrification should not be delayed. We are an exporting nation, and electric railway manufactures are an important item of our exports. So far we have no great reason to complain; France, Japan, South Africa, Australia and New Zealand have all purchased electric railway material in this country. But it is a definite disadvantage to manufacturers to have no English railways supplied with their material. It is an advantage to be able to exhibit such a system but—and this is even more important—it keeps the manufacturer continually in touch with railway requirements and conditions. This advantage to the industry would be lost if the railway companies adopted the policy of manufacturing their own electrical gear. That policy was adopted in the case of steam locomotives and it practically killed the manufacturing industry. As the author has stated, the battle of the systems is finished. From the manufacturers' point of

view it is desirable that we should be able to compete in the world's markets both for single-phase and direct-current material, since it seems certain that both systems will be used impartially all over the globe. It would therefore be desirable to use both systems in this country. The main difficulty is the strategic one, for it is unthinkable that the systems should be such that free intercommunication would be interfered with. Prior to the adoption of 50 cycles by the British Engineering Standards Committee, no manufacturer would have offered a 50-cycle, 1 500-volt rotary converter on one commutator. These rotary converters are now in successful use, but it was the Committee's action that forced the manufacturer to meet the demand. If interchangeable running were insisted upon it might equally force a solution. If the technical difficulties cannot be overcome, the solution may be found to lie with the traffic departments, whose views are not, in my opinion, made sufficiently public. If these were more generally made known they would modify many opinions on the subject of main-line electrification in England.

[Dr. S. P. Smith's reply to this discussion will be found on page 324.]

North Midland Centre, at Leeds, 22 January, 1924.

Mr. P. Furness : I noticed in the lantern slides that the locomotives have straight-cut gears which I should expect to be very noisy. Has there been no development of the helical and double helical gears on the electrical work which the author has described ?

Mr. R. M. Longman : In some of the slides shown, the American locomotives apparently have outside seats on the front, and I should like to know for what they are intended. I thought that a considerable portion of the New Haven and Hartford lines had been changed over to direct current as a result of the controversy on the subject during the first few years of operation. When one bears in mind the numerous papers on the subject of railway electrification which have been discussed before this and other Institutions in this country, it is rather surprising that we have made so little advance. Can the author tell us what results have been obtained with the main-line electric locomotives which were so much referred to by Sir Vincent Raven about a year ago, and can he also give us any information regarding the operation of the mercury rectifiers on the French railways ?

Mr. A. F. Carter : I should be glad if the author would say whether difficulty is experienced in the collection of current from the line in snow-bound countries. Some of the electric locomotives require several thousand horse-power, and I have noticed that difficulties are occasionally experienced in this country when taking only about 150 h.p. from the line. Another interesting problem when taking electrical energy for traction from public supply stations is the maximum demand. It seems to me that for a locomotive suddenly to take 2 000 or 3 000 kW from a station of possibly only 10 000 kW or less capacity for perhaps half an hour, two or three times a day, would not be conducive to goodwill and efficiency.

Mr. M. Wadeson : I had the idea that there was a lot of railway development under way in this country and that British manufacturers were doing and had done quite a lot of railway work ; but I rather gather from the author's remarks that practically nothing is being done in this respect.

[Dr. S. P. Smith's reply to this discussion will be found on page 324.]

Scottish Centre, at Glasgow, 12 February, 1924.

Mr. M. Blacklock : Economic considerations have to some extent caused Continental countries to electrify their main lines. Many of them are short of coal and do not possess the comparatively cheap supply which is available in this country. The author states that the adoption of electrification results in a saving of about half of the coal which would have been consumed in a steam system. To save 25 lb. of coal per mile is very desirable, but is it not possible that this saving will be more than swallowed up by very high standing charges, particularly in the case of lines which have no very great density of traffic ? I gather from the lantern slides that the angular connecting-rod drive is being discarded in favour of the geared drive with coupling rods. The electric locomotive of the future will apparently bear some sort of resemblance in its running gear to the well-known features of the steam locomotive. Electrification seems to be bound up with the question of density of traffic. If it is contemplated to equip the whole of the country with superstations and substations, and to electrify every mile of line and every siding, it is obviously a gigantic undertaking and one which cannot be undertaken lightly or without due consideration of the question in all its bearings.

Mr. G. G. Braid : Britain has been the birthplace of many scientific inventions, but it has often been left to other countries to develop these inventions on a commercial scale. There may perhaps be some advantage in this ; we learn something from the successes of others, but, I think, a good deal more from their failures. The general tendency of all heavy electrical engineering is to use higher and higher voltages, and hence it seems to me that the two best systems of electric traction are the direct-current system with 3 000 volts on the overhead conductor—such as is used on the Chicago, Milwaukee and St. Paul Railway—and the single-phase system with 15 000 volts on the overhead line as in Germany, Austria, Switzerland and Sweden. The 3 000-volt d.c. system has several advantages over the 1 500-volt system. The substations can be placed much farther apart, and only half the current has to be collected from the overhead conductor. I think that this country, as well as France,

has been rather conservative in proposing direct current at 1 500 volts for main-line electrification. The cost of electrifying the lines in sparsely populated districts will probably be prohibitive, whereas direct current at 3 000 volts or alternating current at 15 000 volts would be more economical. It would be an advantage to adopt both systems. Circumstances will, however, usually determine which system should be used. The ultimate question to be answered in every case is: "Will it pay?" The author suggests that, for political and military considerations, France has adopted a different system from Germany. Possibly for the same reason all the central countries of Europe have adopted the same single-phase system at $16\frac{2}{3}$ cycles per second with 15 000 volts on the overhead conductors. It seems to me that Germany has been more far-sighted than France in this matter, for whereas it is quite possible to adapt an equipment which runs efficiently with single-phase commutator motors over the 15 000-volt lines, so that it may run in the case of emergency over a 1 500-volt d.c. line, or, indeed, off one of the phases of a three-phase line, it would be impossible to adapt an equipment primarily designed for 1 500 volts direct current so as to operate over a single-phase line at 10 times the voltage.

Mr. J. D. Peattie (*communicated*): Is there any tendency to use direct current at voltages comparable with those adopted for single-phase schemes? My reason for asking is that up to the outbreak of war I was engaged with one of the large Continental firms on some high-voltage d.c. investigations. One of the objects was to examine the possibilities of working at much higher d.c. voltages for long-distance railway electrification. At that time we were in the midst of the difficulties encountered in the developments of single-phase traction, particularly with the switching and control of the low-tension currents of the order of 2 000 amperes on the locomotive itself between transformer and motor. I worked for the most part with two machines, and a few figures regarding these may be of interest. The first gave 36 000 volts (d.c.) and, since then, machines working on the same principle have been built in America up to 100 000 volts. They have been used for blast-furnace dust-precipitation plants. The second machine was built primarily to test a commutation device and gave only 4 000 volts (d.c.). Its other characteristics were, however, quite extraordinary. For instance, the measured commutating reactance voltage per segment was 95 volts at full load. I notice from the Press that Dr. Scherbius has again raised the question of high-voltage d.c. transmission, and, as the high-voltage d.c. system for railways appears to offer many possibilities, I should be glad if the author would state whether developments along these lines appear to be likely.

Dr. S. Parker Smith (*in reply*): In reply to Col. Cortez Leigh, although the French Government initiated the electrification schemes, details were left to the technical commission, which found itself undecided on the question of current collection and in consequence advised that all electric rolling stock should be fitted with both methods of collection. It would be wrong to associate railway electrification too closely with water-power utilization, though this has undoubtedly been a prime factor where coal is scarce. In very many instances other factors such as economy, congestion, smoke troubles, etc., have been decisive. A good idea of the kilowatt-hour consumption can be obtained from many of the reports presented to the recent International Railway Congress in Rome. The choice of 45 cycles as the standard in South Italy arises from the fact that frequencies of 42 and 50 cycles are almost equally common in those parts, and 45 has been chosen as a mean value.

In reply to Mr. Partridge, substation spacing is a question not only of voltage but also of geographical and topographical features of the route, grades, location of junctions, branches, etc. On the Arlberg route there are stations 40 km apart, while on the Leipsic-Halle route the intervals are sometimes 60 km. It is possible to build a.c. motors which will work satisfactorily on direct current, but not conversely. The compromise, however, does not give the best motor.

In reply to Mr. Furness, both helical and double helical gears have been used on electric locomotives.

The New York, New Haven and Hartford Railway is equipped on the single-phase system, but the locomotives have to enter New York on the New York Central lines which are on the d.c. third-rail system. Possibly this is what Mr. Longman has in mind. Apparently the work commenced by Sir Vincent Raven has been suspended—no published results are known to me. Mr. Longman will probably find the information which he needs on the operation of mercury rectifiers in Mr. Bachellery's paper and the discussion thereon.*

In reply to Mr. Carter, little trouble is experienced with snow on overhead contact lines. Also with the under- or side-contact third-rail system the difficulty is not serious unless the snow is deep. To keep the maximum demand within pre-arranged limits, current-limiting devices are often used; for example, on the Chicago, Milwaukee and St. Paul Railway.

Mr. Wadeson is correct in assuming that British firms are doing a fair amount of railway electrification, but the bulk is much below our capacity.

In reply to Mr. Blackwell, cases may and do arise where electric traction is used, although it is more costly than steam. Independence of foreign supplies and the reduction of imports, however, have also their economic value, while many technical reasons may make electric haulage the more desirable.

In reply to Mr. Peattie, work is also being done in this country with high-voltage direct current, e.g. on the transverter system, but hitherto a high-voltage d.c. motor suitable for installing on locomotives has been wanting. In this respect, the a.c. system has the charm of simplicity.

* See pages 213 *et seq.*

ELECTRIC PASSENGER LIFTS.

By H. MARRYAT, Member.

(*Paper first received* 28*th July, and in final form* 20*th November*, 1923; *read before* THE INSTITUTION 17*th January, before the* NORTH-WESTERN CENTRE 8*th January, and before the* SOUTH MIDLAND CENTRE 20*th February*, 1924.)

SUMMARY.

The author makes a plea for British investigation and design in order to produce a lift more especially suitable to conditions in this country than is possible by following American practice too closely. A number of problems requiring investigation are referred to. The essential parts of a lift and the factors of cost are stated. The advisability of consulting specialist engineers with regard to new construction is suggested. A complaint is made that lift makers are often consulted too late in the development of a new building to enable them to offer the best and most economical scheme. It is maintained that a lift service is more important than the provision of stairs.

The methods employed by the author in calculating the lift capacity required in a building are outlined. A plea is advanced for the employment of lifts of higher running speed and improved acceleration, and the method adopted by the author in an investigation of acceleration problems is described.

A comparison is made between drum and sheave driving. The effects of the position of the winding engine and of rope-reeving upon maintenance cost are discussed. Types of worm gearing and methods of control are described and the limitations of automatic control emphasized. Micro-drive and decelerator devices for attaining automatic floor levelling are detailed and reference is made to a new system of control—the "Auto-Pilot."

Safety devices employed in connection with passenger lifts are described, and the record and infrequency of accidents are discussed and commented upon.

A lift is a machine designed to transport a load from one level to another in a vertical or nearly vertical direction by means of a suitably guided car or platform.

Electricity was first used to operate a lift about 1885, and since 1893 has been increasingly employed for the purpose, until now, where electricity is available, it has practically superseded all other forms of energy for new construction. Existing hydraulic lifts are rapidly being converted or replaced by electric lifts. Except where certain special conditions prevail—for instance, short travel and heavy load—when the direct-acting hydraulic lift offers certain advantages, the electric lift has proved itself to be the most economical and convenient machine yet designed for the purpose. This statement being accepted in principle, it will not be necessary to enter into a comparison between electricity and other forms of energy for operating lifts.

The electric lift is becoming an increasingly important feature in modern buildings. The tendency of the great and increasing commercial population of cities to congregate in central areas, and the corresponding increase in site values, are bringing about a continual replacement of older and smaller buildings by newer and larger ones, in which by means of lift service it is possible to take the utmost advantage of the upper floors. Again, the tendency to work shorter hours and at higher speed reinforces the demand for a rapid lift service to replace stairs. It is, therefore, perhaps remarkable that so little has been written or published upon the subject in this country, although there are a large number of works dealing with cranes, conveyers, etc.*

The electric lift was first introduced in America, and in that country has developed in a direction and to an extent to which we are hardly likely to go. We have, however, followed American practice so far as we have been able. In doing so, we no doubt follow the course of least resistance, but the time seems to have come when we should undertake investigation and research upon our own account, with a view to developing a lift more particularly applicable to our own requirements. The conditions in this country are totally different from those existing in America. Here we are restricted in our buildings to a capacity of 250 000 cubic feet, whereas in America there is no such restriction and buildings range in size up to those with 30 to 60 floors and a floor area of 40 acres. On the other hand we are delightfully free from "red tape" or restrictions of any sort in the design of our lift machinery; whereas in America, where the lift is so important a factor in the daily life of the citizen that it is calculated that in the big cities the lifts run more miles per day than the combined road car and underground services, it has been found necessary to impose restrictions and bye-laws which, whilst protecting the interests of the community, are nevertheless a deterrent to the progress of invention and design.

The reason that so little has been written on this subject is no doubt partly because an electric lift is a combination product in which the builder, the electrician and the engineer all take part under the general direction of the architect, and sometimes—too seldom—of the consulting engineer. There are a number of problems concerning the construction of electric lifts which, so far as I know, have not been investigated, and the solution of which would be of great interest and benefit to the industry. It may be that these problems have been dealt with by individual manufacturers, in which case I hope that this paper will be an incentive to publication.

A fundamental problem is that of definition. Owing to the lack of other literature, one in search of information must refer to makers' catalogues and is at once confronted with a confusion of terms, sometimes used to designate the same thing and sometimes employed by certain makers to differentiate between different things.

* Since this paper was drafted a comprehensive work entitled "Electric Lift Equipment for Modern Buildings" by Ronald Grierson has been published by Messrs. Chapman & Hall.

Thus the terms "Vee" wheel drive, sheave drive, traction drive, friction drive, and half-wrap drive, are all used to designate the same thing. Lift, hoist and elevator are interchangeable terms, as are also service lift and goods lift. I suggest that it would be useful for lift makers to get together and adopt a code of definitions.

An electric lift consists essentially of:—

(1) A car or platform suitably designed to transport the required load.
(2) Guides, usually of wood or steel, rigidly attached to the building structure.
(3) Guide shoes attached to the car or platform so as to engage the guides.
(4) A counterweight.
(5) A rope or chain by which the car or platform and counterweight are suspended and which transmits motion from the driving engine.
(6) A driving sheave or drum with which the rope or chain engages.
(7) Gearing (usually worm and wheel) by which power is transmitted from the electric motor to the driving sheave or drum.
(8) An electric motor.
(9) An electromagnetic brake, usually operating upon a drum constructed in one with the coupling between the motor and worm shaft.
(10) A controller designed to start and stop the motor by means of suitable provision in the car or on one or more landings.
(11) Safety devices which may be simple or complex according to the circumstances and are intended to render accident impossible from the failure of any part of the lift or supply, or from the opening of a landing gate when the car is absent.

The cost of electric lift service comprises interest and sinking fund upon capital expenditure, rent, insurance, maintenance and renewals, energy and attendance. These factors of ultimate cost should be weighed before deciding upon the preliminary specification for any particular lift installation. It follows, then, that this consideration should be given before any scheme has gone so far as to impose limitations upon any of the factors. It also follows that where the architect takes the sole responsibility for the preliminary specification, very great care is required in comparing and examining tenders, as no two makers ever offer quite the same thing. An electric lift is too complicated a piece of machinery to admit of two makers quoting for the same equipment, unless to a very detailed specification such as can only be prepared by a lift engineer, and such important factors as maintenance costs, energy consumption and attendance are greatly affected by the details of the design offered. The actual service given by lifts built to the same general specification and designed to run at the same speed under the same general conditions will also vary considerably, and the number of trips which will be completed and passengers carried in a day by a lift acting upon a smooth and rapid acceleration curve, with accurate floor levelling, will be far greater than with a lift less carefully designed.

It is advisable, therefore, in all important new construction that the architect should, in the earliest stages of the project and before any building plans are settled, call in either a consultant specializing in lift engineering, or a manufacturer of experience. Such a consultant, after considering the size and purpose of the building, its situation, the position of entrances, etc., will be able to calculate the probable traffic and advise on the number, size and best position of the lifts required. He will also, upon the same basis of information, be able to advise upon the most economical scheme and the most suitable method of control.

Lift makers complain that they are not consulted until it is too late to influence the general specification, and therefore it often happens that two lifts are installed where one would be more suitable, or, conversely, that one large lift is installed where two smaller ones would give better service. The winding engine has frequently to be fitted in a position where it is impossible to get the best results, and the conditions are sometimes such that the rope-reeving is bad and the total cost of maintenance doubled as a result. Automatic push-button control is installed in places where car-switch control is essential, and expensive alterations have to be made after erection. Again, car-switch control is installed in places where automatic push-button control would be better and would save the cost of attendance.

A really efficient lift service serving the incoming and outgoing as well as the floor-to-floor traffic, is of far more importance than the staircase. Its location should be a primary consideration, and the staircase considered principally in relation to its effectiveness as a fire escape.

I have said that, given the necessary particulars of a building, the lift engineer will be able to calculate the probable traffic. It must be admitted, however, that the lift engineer himself does not usually employ any scientific method in arriving at the number of passengers per minute which will require lift service on each particular floor during the busy part of the day. Each will draw upon his own experience and home-made formulæ. If these could be collated, the general advantage would be served and many mistakes avoided.

Some interesting figures derived from American practice are given in a paper* by Mr. Harrison P. Reed, from which we learn that in New York City from 65 to 100 sq. ft. of rentable floor space is the average allowance per person occupying an office building. In other cities the allowance should be increased to 150 sq. ft. per person, and it is estimated that a lift service should be provided to empty such buildings above the first floor in from 40 to 60 minutes. It is, however, doubtful if American figures of this description apply to this country. The only English pronouncement that I can find is contained in a paper read recently by Mr. C. H. J. Day before the Association of Engineers-in-Charge, in which he says—referring to a large office building—that the average density of population is about 120 sq. ft. of floor space for each occupant, but

* "Electric Power Applications to Passenger and Freight Elevators," *Transactions of the American Institute of Electrical Engineers*, 1900, vol. 41, p. 325.

when one or two large firms occupy a whole building the population is almost certain to be denser than this, amounting perhaps to as much as 80 sq. ft. of floor space per person.

In the absence of any definite information on this point, Mr. Day says that it is considered safe to assume about 110 sq. ft. per person as a fair average. He also says that in buildings where tests have been made, the rate of traffic flow at the busiest time of the day has been found to be such as to include the equivalent of the entire population of the building in 45 minutes, and that the passenger traffic can be predetermined by allowing for a period of rush from 15 to 20 minutes, during which time a number equal to one-third of the population of the building is dealt with.

Figures derived from my own observation are not in agreement with this, but I must confess that although I have been investigating the subject for some considerable time I have not yet amassed sufficient data to

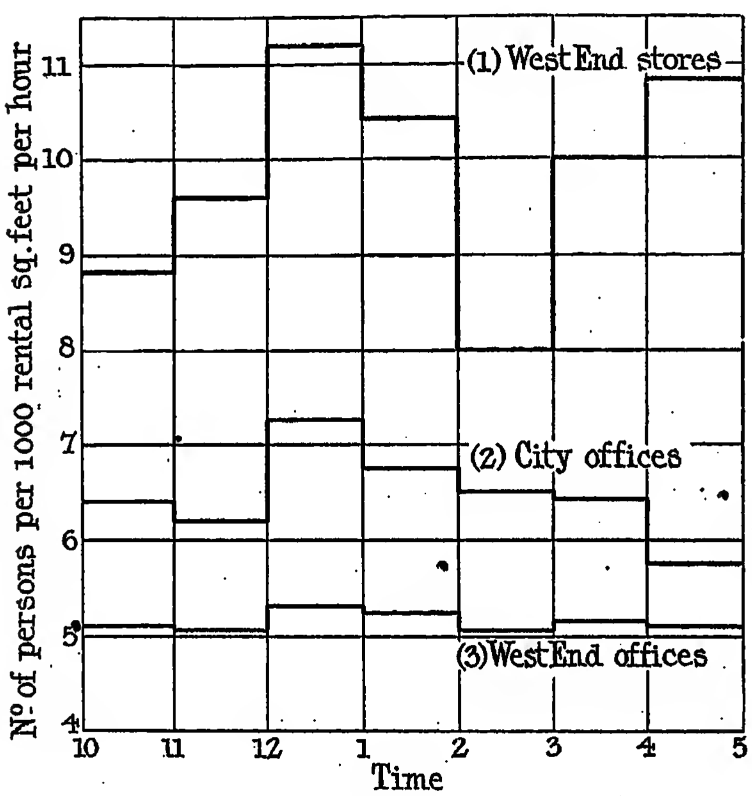

FIG. 1.

permit of my making an authoritative pronouncement. The means adopted in this investigation may be of interest and may possibly lead to the suggestion of better methods in the course of discussion.

In the first place the buildings in which lifts are usually installed have been divided into a large number of classes and each class has been separately examined under conditions which, I believe, apply to that particular class. For instance, in large drapery establishments and multiple-store buildings I count the number of persons per minute proceeding from the ground floor to upper floors. In office buildings of the class usually sub-let to a large number of different tenants I take no notice of persons arriving at or departing from the basement, ground floor or first floor, but make the count upon the second floor, of all persons arriving at, passing, or departing from that floor. In office buildings in which several or all the floors are occupied by the same tenant—an insurance office, for instance—I count the number of persons arriving at and departing from each floor, so as to check the inter-floor traffic; and in buildings where there is a restaurant on one of the floors a separate census is taken of the number of persons arriving at and departing from the restaurant, in order to check the special traffic so created. In taking this census of traffic in existing occupied buildings, I have at the outset been faced with the fact that existing lift accommodation is, in almost every instance, insufficient. It has been necessary, therefore, to count not only persons using the lifts but also those using the staircases.

For the present I will confine myself to a few examples to indicate the nature of the results obtained. In each case the figures have been reduced to per 1 000 sq. ft. of rental floor space served by the lifts.

In Fig. 1, curve (1) represents the average traffic counted in a group of West End drapery establishments. In each case the number of persons proceeding per hour from the ground floor to any other floor has been counted, and the curve represents the average of all establishments examined. Curve (2) represents a similar average deduced from a count taken in a large group of city office buildings of the class in which the floors are sub-let to a variety of tenants. The

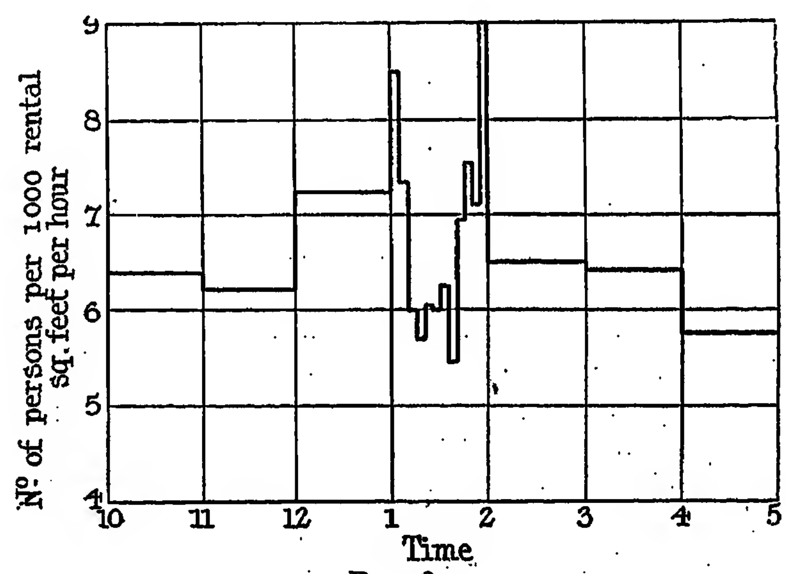

FIG. 2.

curve indicates the number of persons per hour who arrive at or pass the second floor. In order to obtain a more accurate estimate of the period between 1 o'clock and 2 o'clock mid-day, the more detailed curve shown in Fig. 2 was prepared. The third example in Fig. 1 comprises a similar group of offices situated in the West End of London. The different characteristics are strikingly shown. In this case there is no "rush" period, so that, in order to provide the same lift facilities for the same population, less lift capacity is required.

To arrive with more accuracy at the lift capacity required for a city (London) office building of the class usually sub-let to a variety of tenants, we refer again to Fig. 1, from which it will be observed that the largest amount of traffic occurs between noon and 1 p.m. As the effect of the dinner-hour traffic is not clearly indicated, it was decided to take detailed obser-

vations over the whole period from 11.30 a.m. to 2.30 p.m., in order to arrive at the true maximum traffic requirements on the building.

Eleven office blocks comprising both large and small buildings were selected. In every case care was taken to watch not only all lifts but all staircases simultaneously. A count was made upon the second floor of every person arriving at, departing from, or passing that floor in each direction. The result of this count has been carefully reduced to persons per hour per 1 000 sq. ft. of rental floor area above the first floor. The observations were recorded at the end of every minute, and plotted for each separate building in the series of curves shown, the average of which is given in Fig. 3. Some interesting things may be learnt from this figure. It will be noticed at once that the traffic is inclined to move in bunches, and that had the observations been taken over 2-minute intervals the curve would have been very different in form. A curve has been prepared to illustrate this, and shows clearly the errors likely to arise from taking a count gauged by reference to Table 1, which gives figures for city (London) office buildings.

TABLE 1.

Lift capacity in persons per hour per 1 000 sq. ft. rental floor area above first floor	Number of minutes during the day when lift capacity will be insufficient
7	84
7·5	56
8	33
8·5	14

9·5	1

Assuming that we allow for a lift capacity of 9·6 persons per hour per 1 000 sq. ft. of rental floor area above the first floor in the class of building specified, and taking the New York allowance of 65 to 100 sq. ft.

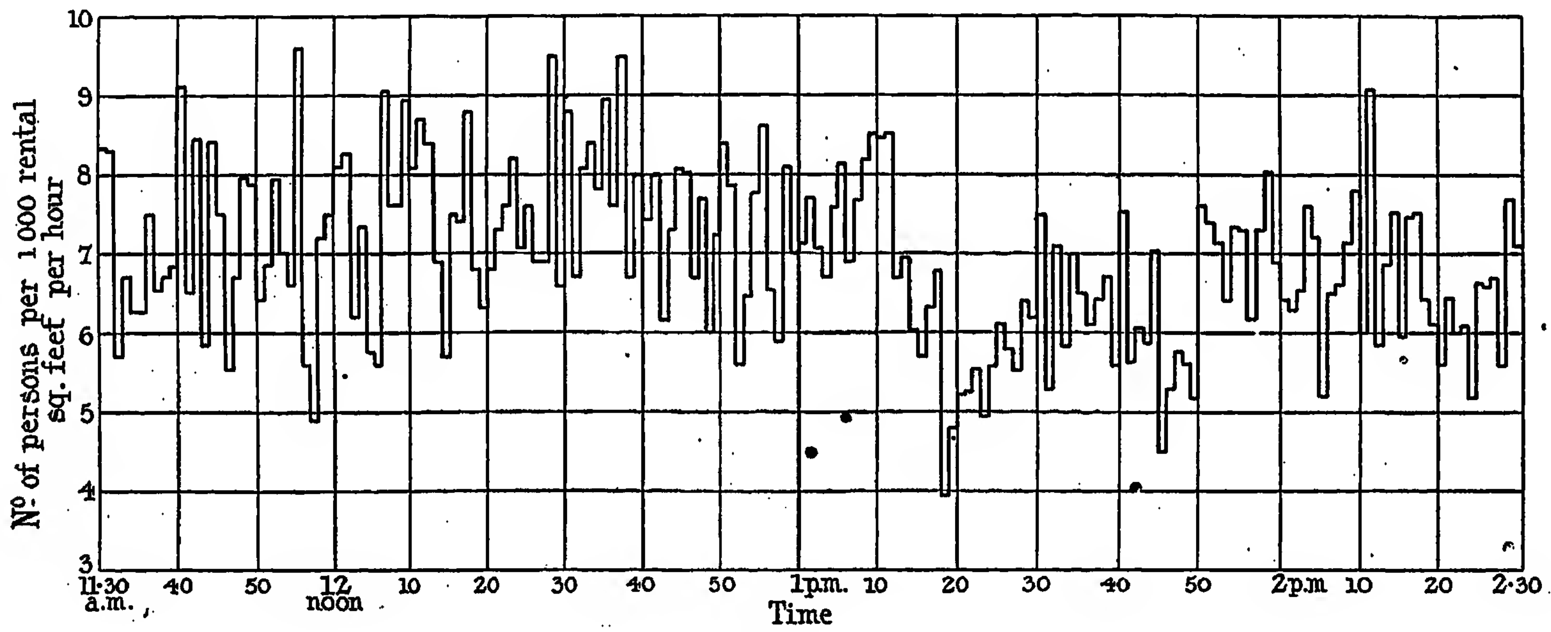

FIG. 3.

over any period longer than 1 minute, as it is the maximum traffic and not the average with which the lift engineer has to deal.

Referring to Fig. 3 we find that the average traffic per hour per unit of floor space taken during the period 11.30 a.m. to 2.30 p.m. is approximately 6·98, and between 12.10 p.m. and 1.10 p.m., 7·5. If, however, provision is made for the average traffic only, it is obvious that many people will either wait for several minutes for lift service or use the stairs in preference.

It may be considered unnecessary to provide accommodation calculated upon a maximum traffic which may only occur during a single minute of the day, but in this connection it must be remembered that this curve itself is an average of 11 typical buildings and that the maximum of 9·6 must be compared with the maximum of over 20, shown for a 1-minute period on three of the individual buildings. It is reasonable, therefore, to provide for the maximum indicated in Fig. 3.

The effect of providing a lesser lift service may be of rental floor space per inhabitant—say 82·5 sq. ft. —the lift capacity at which we have arrived would allow for the emptying of the building above the first floor in 1 hr. 15 min., a figure which, it will be noted, differs altogether from those arrived at by American authorities and by Mr. Day, but which is, I believe, when applied to buildings in the City of London, a more accurate one.

In order, then, to discover the lift capacity in such a building, the following formula may be used:—

$$\frac{9 \cdot 6 A}{NL}$$

where A = thousands of sq. ft. rental floor area above the first floor;

N = number of circular trips, including stoppages, which can be made per lift per hour; and

L = number of lifts.

Having discovered the total lift capacity required, it is next necessary to decide the number of lifts to be employed and their speed.

As about 30 seconds represents the limit of patience to be expected of the average city man waiting for a lift, a building cannot be considered to be adequately served when the occupants or visitors are asked to wait longer. To calculate the number of lifts required to handle a given traffic and give a half-minute service, the overall speed of the lifts—allowing for all stoppages—must be known. The number of stoppages a lift may be required to make in the course of a return journey from the ground floor and back again varies considerably, but in the class of building which we have been considering, it is found to average about one stop for every 42 ft. of running. Allowing 12 seconds per stop for loss in acceleration, deceleration, opening and closing of gates and for the time taken by the passengers in entering and leaving the car, together with a further allowance to cover general loss of time, we find that the overall time in seconds required for the circular trip will be :—

$$\frac{60 \times 2T}{R} + \frac{2T \times 12}{42}$$

where R = running speed of lift in ft. per min.,
T = total travel of lift in feet in one direction.

In the case of a lift with 100 ft. travel and a running speed of 200 ft. per min., the overall time for the circular journey will be 117 seconds. In such a city office building two lifts of given capacity might not provide the required service, whereas three would more than do so, but by slightly increasing the speed the two lifts would suffice.

It will be observed that I make an allowance of 12 seconds for stoppage and lost time in an all-round average service. This will only be found sufficient provided the car is not too large. If the capacity is more than 10 persons—including attendant—the time allowance and the total lift capacity must be increased accordingly. It must also be assumed that the lifts are suitably situated and designed with wide openings for the easy ingress and egress of passengers. Under such conditions the effect of running speed upon overall speed may be set out as in Table 2 for a lift of 100 ft. travel.

TABLE 2.

Running speed	Overall time per circular trip with 100 ft. travel
ft. per min.	secs.
100	177
200	117
300	97
400	87
500	81
600	77

It will be observed that the saving in overall running time falls off as the running speed is increased, so there must come a point at which additional capital cost is not justified by the saving in time. In Table 3, approximate figures are given in order to indicate the relation of running speed to capital cost for a lift designed for a load of 10 persons.

TABLE 3.

Running speed	Extra cost (approx.) of machinery and safety devices (July 1923)
ft. per min.	£
60	—
100	25
200	75
400	150
500	190
600	220

The figures do not represent a large percentage upon the cost of a lift of the travel and capacity we have been considering, and, when taken in conjunction with a consideration of the saving of rent and attendance, will generally work out in favour of the higher-speed lift.

It has been maintained that lifts of a speed of over 250 ft. per min. cannot be justified in this country because of the lesser height of our buildings as compared with those in America, and that the period of acceleration and deceleration occupies practically the whole time of the short average journey, so that there is no opportunity for the lift to run at its full designed speed. The objection is a sound one and is supported by the practice of making the acceleration and deceleration periods long, in the belief that it is necessary to do so if the internal economy of passengers is not to be upset. Nevertheless, as ground space is of so great a value in large cities the importance of designing a lift which will accelerate and decelerate quickly, and so permit advantage to be taken of higher speeds, will be appreciated.

In order to investigate the effect of various forms of lift acceleration upon the average passenger, I have made a large number of experiments. The earlier efforts were very crude, the apparatus consisting of weights suspended upon springs, on the spring-balance principle, and arranged to record their motion upon a paper chart, the passengers at the same time being asked to note their physical sensations. With this apparatus it was discovered that the critical period of acceleration was too brief to be dealt with scientifically in this way. The next step was to devise an electrical method of recording what happened, and with the help of the Cambridge and Paul Scientific Instrument Co., and particularly of Mr. R. S. Whipple and Mr. Barron of that company, the following arrangement was adopted :—

A series of coils of copper wire are wound on the outside of a tube 6 ft. long and about 3 in. in diameter. These coils, which are spaced 2 in. apart and connected in series, are in circuit with a small string galvanometer,

a feature of which is its short period of vibration. An image of the string of this galvanometer is projected by means of a "Pointolite" lamp on to a moving photographic film. The tube is inserted at the bottom of the lift shaft in such a position that the car can pass freely without fouling. Carried from an arm at the top of the car is a cord to the end of which is attached a small cobalt-steel magnet, its position being such that as the lift travels up or down, the magnet is made to move inside the tube, thereby inducing an electromotive force in the coil windings and causing a deflection of the galvanometer string, the movements of which are recorded on the photographic film.

Accurate timing of the record is effected by a synchronous motor run from a tuning fork making 50 vibrations per second. This motor carries a disc, on the circumference of which are fitted five spokes, each being introduced in turn into the path of the beam of light. In this way the record is ruled with a series of lines, the space between any two of which represents 0·04 sec. The film speed employed is approximately 3 ft. per sec., rendering it possible to read the record to 0·002 sec. In the record illustrated, the passage of the magnet through each coil is indicated by a deflection of the string, and reference to the time scale makes it possible to determine the time taken for the lift to rise each successive 2 in. By plotting "time" against "inches rise of lift" information is obtained from which a true acceleration or deceleration curve may be produced. In Figs. 4 (*a*) and 4 (*b*) are reproduced specimens of the films produced in this way. These films illustrate different forms of acceleration on a passenger lift running at 360 ft. per min. It should be noted that the time intervals indicated by the vertical lines upon the films are accurately controlled by the tuning fork method as described, but the space intervals vary, as the result of variations in the film speed. A corresponding correction must be made in taking measurements from the films. This method has not, so far as I am aware, been used before for the purpose of obtaining such data.

From a study of these films we discover that the unpleasant sensations experienced by most passengers at the starting and stopping of a fast-running lift are due not so much to a too rapid acceleration as to a sharp change of acceleration, the result of imperfect control. The remedy is not an extension of the total period of acceleration, but a correction and smoothing out of the curve. Working upon these lines it is found possible to accelerate a lift to 300 ft. per min. within a space of 24 in., or to 600 ft. per min. in less than 48 in., without discomfort to the passengers, and to decelerate in a similar period. This means that the time lost in acceleration and deceleration of a lift at 300 ft. per min. with average runs of 42 ft. need not exceed 5 per cent of the running time, and at 600 ft. per min., 10 per cent, the number of seconds lost being the same in each case. It also means a saving in energy consumption.

Fig. 5 represents a series of time/distance curves taken upon the starting of a 15-cwt. passenger lift running at 360 ft. per min. in a building in Kingsway. The different results are obtained by varying the armature starting resistance and the rapidity of cutting out. No. 6 of this series of curves represents a condition of particularly comfortable starting, and I have chosen this curve to illustrate in Figs. 6 (*a*) and 6 (*b*) the derived velocity and acceleration curves.

In Fig. 6 (*a*) it will be observed that the lift attains a maximum velocity in 1·4 sec. In Fig. 6 (*b*) it will be noticed that the acceleration over the first fifth of a second is not plotted. This is because it has not been found possible to obtain accurate measurements from this part of the film. As more information about this part of the acceleration curve is of great importance, I am now arranging apparatus to investigate in detail what happens in this first fifth of a second. It will also be noted in Fig. 6 (*b*) that the acceleration proceeds in a series of periodic leaps. This is a feature of the whole of these records. At first the explanation seemed simple because in most instances there are eight clearly marked periods, and it so happens that on the normal controller usually experimented with there are eight batches of starting resistances in the armature circuit.

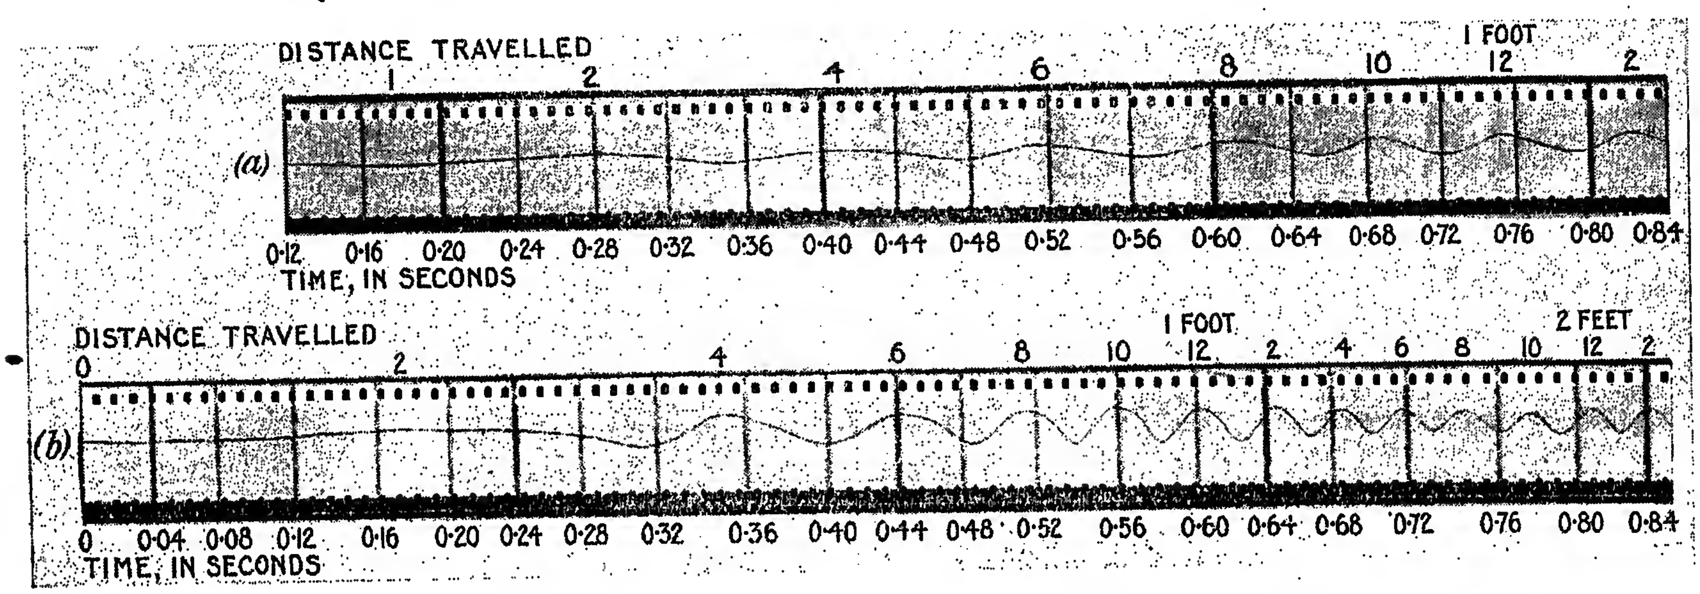

FIG. 4.—Reproduction of two films obtained in connection with

Further examination shows that although the starting contacts undoubtedly affect the shape of the curve they are not responsible for it. For instance, if the number of starting contacts is reduced, the number of periods shown on the acceleration curve is increased.

I am not as yet prepared to explain the cause of this periodic acceleration; perhaps some light will be thrown upon it during the discussion. The variety of the forms obtained and the fact that on repeating the same experiment the same form is repeated, seems to show that the shape is governed by various forces acting sometimes together and sometimes in opposition, depending upon the conditions of starting.

It may be noted, in reference to Fig. 6 (*b*), that the steps in acceleration indicated are too rapid to have any physical effect upon the passengers, for the purpose of considering which question an average curve should be drawn. In this sense the curve indicated in Fig. 6 (*b*) is a good one, provided that the unplotted part in the first fifth of a second does not descend from too great a height.

As a matter of interest I propose to show by means of lantern slides a few other examples of these curves. The first represents the acceleration of an hydraulic goods lift, and the next two represent, I think, a somewhat daring experiment, when a large passenger lift running at 400 ft. per min. and driven by a 21-h.p. motor was switched direct on to the main without any intermediate resistance. The first is taken under conditions of maximum load and the second with minimum load.

It will be observed from the figures given that the 600-ft.-per-min. lift will carry 26 per cent more passengers per hour than the 300-ft.-per-min. lift will do, or to carry the same number of passengers may be of 20 per cent less capacity. There is not, so far as I know, any lift running at 600 ft. per min. in this country, nor to my knowledge is there one running at over 400 ft. per min., but I am quite convinced that with the increasing site values in our cities there is opportunity for the economic use of higher speeds.

Having discovered the total capacity required in a certain building and decided upon the speed and capacity of each lift, the number of lifts required will follow as a matter of course.

Before passing on to the consideration of other lift problems, it is interesting to note here the experience of the London Electric Tube Railways, kindly given me by the Operation Manager, Mr. A. P. Thomas. The number of lifts installed in a tube station depends upon the volume of traffic, and is approximately:—

For 7 000 passengers per day—2 lifts.
For 10 000 passengers per day—3 lifts.
For 13 000 to 30 000 passengers per day—4 lifts.

The number is to a certain extent dependent upon the depth of the shaft. With a 4-lift equipment and a depth of shaft of 72 ft., a general average service of 2 mins. 18 secs. per lift can be observed, allowing

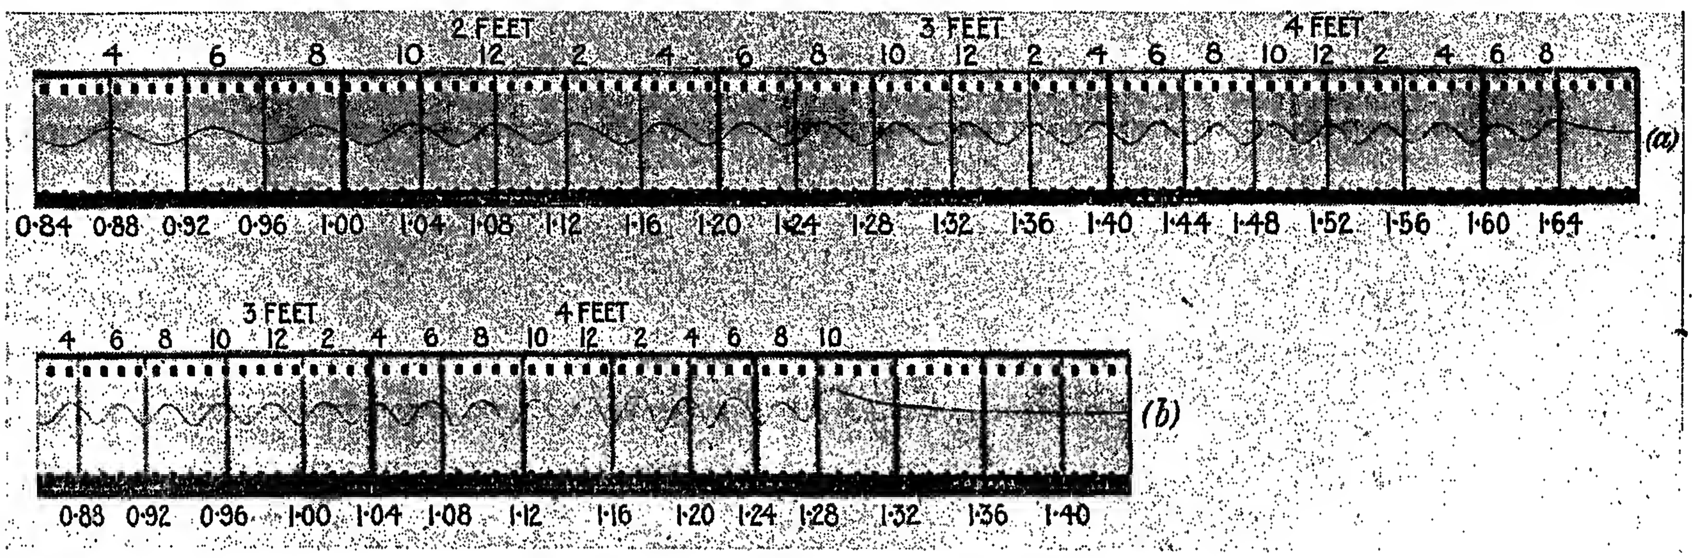
7½ secs. for preparing lift.
30 secs. for loading lift.
7½ secs. for starting lift.
24 secs. for running lift.
45 secs. for discharging lift.
24 secs. for running lift.

Or a total of 138 secs. for the round trip, or 26 trips per hour.

The speeds of the lifts on the London Electric Railways are about 180 ft. per min., except at Hampstead, where the shaft is deeper than that at any other station, viz. 181 ft. There the speed is 200 ft. per min.

There is a tendency to increase the speed of tube railway lifts to meet the desire of the travelling public for faster travel. A lift service, however well run, compares unfavourably with an escalator service, and lifts have been replaced by escalators at a number of stations. No lifts at all are provided on the new stations north of Edgware-road, a convenient escalator system having been introduced. For all shafts of a depth of 60 ft. and under, the escalator provides a better means of transport, but for a shaft above this depth high-speed lifts are desirable.

The winding engine giving motion to the ropes may be fitted with a drum to which the car and counterweight



acceleration tests on a passenger lift having a running speed of 360 feet per minute.

ropes are positively attached, or with a V-groove sheave transmitting motion to the ropes by friction, as a pulley does to a belt. Had I been reading this paper 20 to 25 years ago I should at this point no doubt have entered upon a strong advocacy of the sheave drive, but this is no longer necessary, as most makers have now adopted this arrangement.

Serious danger attaches to the drum method of driving, inasmuch as in the event of overrunning and the failure of safety devices the positively driven ropes will cause either the car or the counterweight to crash. With sheave driving the effect of overrunning and failure of the safety devices is to land the car or counterweight upon the final stops at the foot of the well, and with the ropes thus relieved of load the gear can continue to revolve until the ropes are worn through, which will take many hours—or days.

The cost of maintenance of an electric passenger lift in business premises varies from about £20 to £100 per annum, and is largely affected by the frequency of re-roping. The cost of re-roping is largely made up of labour and is often augmented by the necessity for overtime work, but, apart from the actual cost of the ropes and work, a further loss must be taken into consideration in respect of the discontinuance of lift service whilst the work is in progress.

A prime consideration in the selection of a lift should therefore be the ultimate maintenance cost, with particular regard to re-roping, and to accept tenders for lifts without this consideration is to place a premium on inefficiency.

Frequently the breaking strain of the ropes to be employed on a new lift is specified without regard to the fact, supported by lift engineers having long experience of maintenance, that a rope of less tensile strength, of the super-ductile class, will in many cases give better results over a number of years. If such ropes are to be employed, care must be taken in the first instance that the lower breaking strain is compensated by larger, or additional, ropes, to provide the necessary factor of safety.

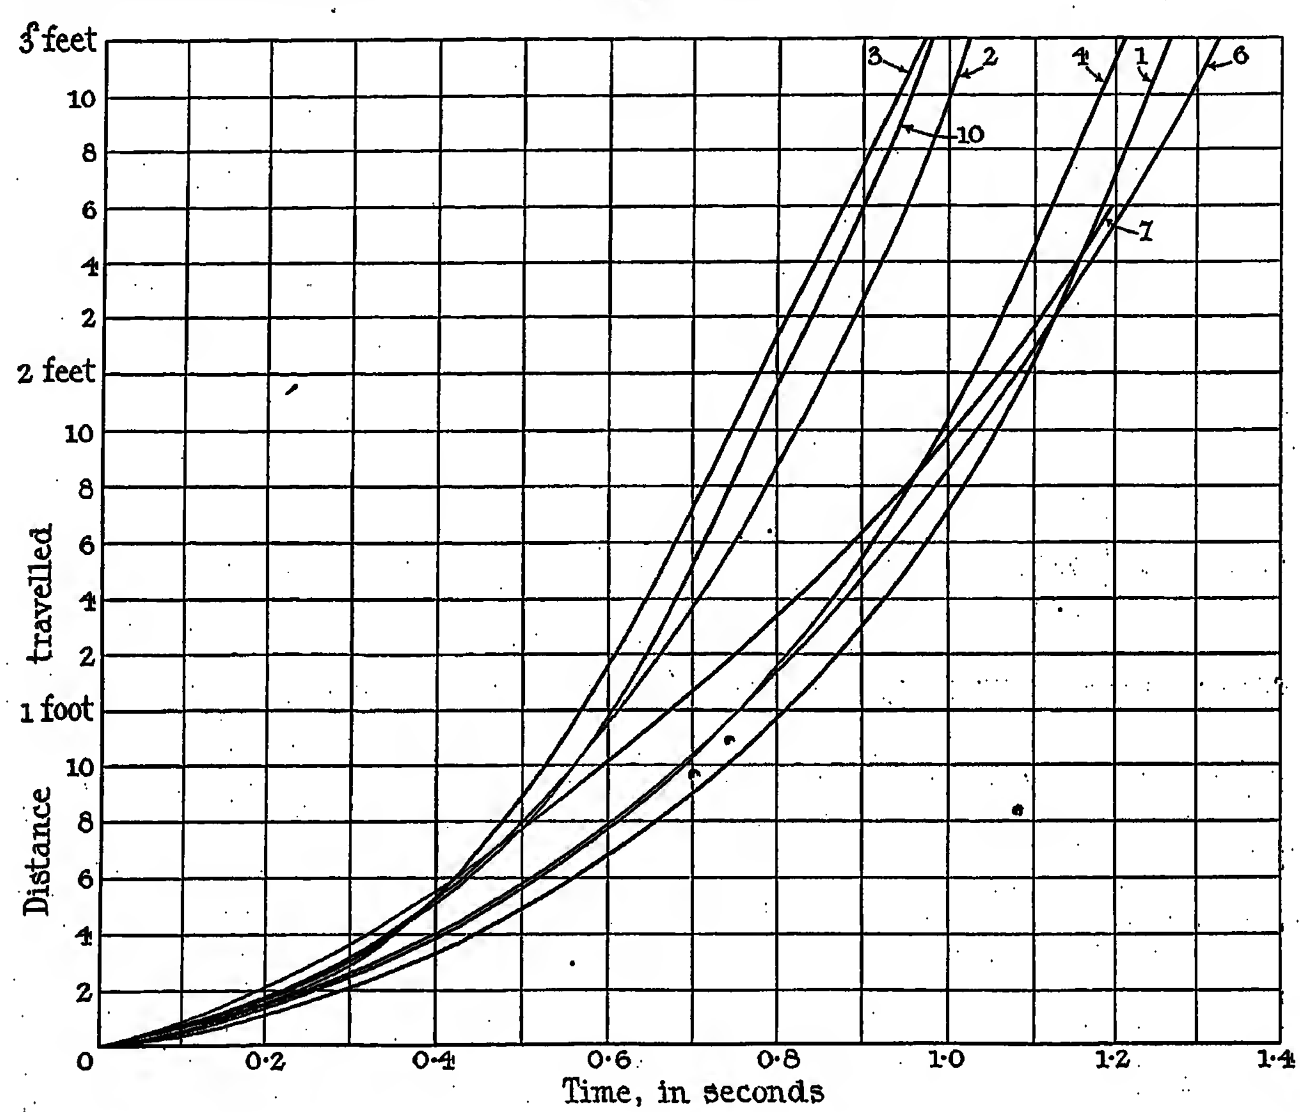


Fig. 5.

Both lift and rope makers differ in their advice as to the most suitable rope for use in any particular case. My own experience suggests the use of a super-ductile steel for ropes which fail on account of damage by bending, and a hard steel of high tensile strength for lifts on which the ropes fail from the frictional wear due to slip between the ropes and the driving sheave.

A most important factor affecting the life of ropes is the method of reeving employed. The option to select the best method is often taken out of the hands of the lift maker by the architect, who advances his plans too far before the details of the lifts are considered, and imposes hampering restrictions.

In Fig. 7 are shown diagrammatically the methods of reeving more usually employed, in (*a*), (*b*), (*c*) and (*d*)

the winding engine being indicated at the head of the well, and in (*e*), (*f*), (*g*) and (*h*) at the foot.

The ideal arrangement is indicated in (*a*), in which the driving sheave spans the distance between the suspension points of the car and counterweight. Arrangement (*b*) is not so satisfactory but may be necessitated by considerations of economy, because the smaller the diameter of the driving sheave the less expensive are the motor and gear, or because the distance between the car and counterweight centres is too great to be conveniently spanned by a single sheave, or in order to comply with the particular building plan. Arrangement (*c*)—sometimes termed the "full-wrap drive"—may be employed where the out-of-balance load is considerable and there is danger of rope slip on the driving sheave. It is possible with this method of reeving to employ U grooves instead of the usual V grooves on the driving sheave, thereby greatly reducing the wear on the ropes. With this arrangement the idler sheave may be so placed [as in (*b*)] as to act as a diverting sheave in cases where the driving sheave cannot be designed to span the distance between the car and counterweight. Arrangement (*d*) shows an adaptation of reeving which may be applied to (*a*), (*b*) or (*c*), introducing a 2 : 1 reduction in car speed. This method and further extension of the same principle may be conveniently employed when very heavy loads have to be raised at low speed. It will be noticed that in this diagram is introduced for the first time an S or backward bend in the rope. Such bends should be avoided where possible as they are much more destructive than a series of bends in the same direction.

Diagrams (*e*), (*f*), (*g*) and (*h*) show similar arrangements but with the winding engine at the foot of the well. In these arrangements the lengths of the ropes are greatly increased and S bends are introduced in every instance. The arrangement with diverting sheave shown in (*f*) is for some reason, which I am not prepared to explain, exceptionally destructive of the ropes.

Whatever system of reeving is employed, the larger the diameter of the sheaves used the longer will be the life of the ropes. In these diagrams only one rope is indicated, but it must be understood that in passenger-lift practice from four to six or more ropes running side by side are employed.

It will be seen that the winding engine may be placed at the head of the well directly over the work, at the foot, or on any of the intermediate floors. The advantages claimed for placing the gear at the foot of the well are:—

(1) Greater accessibility;
(2) Greater rigidity and therefore longer life;
(3) Less likelihood of nuisance due to noise and vibration.

In practice I find these advantages largely non-existent, whereas the obvious disadvantage of employing ropes of at least treble the length is very evident. Not only is the cost of ropes and of re-roping increased on account of this greater length, but the wear of the ropes is also increased by the larger number of bends—often S bends—which the ropes must make.

It is true that under certain circumstances the wear on the ropes can be reduced by so arranging the position of the winding engine that that part of the ropes which passes over the driving sheave does not also pass over the top sheaves—and vice versa; but even where this is done, unless diverting sheaves can be eliminated, the wear is greater than with the plain see-saw arrangement with the winding engine at the top.

The increased cost of maintenance due to a bad roping scheme may easily be sufficient to justify a capital expenditure of several hundreds of pounds in the first place, and may be avoided altogether if proper provision is made in the original plans.

One objection which architects and builders occasionally advance to the placing of the winding engine at the top of the building, is the increased weight on the upper structure. Examination will show that there is nothing in this argument except in the very unusual event of the winding engine weighing more than the combined weight of the car, load and counterweight. Under all other conditions the strain upon the upper structure is greater if the winding engine is located below.

For low-speed lifts, such as are usual in this country, it is essential to interpose some form of gearing between the motor and the driving sheave. Many types of gearing have been tried, but the worm and wheel is almost universally employed because of its many advantages for this particular work. Worm gearing is conveniently built to give precisely the ratios required by the lift engineer, and can be readily designed with a suitable angle of lead to render the gear self-sustaining; that is to say, so that it shall not be possible for the load or counterweight to set the lift in motion by driving the motor back through the gear. This provision requires the efficiency of the gear to be no more than 50 per cent, but the value of this additional safety factor is so great that the loss of efficiency is willingly sacrificed in order to secure it.

Figs. 8 and 9 show two typical arrangements of winding engine, comprising motor, worm gear, brake and sheave. The fundamental difference lies in the arrangement of the worm gear. In Fig. 8 the worm is located above the wheel, whereas in Fig. 9 it is below the wheel. I do not know that the comparative advantages of these types for this purpose have ever been discussed, and lift makers are divided in their opinion and recommendation. To the casual observer I think it will appear at once that the over-worm type is the sounder engineering job. With this arrangement the low-speed main shaft—that carrying the whole of the weight—is placed low down upon the bedplate in the most favourable position. The main part of the bedplate is hollow and forms an ample receptacle for oil, with easy access for cleaning out the bottom of the gear-case so formed.

The advantages advanced by advocates of the under-worm type are, first, that the lubrication is more perfect, and secondly, that any wear taking place in the main shaft bearings allows the gears to drop closer into mesh instead of drawing the worm and wheel apart. On the question of lubrication it is true that with the over-worm type gear the worm is not running immersed in oil, but oil more than sufficient to provide ample lubrica-

tion is brought up by the hollow teeth of the wheel. If the inspection cover of such a gear be inadvertently removed whilst the gear is running, it will quickly be replaced to staunch the flood of oil which is thrown by centrifugal force from the worm. The gear case is so designed that this oil thrown from the worm is collected in gutters and conveyed to the worm and main shaft bearings, whence it finds its way back into the reservoir, which is kept filled to a height some inches above the teeth of the wheel. With this type of gear the main shaft bearings, which are the most important in the whole machine, are subjected to a continuous flow of oil passing through them. The answer to the second point is that if the main shaft bearings wear so much as to make an appreciable difference in the mesh of the gear it is time for these bearings to be

the intervention of gear may be employed. In this case the motor must, of course, be of very low speed and correspondingly expensive, and, as the self-sustaining feature of the worm gear is lost, additional precautions must be taken against accident.

Two methods of control are in use with modern electric passenger lifts; these may be referred to briefly as the "push-button" and the "car switch." The push-button method is automatic; that is to say the car stops automatically at the floor desired and the lift can be operated by the passenger without the assistance of a lift attendant. The car-switch method requires the employment of a lift attendant and some skill to ensure stopping at floor-level.

The push-button lift is the more expensive, but the difference in cost is far more than justified by the

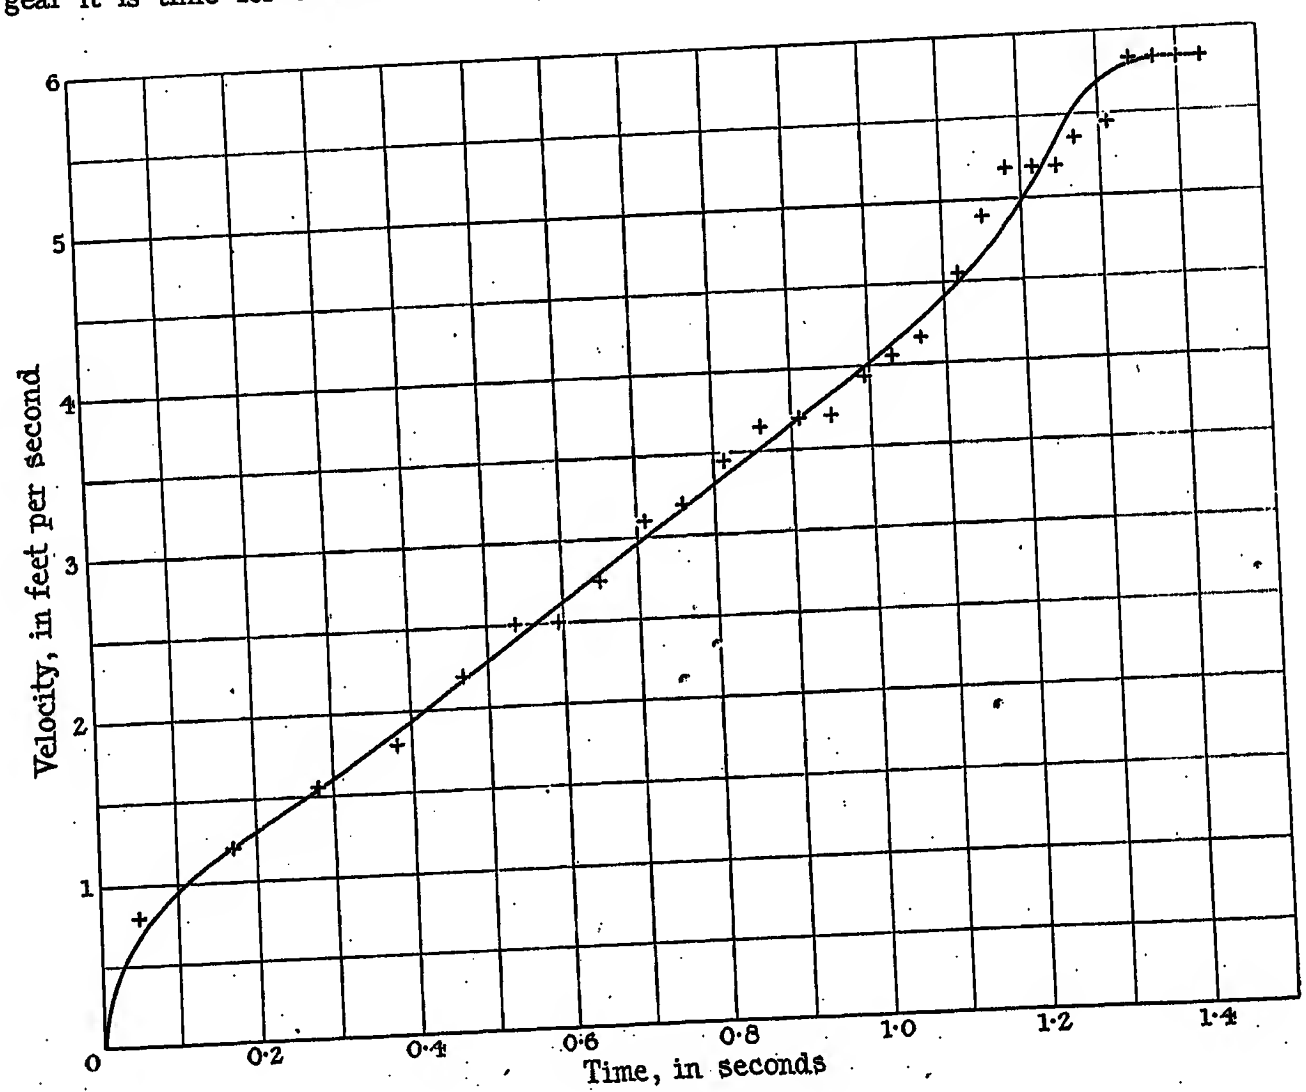

Fig. 6 (*a*).

re-bushed. To meet extreme cases, where no backlash of any sort is permissible between the worm and the wheel (these cases do not, in fact, concern lifts, but occur in certain pumping problems), a device of wedges below the main shaft bearings is introduced by means of which very fine adjustment of mesh can be obtained.

It will be observed that the over-worm type of gear that I am advocating is the more expensive, and, if it has the superiority I claim, deserves a due allowance in the consideration of competitive tenders.

For high-speed lifts such as I have advocated in the earlier part of this paper, the American practice of coupling the driving sheave direct to the motor without

saving in the cost of attendance. Its capacity is, however, far less than that of a car-switch lift of the same size, because there is some difficulty in employing a higher speed than 150 or 200 ft. per min. with an automatic lift, and because a single passenger on entering the car obtains complete control over the lift until he has completed his journey, although there may be many passengers waiting at intermediate floors. The automatic lift is therefore only suitable for places where the traffic is never so dense as to require the full capacity of the lift for many minutes at a time. The scope of the automatic lift might be considerably extended by the introduction of a satisfactory self-closing gate

to overcome the annoyance of the lift being thrown out of action by some careless passenger forgetting to close the gate after him, and by the incorporation of a suitable floor-levelling device which would permit of a higher running speed being employed. Lift makers are engaged upon these problems, so that there is a possibility of some advance being made in the direction of increasing the capacity of automatic lifts.

Automatic control lends itself to many variations in detail, but the general principle is much the same in all cases. One push-button is fixed at each landing gate and this will call the car to that landing, provided affecting the direction of rotation of the motor; also a solenoid the function of which is to overcome the force of the springs holding the brakes in position; and finally a solenoid operating the motor-starting rheostat. The particular solenoid which comes into operation in connection with the change-over direction switch depends upon the position of the car in the well at the time, so that if the car is at the foot of the well and the button for the first floor be pressed and the direction of rotation is found to be clockwise, then if the car is at the fifth floor and the same button is pressed the direction of rotation will be counter-clockwise.

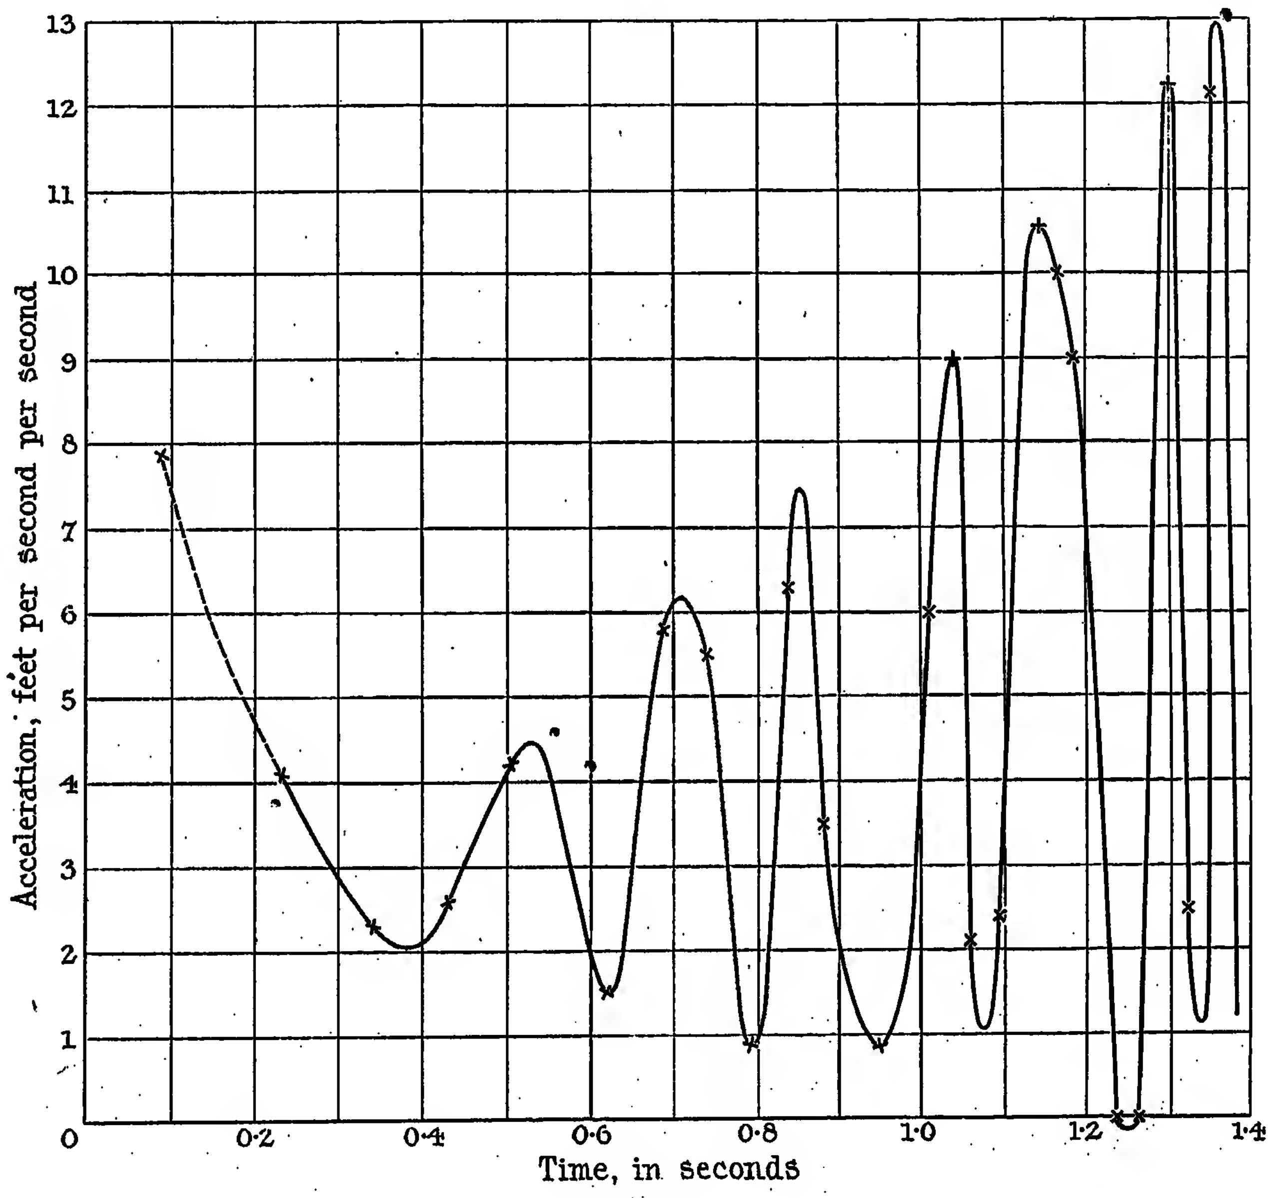

FIG. 6 (b).

it is at the moment disengaged and that all other landing gates are closed. A series of buttons fixed upon a tablet in the car—one button corresponding to each floor served—enables the car to be directed to any particular floor by pressing the corresponding button. On arrival at that floor the car will stop automatically. In a typical arrangement the push-buttons are connected to a series of relays representing each floor, by means of a circuit which is completed through contacts attached to each gate, so that when a button is pressed—subject to all gates being closed—the particular floor relay will operate. This relay closes the circuit of one or other of two coils operating a change-over solenoid switch

With car-switch control the connections are simpler, inasmuch as the push-button circuit and relays are omitted, the connections from the car switch being made direct to the solenoid direction switch. The diagram of connections of the control panel with which I am more particularly acquainted is given in Fig. 10. The same panel is used in connection with either the push-button or car-switch method of control. With this controller the shunt field of the motor is always left connected across the armature when the main current is disconnected. This arrangement entirely eliminates failure due to inductive discharge on opening the field circuit, and another valuable feature is that the

controller is of the double-pole type, the main source of supply being switched on and off at both poles at each operation of the lift. This eliminates a most insidious form of fault inherent in almost every other form of controller, in which an earth developing on one or other part of the control system may under certain circumstances allow of uncontrolled movement of the car.

As illustrating the service which these controllers are sometimes called upon to perform, a count was recently made in a drapery establishment in Oxford-street, London, in which two lifts each performed an average of 2 000 journeys per day. In making these tests great care was taken to eliminate any possibility of error. The motor rooms were kept locked, and accurate instruments were employed for counting and registering

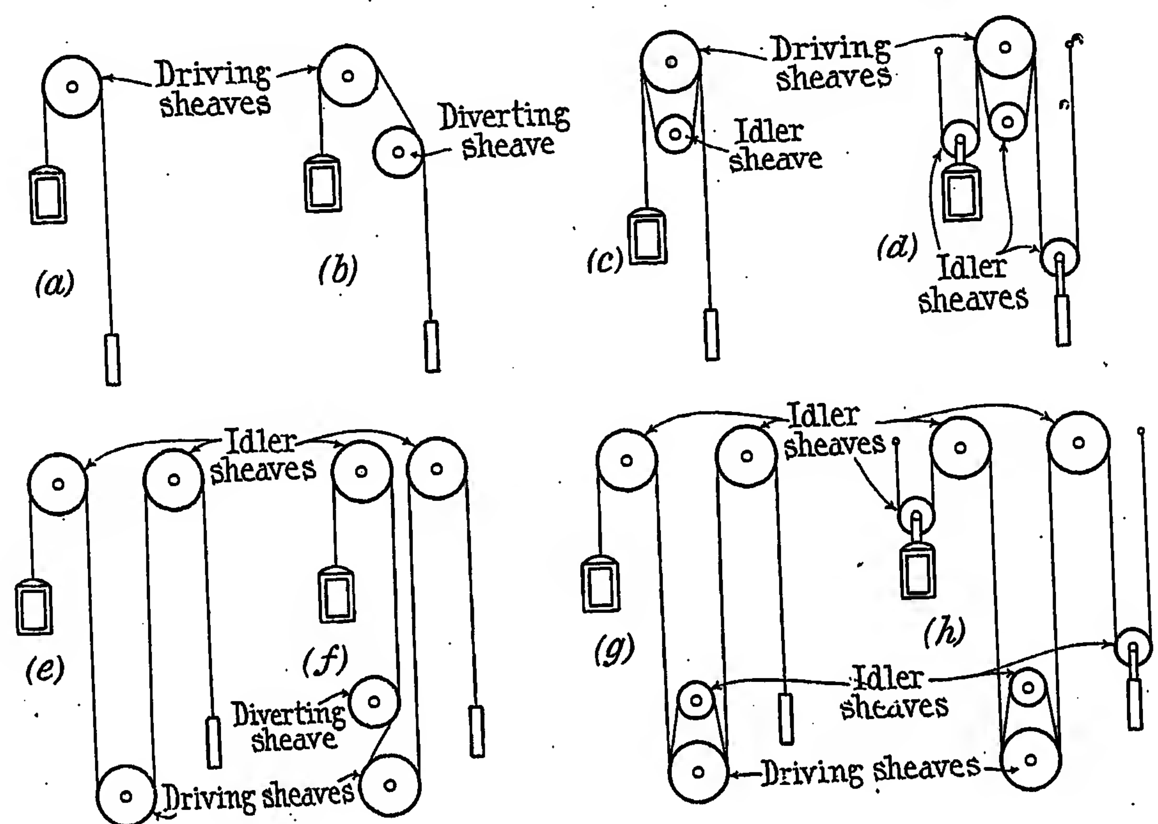

FIG. 7.

the work done. Independent observers were employed to check the results. During the whole month the only stoppage that occurred was one of 10 minutes upon one of the lifts to replace a car-switch contact.

It may be claimed, then, that electric lift controller designs have attained a high state of reliability. The most promising line for further advancement would

A very useful form of control, and one not sufficiently employed, consists of a combination of the push-button and car switch with a change-over device, so that during busy periods the lift may be car-switch operated at high speed by an attendant, and during slack periods push-button operated at a lower speed by the passengers.

The essentials of a good lift controller are that it shall start and accelerate the lift in the minimum of time consistent with the comfort of passengers, and

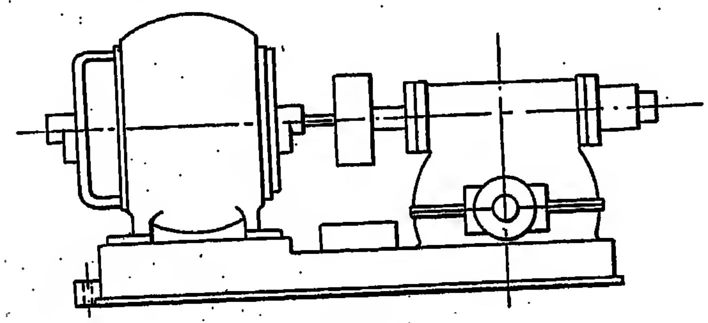

FIG. 8.

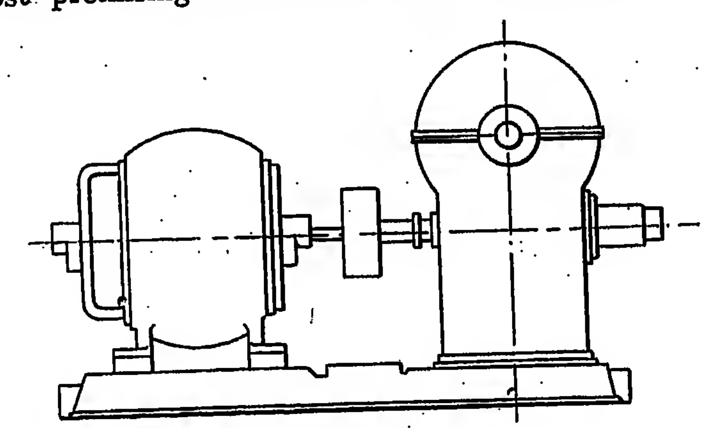

FIG. 9.

decelerate and stop in like manner, at the will of the operator. It must be reliable for a service sometimes extending to thousands of operations per day, and must be thoroughly robust and so constructed that a replacement or adjustment can be made readily without the possibility of upsetting the accuracy of its action. For many positions also it is often desirable that the controller should be silent in its operation.

seem to be in the direction of deceleration control, especially in conjunction with automatic lifts, thus permitting higher running speeds to be employed.

The energy consumption of an electric lift is principally dependent upon the number of times the lift is set into motion. The current required to accelerate the moving parts is far greater than that necessary to maintain the lift running, and very little,

if any, of this current is returned to the line during deceleration.

It follows, then, that with a car-switch lift the energy consumption depends very largely upon the skill of the operator in stopping the lift at floor-level. If he finds it necessary to "inch" at each stop, the energy consumption is enormously increased. This must always be the case when a new or an unskilful operator is employed. The higher the running speed of the lift the more likely is this loss to occur, owing to the increased difficulty of gauging floor-level.

Each lift maker has developed one or more devices to overcome this difficulty, but the fact that various makers recommend various solutions is in itself indicative that finality is not reached. Two-speed or three-speed control is sometimes made use of, the connections being brought back to the car switch, upon which two or

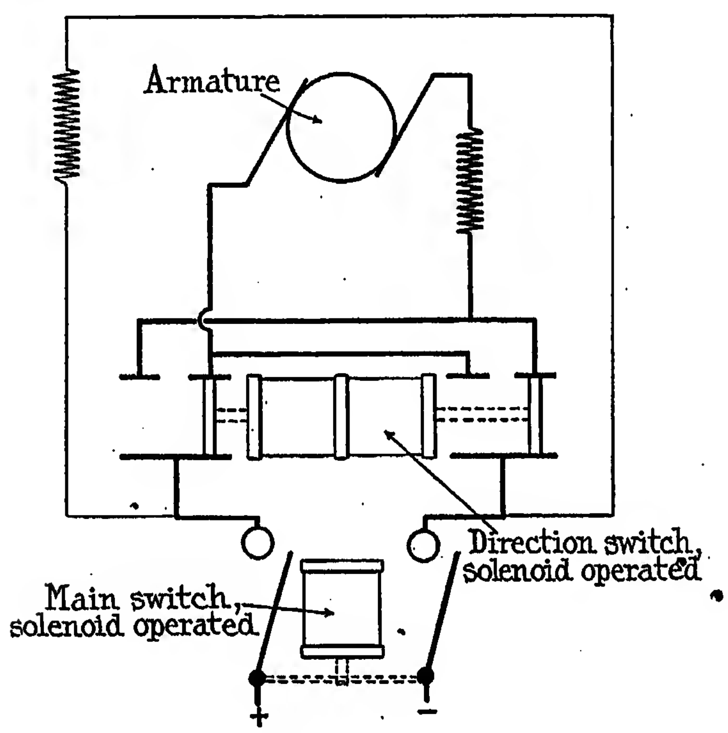

FIG. 10.

three stops in each direction are provided. Messrs. Waygood-Otis have introduced a device termed the "micro-drive" which not only attains the end in view but also maintains the car at the exact floor-level irrespective of the stretching of ropes or any other circumstance. That is to say, the lift having stopped at a particular floor, a heavy load wheeled into it may cause the car to sink—say half an inch—then the micro-drive machine will at once get into action and raise the car that half-inch. Mr. C. H. J. Day, in describing the micro-drive lift before the Association of Engineers-in-Charge, stated that it embodies two essential parts, the main hoisting machine and the micro-attachment.

The main hoisting machine, with the exception of the magnetic brake, involves no special features. The main brake is usually of the regular shoe type, except that the housing or frame, instead of being bolted to the bedplate, is fastened to the worm-wheel shaft of the micro-gear and revolves with it. This main brake performs a double function; first, with the micro-gear at rest it acts as a brake to stop the main machine, and secondly, when the micro-gear operates, it acts as a friction clutch driving the main machine. The micro-gear is in itself a small machine consisting of a motor, brake, and worm-gear reduction.

With the micro-levelling machine two controllers are combined in one, one to control the operation of the main motor and the other to control the operation of the micro-motor. The main controller is operated in the usual manner, i.e. by push-button, car-switch or mechanical control. The micro-controller is operated by a levelling switch mounted on the car frame. This levelling switch consists of two sets of contacts which control the micro-motor, one for the up and the other for the down direction. These contacts are operated by stationary cams in the lift shaft, there being two cams at each landing, one of which operates the up contacts and the other the down contacts. As the car approaches the floor at which it is intended to stop, the circuit of the main motor is interrupted, either automatically in the case of push-button control or by the car-switch or mechanically-operated mechanism.

If the main machine brings the car or platform above or below the desired floor-level the levelling switch engages with the cams in the lift shaft, thus operating the micro-motor. The micro-gear will then automatically lower or raise the lift until it is absolutely level with the floor, when the levelling switch will interrupt the circuit of the micro-motor and stop the car, due to the lever having disengaged itself from the fixed cams on the wall. This position of the car will now be maintained under all conditions of loading, as the automatic control of the micro-motor is independent of the door or gate contacts, i.e. if the position of the car relative to the floor should be slightly changed, perhaps by increasing or decreasing the load, the lever operating the levelling switch will once more come into contact with the cam, and the micro-gear will be started up and immediately return to its proper level.

Of course it is necessary to provide some means of preventing the micro-gear from operating when passing floors at which it is not desired to stop. This is accomplished by means of a magnet mounted on the levelling switch. When the car is being operated from the main motor, this magnet is energized and prevents the levelling switch from engaging with the cams in the lift shaft. When the power is cut off from the main motor this magnet is de-energized, and if the car is in the micro-zone, i.e. near to but not level with the floor, the levelling switch engages with the cams.

There are no doubt many special applications for such an arrangement, but for the purpose we have in mind at the moment it is questionable if the expense, as compared with that of other methods, is justified. There would also seem to be some danger, if the micro-drive can move the car whilst the gates are open, of a passenger being caught by the toe or in some other way between the slowly moving car and a fixed part of the well—a class of accident which has frequently occurred with hydraulic lifts.

A device to attain the same end—evolved and patented by Mr. Murray D. Scott—is inexpensive and has the advantage that the motor and controller employed are normal in every way and that a certain amount of the energy utilized may be returned to the line. The

Scott automatic decelerator may be described by reference to Fig. 11, (*a*), (*b*) and (*c*). The first shows the normal arrangement of a d.c. motor (compound wound) to the armature of which a winding drum is attached, and having two unequal weights suspended by cables therefrom. If we imagine the armature rotating in a clockwise direction and the machine being started up in the usual way, it will readily be appreciated that on the current being switched off the armature will be brought to rest rapidly, the load L′ being considerably heavier than the load L″. If we now imagine the armature rotating in an anti-clockwise direction, on switching off the current the load L′ will continue to

If the motor be running in an anti-clockwise direction, the preponderance of the weight L′ may cause the motor to generate current. Closing the diverter resistance circuit will put a load on the armature, and additional short-circuiting switches will cause the machine gradually to decelerate as before until the main switch S is finally opened for stopping the machine.

It is found that by correctly calculating the diverting and starting resistances the motor deceleration may be accurately predetermined and will be practically independent of varying loads. An improvement is shown in (*c*), Fig. 11, which illustrates the motor wound with an auxiliary shunt field connected in parallel with

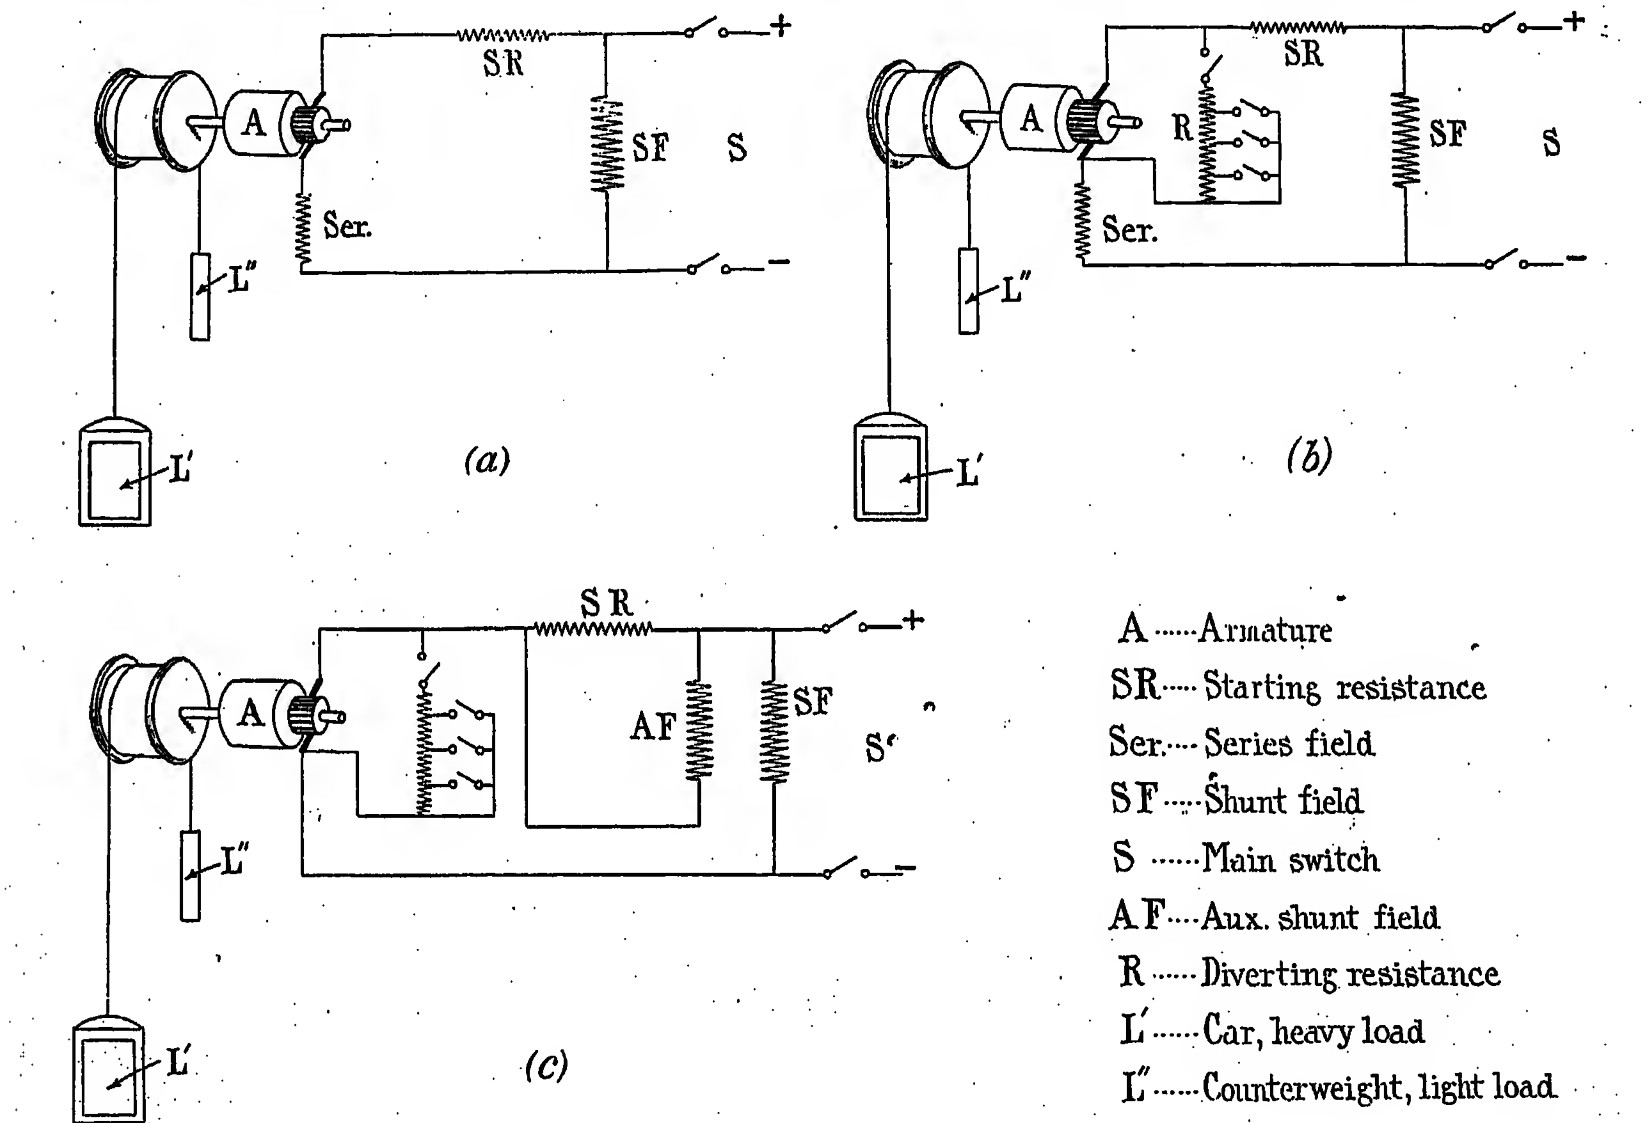

Fig. 11.

exert a rotating torque on the armature shaft, thus prolonging the period of deceleration.

In Fig. 11, (*b*) is a similar arrangement, except that a resistance R is arranged in parallel with the armature, a switch being inserted to throw this resistance in or out of circuit.

Let us now consider the case of the armature revolving in a clockwise direction. If before opening the main switch we close the diverting resistance circuit, the voltage across the armature terminals will be reduced, thus causing the motor to decelerate to any predetermined minimum governed by the additional short-circuiting switches on the resistance R. The motor may be finally brought to rest by opening the main switch S.

the starting resistance. This has all the starting advantages of a heavily compounded machine without the consequent disadvantage of speed variation, the auxiliary field being automatically cut out as the starting resistance is short-circuited, and being again automatically strengthened as the armature voltage is reduced by the decelerator resistance.

A further development of this idea with special relation to automatic lifts permits of comparatively high running speeds being employed with the surety of accurate floor-levelling under all conditions of load. The design, which is termed the "Auto-Pilot," has only recently been protected and is in the experimental stage. Two knobs or large buttons in the car are marked distinctly "up" and "down." On one of these being

depressed the lift accelerates and runs at normal speed. As the car passes each floor a signal light glows, and if the knob or push be released during the period of illumination the car will decelerate and stop level with the next floor.

Although there is no official supervision of electric passenger-lift installations in this country, the percentage of accidents is extremely small and apparently rapidly decreasing, a fact reflecting high credit on the firms responsible for their design.

I have endeavoured to obtain some exact information as to the percentage of accidents, but without success. The insurance companies have been unable to give me any figures, and the Home Office Reports deal with factory and workshop hoists only. I have had a search made of a large number of newspapers over a long period of years and a précis taken of all the lift accidents reported, but a study of these has proved useless, inasmuch as it is usually impossible to discover from the newspaper report what type of lift is referred to, what is the cause of the failure, or exactly how the accident occurred.

One is thrown back, therefore, upon one's own experience, and mine is that the majority of accidents have resulted from one or other of the following conditions:—

(1) Absence of gate and interlock contacts on the car.
(2) Failure of gate locks.
(3) Insufficient enclosure.

It is dangerous to permit a passenger lift to operate without a gate and interlock upon the car. Without interlocking contacts the attendant will insist upon starting the lift, and possibly closing the landing gate after the lift has started, before closing the car gate, and quite likely the car gate will never be closed at all. It must be remembered that a certain running clearance between the moving car and the face of the lift well is necessary, and, however smooth the face of the well may be, with this running clearance reduced to a minimum it is always possible for part of the clothing or the foot or hand of a passenger to become jammed between the face of the lift well and the moving car.

The failure of gate-locking devices, in which I include the electrical interlock that prevents the lift from operating whilst a gate is open, has been responsible for a large percentage of accidents. If the lock is out of order it may be possible to open the landing gate and to step into the lift shaft in the belief that one is stepping into the car; or on an automatic lift it may be possible for the car to be moved, by someone operating from some other floor, whilst a passenger is stepping into or out of the car. The remedy is the improved design and construction of the door-locking device, to which I will refer later, but a most valuable contribution to the safety of passenger lifts is to be found in efficient lighting. Too often the lift is stowed away in a dark corner. There should always be ample natural or artificial light immediately facing the lift entrance, and the car itself should be illuminated.

It is very difficult to persuade architects, builders or property owners of the necessity of carrying the enclosure above 6 ft. 6 in. in height in stair wells and other open places. A lift enclosure should be what its name implies and not, as many architects seem to think, a means of expressing their architectural ambition in iron and bronze. An enclosure which will allow an arm or leg to be thrust between the bars or below the bottom rail is dangerous, and there are hundreds of such enclosures in London. Cleaners and others will reach through on some pretext or other. The triangular space above each stair tread is a particularly dangerous point and should always be filled in. Apart from the danger to cleaners who thrust their arms and brooms through, articles—bottles sometimes—dropped on the stairway roll through here, and I have known a heavy bottle to smash through the top of the car. Dirt and rubbish is swept from the stairs through these convenient openings; this litters the top of the car and attaches itself to the greasy guides.

Upon the counterweight side, at least, the enclosure should extend from the floor to the ceiling, the reason being the large percentage of accidents which have occurred to cleaners, painters and others reaching over the enclosure for one reason or another, and, whilst observing the lift car, failing to notice the descending counterweight.

It is also often desirable to fit a wire screen in the well at the point where the car passes the counterweight, for the protection of men who may be working on the top of the car—always an occupation of considerable danger. For the same reason a screen should be fixed in the pit so as to protect any person engaged in cleaning out the pit, from injury by the balance weight.

Collapsible gates should be constructed on the "mid-bar" principle, so that the space between the bars is insufficient to tempt any person to try to put his hand through for any purpose whatever.

I have briefly referred to what I believe to be the three principal causes of accidents in connection with electric passenger lifts. I shall now endeavour to review the subject more closely by suggesting the various possible types of accident and the preventive measures to be taken in each instance.

The moving car or counterweight may come into collision with some dislodged portion of the lift enclosure or with some article projecting into the lift well.

Counter provision.—The enclosure must be sufficiently substantial to prevent this possibility, and there must be no opening or ledge upon which it is possible to rest any article with which the car or counterweight may come into contact.

The car coming into collision with the permanent stop at the top or bottom of the well, owing to the attendant omitting to operate the control circuit.

Counter provision.—Limit switches fixed in the well and operated by a ramp on the car and so connected as to open the control and brake circuit.

The car coming into collision with the permanent stop at the top or bottom of the well owing to some failure of the electric circuit rendering the control and the control limit-switches ineffective.

Counter provision.—Main limit-switches operated by a ramp on the car and so fixed and connected as to cut off the main electricity supply at both poles upon the car passing a certain distance beyond the top or bottom

floor. It will be noted that the brake, being normally in the " on " position and held off when the car is running only by means of an electric solenoid, must come into action when the main circuit is opened.

The car colliding with the permanent stops at the foot of the well due to excessive speed, the result of failure of the motor field circuit.

Counter provision.—A centrifugal governor gear operated by a cord attached to the car and so designed that a fixed excess of speed in the downward direction causes the main supply circuit to be opened and a safety gear attached to the car sling to come into operation. The function of this gear is to stop and support the car by means of grips pressed and wedged on the guides or guide backings.

The car coming into collision with the girders at the head of the well, due to a similar cause.—This cannot occur if the traction drive is employed and the counterweight allowed to land before the car reaches the permanent stops. Shock due to the counterweight landing at high speed may be minimized by the use of suitable buffers. In the case of drum-winding machines the only safeguard against this class of accident usually employed is the limit-switch and extra clearance for over-run of the car.

The centrifugal governor as usually employed is operative only in the downward direction of travel, but it can be designed to arrest the motion of the car in case of excessive speed in either direction.

The car falling due to failure of support.—This may occur in the case of :—

(*a*) *The car becoming jammed in the well whilst the ropes continue to be paid out by the engine above, and then becoming free and falling to the extent of the slack rope.* (*This is a class of accident confined to drum-driven lifts.*)—In the case of traction drive, if the car or counterweight jam, the result is either an extra load which causes the main fuses to blow, or a relief of load which causes the traction sheave to revolve harmlessly within the slackened rope. In the case of drum drive the counter provision is the slack-rope safety switch applied to both car and counterweight ropes in such a way that if any one of these ropes slackens, the switch will operate and cut off the main supply current.

(*b*) *Fracture of the supporting ropes.*—The counter provision is a safety gear attached to the car sling and operating as above described, to support the car by friction upon the guides in the event of the ropes breaking. In the best form of such safety gears the wedging action takes place and the car is brought to rest in the event of any one of the supporting ropes stretching beyond a certain limit. As a rope invariably stretches before breaking, the result is to anticipate a break taking place. If the well is totally enclosed and fitted with doors necessarily locked before the car can be set in motion, it is possible to use the column of air below the car as a cushion to prevent the too rapid descent of the car. Suitable buffers may also be employed as an additional protection.

(*c*) *The ropes becoming disengaged from the winding engine.*—This is a most serious class of accident, because if the safety gear on the car is operated by the supporting ropes themselves, or by a cord passing over the same sheave and therefore probably disengaged like the ropes, the result is that the safety gear is inoperative and the car and counterweight fall together without any brake. Ropes may leave the top sheave during the momentary slackening due to a jam of the car or counterweight, and from other causes. The counter provision is the employment of a centrifugal governor or other device to operate the safety gear by means of a cord reeved over pulleys entirely independent of those over which the supporting ropes pass. In this connection the extreme danger of using an overhung traction sheave may be noted. There should always be a substantial bearing on each side of the sheave so that the ropes—if by any means they are thrown off the sheave—cannot fall clear.

Three typical forms of safety gear, as usually applied to the cars of passenger lifts, are illustrated in the lantern slides.

The safety gear is now usually fixed below and not above the car. This is a wise precaution, as cases are on record in which the car has become detached from the gear fixed to the sling above and has fallen unchecked into the well.

It is not usual to attach a safety gear to the counterweight, except in places where the well does not descend to the lowest level and the counterweight might therefore fall into an inhabited space. Nevertheless, if it were the invariable practice to equip the counterweight with safety gear a few accidents might be rendered less serious in their effect.

(*d*) *Failure of a portion of the mechanical gear allowing the traction sheave or drum to revolve under the influence of the loaded car or counterweight.*—This may happen if the keys fixing the sheave or worm-wheel fail, or the rim of the worm-wheel becomes detached from its centre, or the teeth of gears wear out or fracture. The only preventive, apart from sound design and construction, is regular inspection, but, if the lift is allowed to get into a state in which such an accident can occur, the centrifugal safety gear—if designed to operate in both directions of travel—will check and support the car.

A passenger becoming crushed between the moving car and some portion of the lift well.—This cannot happen if a gate is fixed to the car entrance and so interlocked by means of a contact on the gate with the control circuit that it is impossible to move the lift unless this gate is completely closed.

Car starting whilst passenger is entering or leaving.—The counter provision is electrical interlocking contacts on both landing and car gates, preferably connected on opposite poles of the circuit.

Falling into the lift well.—The counter provision is a mechanical lock upon each landing gate, rendering it impossible to open the gate from the outside unless the car is at the landing in question. These locks are released by a ramp on the car which operates a roller connected with the gate lock.

A gate lock, to be absolutely reliable for use on an automatic lift, has to meet a great many requirements, and many of those already installed are defective in one way or another. Locks are now available which do meet all requirements and are safe. Existing locks of the older types should be exchanged for these.

One of the conditions of the perfect gate lock is that it shall not allow of the gate being opened when the car is only passing and not stopping. This condition can be complied with by the employment of a movable solenoid-operated ramp on the car, but the complication is not usually considered worth troubling about, because the effect of opening a gate whilst the car is passing is only to stop the lift, and the result, though annoying to the passengers, is not dangerous.

The other accidents which may occur on electric passenger lifts mostly concern men engaged upon construction or maintenance and do not come within the reach of this paper.

It will be observed that in order that a passenger lift may be safe it must be provided with a number of mechanical and electrical safety devices. In the design of these the guiding principle must be that any failure of the safety device itself, whether mechanical or electrical, shall only result in rendering the lift inoperative. If this principle is faithfully carried out the lift will be put out of use upon the least derangement of any one of the large number of minor parts. The only steps which can be taken to prevent this are regular inspection and adjustment by men trained to the business.

As it is not desirable to allow wearing parts, ropes, bearings, gear, etc., to wear to anything approaching breaking point, inspection is necessary to ascertain when renewals should be made. The frequency of such inspection may vary considerably, according to the amount of service the lift is called upon to perform, but I have found it reasonable to insist upon an inspection after every 6 000 journeys, with a maximum interval of three months between inspections.

Discussion before The Institution, 17 January, 1924.

Mr. W. S. G. Baker: The author suggests that it is necessary in this country for a special type of lift to be developed, and implies that the types of lifts used in America are not quite suitable for this country, but I do not understand why this should be so. There are many places in America where the conditions must be exactly similar to those existing here. I do not, of course, mean to suggest that that is a reason for not seeking improvements. I am in agreement, from rather a different point of view, with the author in his remarks regarding the location of lifts by architects. It is quite usual for an office lift to be placed in the basement, generally next to the boiler, where the conditions, both mechanical and electrical, are by no means of the best. The cost of maintenance of such a lift must necessarily be greater than if it were placed at the top of the shaft. The question of lift speeds is almost entirely one of control. The kinetic energy in a lift will vary as the square of the speed, and therefore the stopping of a lift at high speeds is distinctly difficult. In this country the majority of lifts running at ordinary speeds are stopped by the current being switched off and the brakes being applied. That is satisfactory under some circumstances and at low speeds; but with high-speed lifts, or lifts which have to deal with considerably varying loads—for instance, a railway lift with a load of either nothing or 60 or 70 passengers—it is necessary to reduce the speed of the lift to some predetermined constant. The author shows in Fig. 11 how this can be done by means of dynamic braking. The system illustrated in Fig. 11 (*b*) is almost identical, in fact, with that in use on the Underground Railways' lifts. The periodic variations of the acceleration curve shown in Fig. 6 (*b*) are very curious, and it occurred to me that they might be, in part, due to variations in the torque of the motor, and also to variations in the angular velocity, due to the fact that the gear is a worm gear, which gears are sometimes not very easy to control so as to give an absolutely uniform speed. I agree with the author that ropes of not too high a tensile strength will undoubtedly last longer. In many cases I have found it an advantage to use ropes of a heavy-gauge wire rather than of very fine-gauge wire, particularly where a sheave is driven by the rope and moves along a shaft, with a tendency for the wires to be plucked out. Nearly all our lifts are built with S bends, and these cause much wear on ropes, more particularly on the counterweight ropes. The author does not refer to the methods adopted for attaching ropes to the car and to the counterweight. It is absolutely essential that the strain should, as far as possible, be equalized throughout the wires of the rope. We have tried a number of different methods. The first was the spliced eye, and we have finally adopted a metalled-in end somewhat on the same lines as a colliery fixing, choosing a metal of rather definite proportions which seemed to give very good results. Our fixings will actually withstand a greater strain than the rope. On the question of the position of the worm, my own personal preference is for the worm to be below the wheel, for this reason: there is no perceptible difference in the two cases as to lubrication while the load is on, but when the lift has been standing for some time, if the worm is above there is a tendency for the oil to be squeezed out from between the wheel and the worm, owing to the constant weight on the machine. The result is that the worm has to start and the wheel has to make some part of a revolution before any oil is carried up to the working faces. If the worm is below, it is constantly immersed in oil and a partial turn of the worm is enough. The design shown in Fig. 8 appears to be very ugly, as determined by the height of the centre-line of the motor shaft from the bed plate, due to the motor height. I see no reason why a special motor should not be developed in this country for lift work. The first consideration is that the armature should have low mass and small radius. The author refers to gearless lifts developed in America. I have had the opportunity of seeing these lifts, and from a maintenance point of view I think rather highly of them. They have only two bearings, and there is nothing else renewable in the ordinary mechanical wearing sense. The machine is more costly, but with a 2 to 1 roping on the car and on the counterweight I think it is a very attractive proposition indeed, more particularly if one is not tied down to a low speed.

There is another interesting point of difference between American practice and English practice. The English lift manufacturer seems to rely for control very largely on sliding contacts, the bulk of the lift controllers being more or less motor starters. The American gear is almost entirely built up of what are known as "clapper" switches, and from a maintenance point of view, as there is very great difficulty in these days in getting really skilled men, this type of switch is, in my opinion, far preferable. It should be quite easy to renew the contacts, and I have found the gear to give very little trouble indeed. I am entirely in agreement with the author's views on the question of safety devices. I have urged these views from time to time. On the Underground Railways we interlock very much in the manner indicated by the author, although we may not be quite so up to date in some respects.

Mr. J. T. Mould: I am particularly interested in the author's statement in regard to the importance of acceleration and deceleration. All the examples which he gives refer to direct-current lifts, but I should like to hear his experience with alternating-current lifts, particularly with regard to deceleration. The device patented by Mr. Murray D. Scott, which he mentions, is one that I saw used about the year 1902. At any rate the principle of the armature diverting-resistance was used and the same principle was adopted by the Cutler Hammer Manufacturing Co. in connection with cranes as long ago as 1898 or 1899. It is quite possible to get perfectly reliable and smooth deceleration and acceleration, but the control apparatus must be very carefully designed. Mr. Baker mentioned the superiority of clapper switches over sliding-contact switches. My company used to supply a great many lift controllers with sliding contacts, but now all our designs have butt contacts.

Mr. B. A. Siden: The maximum capacity of a building is a very vital factor in arriving at the lift equipment. The author of the present paper is rather in disagreement with the American figures and those given in Mr. Day's paper, but they tally with my experience, i.e. they run from 80 to 100 sq. ft. per person in office buildings. From the rest of the information given in the paper, it will be more easy than formerly to deduce the lift service required. One important point which the author raises is that the specialist is too seldom consulted in these days with regard to lifts, which are becoming more complex every year. The most important thing in connection with a lift is the maintenance, and this has a very considerable bearing on the question of design. There is a great difference of opinion between the relative merits of sliding contacts and clapper, or contactor, types of contacts. A great difficulty is, in my experience, to get the maintenance staff properly to maintain a sliding contact. If that were done I should always prefer a sliding contact where it is allowed to be self-cleaning, i.e. where the pressure is correct and where the surfaces are ample in area and the current density consequently low. If a carbon-block contactor gear is adopted it is essential to keep the current density very low. In many of these devices the current density is high, with the result that the contacts, flexible connections and springs become heated in the course of the day's run. I am of opinion that the running of lifts should be governed by regulations, but until that is done people will be inclined to scamp the maintenance because it is expensive, with the consequence that the lift may be allowed to run until a breakdown occurs. I have had experience of lifts by almost every maker and under varying conditions and I prefer the over-driving worm. The worm is the portion of the worm-gear which gets the most wear, as the wear occurs practically on one tooth of the worm, whereas on the wheel it is distributed completely round the periphery of the wheel. When the worm is above it is very easy to inspect, but if it is underneath it involves opening an inspection door and removing the oil from the gear case. The fitters will not do this unless they are specifically instructed. There are several makes of winding gears which have unbushed bearings. The result is that in a few years the whole of the gearcase may have to come out and be put on to the boring machine, which is a big and costly operation, whereas if the bearings had been bushed the only renewal necessary would have been two gunmetal bushes at a cost of, say, £5. With regard to the question of the height of centres, in a high-speed lift there is bound to be some vibration, however well the armature of the motor is balanced. The higher the centres of the main shaft, the more the vibration is transmitted through the ropes to the car. By keeping the main driving-shaft centres low, I find that the vibration is kept within reasonable limits. I think that the question of alternating-current lift practice should have been raised. Alternating current is becoming more and more important through the activities of the Electricity Commissioners, and its use is being developed considerably, especially in provincial areas, and the application to lifts will cause difficulties, as at the present moment the practice in regard to alternating-current lifts is, I consider, very much behind. There is a type of controller known as the "eddy-current control" in connection with two- or three-phase lifts, and for simplicity it cannot be excelled. It consists of the usual rotor with three slip-rings, and a double-pole reversing contactor for the stator. The three-core choker is connected across the slip-rings and takes charge of the heavy currents which occur when the stator circuit is closed. This apparatus can also be used as a dynamic brake, but, of course, is only suitable for polyphase work. Much development is needed in motors and control gear for single-phase a.c. lifts. I think that few people will dispute the fact that the top of the shaft is the ideal place for the winding machine. The question of roping is very important, and it is not only the cost of the ropes which is of consequence but the cost of fixing also, and this is usually about 40 per cent of the cost of a set of ropes, so that the saving in the cost of rope renewals by proper selection of machine position is very considerable. In general, my experience is that unless high-speed lifts are limited to certain floors in a building no advantage is gained. In a building of 9 or 10 floors a real advantage is only gained by using express lifts to serve floors above the third or fourth, but the better way is to employ a fast and a slow lift, and let the latter take charge of the intermediate traffic

and the lower floors, leaving the upper floors to the high-speed lift. Failing that, if there is only one lift and that has to serve the whole of the building, a moderate speed of about 250 ft. per min. is best.

Mr. B. P. Walker : The author mentions the inadequacy of the services provided in most of the buildings in the city. As time goes on and building restrictions are less limited, the height of buildings will be still greater and there will be still more demand for lifts. A large amount of consideration has been given to the question of acceleration during the past few years, and present-day and future lifts will accelerate faster than the old ones. The important point is to aim at even acceleration, no matter how fast this is. The author refers to the micro-drive lift, which possesses the advantage that it stops dead level with the floor under all conditions of load and speed. In addition, it is self-levelling should the position of the car vary due to the variation in the load. For example, should a very heavy load be pushed in on a trolley, when the front wheels enter the car the lift will drop, due to the stretch of the ropes, but the micro-drive lift automatically levels itself so that the back wheels of the trolley can be wheeled straight on. The automatic decelerator was mentioned by one speaker as being an old method of connection. To my knowledge the same forms of connection have been used for many years not only in lifts controlled by a car switch but also in those operated by a push-button. As Mr. Baker remarked, most of the lifts on the Underground Railways are arranged in this manner. That method of connection does not, however, give absolute accuracy in the stopping of a lift, and it cannot effect automatic self-levelling, so that, while it is claimed to attain the same ends as the micro-drive, it is a rather different proposition and will not meet the same conditions. Moreover, when applied to alternating current, which is becoming more and more common in this country, the micro-drive is quite a simple matter, whereas I think there would be some difficulty with regard to the automatic decelerator.

Mr. W. D. Brakenridge : I agree with Mr. Walker that the micro-drive is a very sound proposition. In regard to the automatic closing of the gates, there are on the market a good many fittings which appear to achieve this object satisfactorily. It is stated in the paper that the percentage of accidents is small. This may be so, but it should be less. Gate locks will reduce the risk to a large extent, especially in the case of hydraulic lifts, very few of which are to-day fitted with electrical interlocks, or locks of any description. In Denmark locks are compulsory. Dual control, i.e. alternative car switch or push-button control, is a great advantage in a number of cases, especially in hotel lifts.

Mr. P. Good: In the early part of the paper the author refers to the need for fundamental terms and definitions, so that people interested in the subject can understand each other more readily. It may be of interest to mention that the British Engineering Standards Association is preparing a comprehensive list of electrical terms and definitions which, with the author's help, could be made to meet his requirements. The author has set himself the difficult problem of gauging the lift requirements of buildings. I think that he attaches rather too much importance to the total number of people using the lift at one floor, as the majority walk down. For lifts in London, where there are a large number of comparatively small buildings, the delay is very largely caused by the human factor, and the automatic lift which returns automatically to the ground floor should be much more widely used. In office buildings of three, four or five stories, an automatic lift returning to the ground floor, with satisfactory automatic door-closing, would most frequently meet the requirements and eliminate much of the human factor. The author refers to the safety gear for preventing a lift from falling in the event of the ropes breaking. On one occasion I was asked by a lift maker to satisfy the consulting engineer that his gear would, in the event of the ropes breaking, actually stop the lift within 12 inches, in accordance with his guarantee. We took a bight in the ropes with a slip hook, leaving a fairly considerable amount of rope loose, and loaded the lift to its full capacity. We then started the lift downwards until it was travelling at full speed, and released the slip hook at a predetermined place. The lift pulled up within 8 or 9 inches. It was the only time that I have ever seen the safety device on a lift actually tested, and it was quite a damaging and expensive test. Perhaps by now a simpler test is available, as it seems desirable to have a suitable means of testing safety devices.

Mr. W. R. Rawlings : Can the author say why the continuous lift was superseded ? The paper makes no reference to the cost of energy in connection with electric lifts, and it would be interesting to know how it compares with that for hydraulic lifts. In one case where I put in a service for a push-button-call lift, the proprietors were agreeably surprised to find that the total bill per week was only 1s. 6d., although it was open for the use of the public and their own staff. One interesting installation with which I had to deal was an isolated case of a 2-ton goods lift to serve six floors in a large furnishing warehouse. The plant consisted of a 4-h.p. gas engine with a 190 ampere-hour battery working at 200 volts. A test was applied by running a 2-h.p. motor and twenty 30-watt lamps for one hour. During this period the lift was operated 30 times from basement to top floor with a 2-ton load. At the end of the test the battery had only discharged one-third of its total capacity. The first year's gas bill amounted to only £10, again illustrating the very low cost of running an electric lift.

Mr. H. Marryat (*in reply*) : I agree with Mr. Baker that there are many places in America where the buildings are similar to those in this country, but I do not agree that the conditions of traffic are the same or that calculations arrived at from counting lift traffic per occupant of a building in America are applicable to a similar class of building in Great Britain. Big variations in lift requirements are found to exist in different American cities, and there are still greater differences between American and European requirements owing to variations in the conditions of employment, daily routine, and psychological reasons.

The suggestion that the periodic variations in the acceleration curve shown in Fig. 6 are due to the fact that the reduction gear employed is the worm and wheel type is distinctly interesting. It was suggested in the paper that this effect is due to a combination of

causes, and possibly this is one of them. The whole matter is being investigated further with improved apparatus.

Passenger-lift engineers do not generally experience trouble due to the ropes failing at the point of fixing to the car or counterweight, such as is common in mining and large public railway lifts, the reason being that the smaller sheaves and sharp bends which have to be negotiated with the ordinary passenger lift cause the rope to wear or fracture at the running surface before fracture develops at the fixing.

I note with much interest Mr. Baker's preference for the arrangement of worm gear with the worm below the gear wheel, in order to secure lubrication of those teeth of the wheel which come first into engagement when the lift is started after being at rest for a long time. I do not think that this applies to the class of gear which we are using for the ordinary passenger-lift service in which a considerable amount of oil collects in the hollows of the worm-wheel teeth standing at the top, so that when after a considerable rest the gear is set in motion there is still sufficient oil to lubricate immediately the worm and the few teeth which immediately follow, until the part of the wheel which has been resting in oil comes into engagement.

The suggestion that a special motor should be developed in this country for passenger-lift use is excellent. Attempts have been made in this direction, but owing to different makers each developing his own particular motor, spare parts are apt to become expensive. This is a difficulty which might be overcome if it were possible for lift makers to co-operate with the B.E.S.A. in the standardization of leading dimensions.

With regard to the use of clapper switches, the advantages are mostly on the side of reduced cost of manufacture. Owing to the ease with which gear of this type may be standardized, the parts can be turned out at a very low cost. My own company, in common with other lift makers, has employed them to a large extent in the construction of lift controllers. There is, however, an outstanding objection to clapper switches in the noise which they create in operation. The sliding-contact type of controller is practically silent and when properly constructed requires no more attention.

In reply to Mr. Mould, the difficulties which are supposed to exist with regard to alternating-current lifts can be solved in a great number of ways, and it is a question rather of experience and choice between them than anything else. Two-speed squirrel-cage motors are satisfactory where the stops are not too frequent, but as the starting energy and the braking energy from high speed to low speed are entirely dissipated in the motor itself the machine is likely to overheat if the stops are frequent. In such cases another solution must be sought.

With regard to the devices patented by Mr. Murray D. Scott and referred to by both Mr. Mould and Mr. Walker, I understand that there is no claim of novelty as to the diagram employed but only as regards the practical means adopted to put this diagram into effect for starting and decelerating an electric lift—especially one running at high speed.

With regard to the remarks of Mr. Siden, I do not wish to question the American figures of 80 to 100 sq. ft. per inhabitant for certain classes of building, but I do say that the use which the inhabitants of a building and their visitors make of the lifts in London is not that of the same number of people in New York. I am in entire agreement with Mr. Siden in his remarks regarding sliding-contact switchgear, and I am glad to note that with his long experience he is able to support the views expressed in the paper as to the best arrangement of the worm and wheel and the best position for the gear in the lift shaft. I need hardly say that I am in agreement in condemnation of unbushed bearings in the gear box.

As Mr. Brakenridge observes, there are many devices for effecting the automatic closing of gates, but I know of none which is at once effective and reasonable in cost.

I am glad to hear from Mr. Good that the British Engineering Standards Association is prepared to include lift terms in its comprehensive list of definitions now in preparation, and I shall be very pleased to assist in any way possible. Mr. Good has referred to the automatic lift which returns automatically to the ground floor. This is an excellent solution of certain specific propositions, but has its limitations. Such a lift is a positive annoyance where the down traffic is considerable, as a person wishing to go down must wait for the lift to come up unless he happens to catch it at the particular floor where he is waiting. The method of testing mechanical safety-gear is that still usually employed. Governor safety-gear may be tested by increasing, by means of a field resistance, the speed of the motor above the prescribed maximum.

Mr. Rawlings has pointed out my omission of any reference to the energy consumption of electric lifts and has given some interesting examples. In the paragraph dealing with the total cost of lift service, I referred to energy consumption as an item. It is a small one compared with the more important items—rent, maintenance, interest upon capital, etc.—a point which I have endeavoured to emphasize. The energy consumption of similar lifts running under different conditions will vary very much because acting upon the see-saw principle, with the average load counterweighted, the running current is only considerable with full load or no load and is negligible with average load. It has often been found possible to effect a large saving in energy consumption by adjusting the counterweight after the average load has been ascertained. This should always be done where a lift has been installed of too large a capacity for the work which it is subsequently called upon to perform. This principle is of even greater importance when dealing with goods-lift installations where the conditions of average load sometimes alter completely with a change of works' routine.

In reply to the question as to why the continuous running lift has been superseded, the reason is that in order to allow passengers to step on to and off the continuously running cars the speed must be so low as to be inconsistent with modern requirements. The successor to the continuously running lift is the escalator in which the very slow motion is compensated by the fact that there is no waiting for a car, and by the possibility of shortening the travelling time by walking up or down the steps of the escalator.

North-Western Centre, at Manchester, 8 January, 1924.

Mr. H. C. Crews: In his opening statement the author says: "Where electricity is available, it has practically superseded all other forms of energy for new construction." I agree with that statement if the author will add the qualification "if the price of energy allows electric driving to be a commercial proposition." I do not think he meant to convey that in his opinion electricity is always preferred for driving lifts irrespective of the cost of energy. In a place like the West End of London, say in Bond-street, we do not look for a commercial proposition as we should in Manchester, where we do expect to buy things cheaply. I am responsible for a lift which is running in Bond-street, London, where the supply undertaking charge $1\frac{1}{2}$d. per unit. For similar machines used in Ancoats, Shudehill, or almost anywhere in Manchester to-day, the lift rate is $3\frac{3}{4}$d. per unit. There is also a municipal high-pressure hydraulic supply in Manchester, but I do not think that that quite accounts for the difference. The same firm who use an electric lift in Bond-street also have a similar office block in Manchester, and there they have had a hydraulic lift installed. I could not persuade them to use an electric lift. Both are modern up-to-date machines doing much the same work and the cost of energy was the deciding factor. I quite agree with the author's remarks in regard to specifications for lifts. A number of the leading architects do realize that this is rather too technical a matter for them, but there are thousands of architects who expect good results without technical knowledge of the subject, and too late in the day ask makers to quote on the very brief specification which they have drawn up. I cannot agree with the author's remark on page 332 that "Serious danger attaches to the drum method of driving," etc. The V sheave or the drum-drive alternative is a very old controversy, and there is much to be said on both sides. I agree that more sheave drives are put in, mainly because they are cheaper, usually simpler, and to some extent more efficient; but there are many advantages in the drum drive, particularly in cases of heavy weights, for which purpose I consider them to be usually the best practice. The author says that rope cost is a very serious factor in the cost of a lift, but I have only once in a long experience had to renew drum-driven ropes. If of suitable quality, a useful life of from 10 to 20 years can be certainly expected on an average drum lift, but the sheave-driven rope has, in my experience, an average life of about 5 years only—on a fairly busy lift in each case. I also disagree with the author when he says: "The cost of maintenance of an electric passenger lift in business premises varies from about £20 to £100 per annum." I think that those figure are too high. In 1906 I obtained from users, or my own records, the actual maintenance figures of 12 hydraulic lifts, and the average cost was only £10 2s. per annum. I also took 12 electric lifts and their average maintenance cost per annum was actually £9. Allowing for the difference in present-day values, I think £20 should be a maximum. It must be a very busy or expensive lift where this cost is exceeded. The method of reeving the ropes is, of course, very important. As regards the efficiency of worm drives, I still specify self-sustaining conditions, but always somewhat reluctantly; it seems a pity to confine oneself to something like 50 per cent efficiency when 90 per cent can be easily obtained with a worm. In some of the high-speed long-travel lifts, makers put in a high-efficiency worm and take extra precautions in safety gear. So many good safety gears have been shown in the lantern slides that I feel sure we need not in the future confine ourselves to self-sustaining conditions and introduce the low-efficiency worm. This is what I suggested in a paper which I read in 1906*: "In the author's opinion, if higher efficiency gear is generally adopted by makers in this country for busy electric lifts, a second brake will become imperative. Possibly a modified power band brake, acting on an extension flange of large diameter overhead sheave, and arranged for mechanical operation from cage in case of emergency, may ultimately be adopted, with an 85 per cent efficiency worm gear, in addition to usual electric brake." I do not think that that suggestion has been adopted, and perhaps it is not to-day the best method, but some modification of it would, I believe, prove to be a simple and cheap arrangement. I agree that the combination of press-button and car-switch control is often a most desirable thing. I have in some cases adopted this and found owners very satisfied with it. There is nearly always a slack time on a lift, particularly in such places as hotels. In such cases an attendant is employed to work the car switch, with rather quicker running, for the busy period, and when traffic is quiet the slower automatic press-button control is used. Nowadays most people are able to use a press-button lift intelligently. The double equipment does not cost very much more, if it is done at the outset, and in many cases it results in a saving in wages and proves a great advantage. On page 337 the author refers to a method by which current may be returned to the line. A great deal can be done in that way, but unfortunately the supply undertakings install a non-reversible meter, with the result that the user obtains no regenerative advantage at all. Lift owners may not be authorized to operate substations, but I do not see why they should not have the benefit of regeneration if done in a reasonable manner, and it is an easy matter to arrange. The failure of cage-locking devices is mentioned on page 339, and in my experience that is the principal cause of accidents. The design of a cage lock is much more difficult than appears at first sight, particularly the mechanical part of the design. Even to-day there are only two cage locks that I consider to be absolutely safe. I agree with the author that the cage should be lighted. In one case after an accident had occurred on a press-button lift, due to the lack of light, a key switch was placed in the cage and the light was switched on during all dark periods. In many cases the supply undertaking will charge such cage-lighting at the power rate, and the cost is negligible. I should be glad if, before the

* "Lifts and Hoists," *Journal I.E.E.*, 1906, vol. 37, p. 245.

paper is published in the *Journal*, the author would add some figures of high-speed lifts upon the lines of those I gave in my own paper, showing first cost, maintenance cost, energy cost, etc., as they would be very valuable to the profession and to the engineering trades generally. I have myself taken out some up-to-date costs of half a dozen typical and most usual types running at from 150 to 200 ft. per min. with 7- to 15-cwt. loads and 40 to 60 ft. travel. I do not think that the cost of energy of more than one of these exceeds £10 per annum. The one exception is a very busy, rather high office block in Manchester, and in two years it has averaged only 1 099 units per annum. A Manchester cotton warehouse employing a lift for their goods uses only 355 units per annum over a three-years' average. A fairly busy 15-cwt. lift in a block of chambers consumes 666 units per annum over a six-years' average. A rather busy clothes warehouse over a three-years' average uses 563 units per annum. A busy hospital, with a bed lift which is used a good deal for patients, only averages 404 units per annum over six years. A rather busy office block in London has averaged 614 units per annum over two years. If power can be obtained at, say, not more than 2d. per unit, the cost is very low; even at 3¾d. it does not amount to anything serious and compares very favourably with most hydraulic charges for similar duty.

Mr. C. E. Raeburn: In view of the further and closer investigations now being made, I would suggest that the author in his reply to the discussion give, if possible, an explanation of the large variations in the rate of acceleration during the accelerating period as shown in, say, Fig. 6 (*b*). These variations are of great interest, but at the same time it would appear to me that the method previously adopted of investigating the acceleration period may have tended to exaggerate the changes unduly. There seems to have been some timidity on the part of lift engineers in this country in hitherto limiting the speed to 400 ft. per min. I would suggest that those engineers study the subject of the design of electric winders which also carry passengers, run at speeds up to 4 000 ft. per min. and are really super-lifts. Acceleration in such lifts may be as much as 6 ft./sec./sec., and hand-decking is accurate. The study also of what has been done in semi-automatic blast-furnace hoists and chargers would also broaden the view. A table hoist, for instance, works at speeds up to 600 ft. per min., acceleration up to 2 ft./sec./sec., and unbalanced loads up to 4½ tons with cages weighing from 2 to 4 tons. They are started by hand control, and retarded and decked level automatically. Ward-Leonard control is generally used. One speaker in the discussion has described passenger lifts as being highly efficient, but presuming he referred to the more general type of d.c. drive, the contrary is the case, as in addition to the series resistance losses in the controller there are large losses due to the diversion of the armature current during starting and stopping. The tendency now in the United States seems to be to install Ward-Leonard control with and without "weak field" speeds, for the purpose of obtaining advantages of efficiency and safety, better acceleration and speed control with little loss. It appears to me that it is on these lines that the future high-speed, high-efficiency lift should be developed in this country.

Mr. A. B. Mallinson: The author refers to the excessive rope wear which takes place with the arrangement shown in Fig. 7 (*f*). I have had the same experience with cotton rope driving, and the conclusion that I came to was that the trouble was due to bending the rope in the reverse direction almost immediately. Even a slight bend will affect the fibres of the rope very materially and shorten their life. I suggest that the same reason may account for the short life of the steel ropes with this system of reeving. On page 330 the author refers to accelerations up to 300 ft. per min. in a distance of 24 inches. That will result in a rather large peak load relative to the motor horse-power, which will possibly cause the supply undertaking to charge a somewhat higher power rate.

Mr. G. F. Sills: A previous speaker referred to the effect on the human frame of rapidly accelerating lifts. I found this most noticeable on the very high buildings in the United States and Canada, particularly after about 10 to 14 stories. Presumably, matters cannot be mended, as for commercial reasons the lifts must be made to travel fast on these extra high buildings; otherwise extra lifts would be needed to carry the traffic. I could never understand why in buildings costing, say, £100 000, there should often be such inadequate lifts. One sees notices to the effect that only so many persons may be carried, a number which does not at all fill the lift, and the attendant has to refuse waiting people when there is plenty of room. Surely a lift serving large blocks of offices should be capable of dealing with as many people as can be got into it, and there should be no question of the rope, the mechanical parts of the lifts, or the motor, not being large enough to deal with an extra passenger. I am inclined to think that when the motor operating the lift is unduly cut down, and on occasions when one person more than the authorized number is taken in, the slower acceleration of the lift is quite noticeable. Offices in a high building, even on the fourth and fifth floor, are of no use to anyone unless there is a very reliable lift.

Mr. J. S. Peck: I think that the irregularities in the acceleration curve may possibly be due to the elasticity of the ropes. I have seen deep wells being drilled by means of a very heavy tool on the end of a long rope. The action in this case was as though there was a weight on the end of a rubber string, where the vertical movement of the top of the string may differ both in time and amplitude from the vertical movement of the weight. In order to get the movement of the tool to synchronize with the crank for lifting the rope, it was necessary to adjust the engine speed very carefully. It seems possible that a somewhat similar action takes place on a lift, where, due to some inequality in the controller, the rope is suddenly stressed and, being elastic, stretches: the lift tends to follow the rope, but at a later period, and thus oscillations are set up which may appear as irregularities on the acceleration curve.

Mr. T. E. Herbert: It has been said that there is nothing that the mind of man can conceive which is so absurd that some fool will not do it, and that would appear to be literally true of many lift accidents. For

example, a certain lift had a double gate, locking in the centre. The attendant had not shut this outer gate properly, and actually put his hand through the inner gate to close the outer one, and with the other hand put on the current, with the result that his hand was seriously injured. Lifts should certainly be made quite foolproof, and it is essential that round the lift locks there should be a plate which would render it impossible for anybody under any circumstances to get at the outer lock from the inside. If an attendant has failed to close the well gate, it must be physically impossible for him to get at it until he has opened the car gate. I think also that in every case there should be a gate not only on the well but also on the car, and both of them should be locked. For alternating-current lifts it is very convenient to have a direct-current supply to operate the controls. In very many cases considerations of safety would render it worth while to install a battery of accumulators and a small motor-generator for the purpose. Post Office practice generally aims at a maximum of safety. I am glad that the author draws attention to the precautions necessary when the attendants are dealing with the maintenance of lifts. In some cases serious risks are taken as the result of familiarity.

Mr. H. C. Lamb: Mr. Crews in the course of his remarks criticized the Manchester supply undertaking, but he went on to instance a number of cases in Manchester of large buildings where the power consumption of the lifts was shown to be very small. The explanation of the high price of current in the case mentioned by Mr. Crews is that tariffs have to be arranged with due regard to the relation between the consumption of power and the demand. If the load factor is very low, the price per unit must be high, but with a reasonable load factor the price per unit for lift motors would be only a small fraction of that quoted by Mr. Crews. Mr. Crews's ideal supply for lift work would evidently be a low price per unit and a reversible meter, so that at the end of the quarter the amount of the bill would be negligible. I believe that there are at present over 1 000 lifts on the Manchester mains, and no doubt the effect of the reduction in charges (which comes into operation this month) will be to increase this number.

Mr. H. Marryat (*in reply*): In his opening remarks, Mr. Crews seems to suggest that with electricity at 3¾d. per unit hydraulic power is preferable for lift service. For ordinary passenger lifts I cannot agree, and I think that Mr. Crews answers the point himself when he says, at the end of his remarks, "if power can be obtained . . . even at 3¾d. it does not amount to anything serious and compares very favourably with most hydraulic charges for similar duty." Mr. Lamb deals with this point later in the discussion. I think that Mr. Crews is mistaken in attributing in any way to cheapness the rapidly increasing preference for the sheave drive. A drum-driven lift, as now very often installed, is less expensive because a drum may be employed of smaller diameter than a driving sheave. The worm gear and motor may therefore be of higher speed and less weight. Such a drum drive as I am referring to necessitates the use of leading wheels and is hard upon the ropes. In my opinion the sheave drive has won in the controversy to which Mr. Crews refers, because of its simplicity and safety. I quite agree that where the drum in a drum drive is of sufficient diameter and leading wheels can be avoided, the best rope condition has been attained. I am extremely interested in the figures which Mr. Crews has recorded for the cost of maintenance, but for the class of lift which I have in mind, namely, high-speed and very busy passenger lifts often built to conform with adverse conditions, much higher costs are involved. Some of these lifts make as many as 2 000 trips per day. It will be noted that the figures given date back as far as 1906 and, allowing for post-war increase in prices, he reaches my lower figure, which represents probably a similar class of lift to those he has in mind. The second brake, which should be installed if the self-sustaining feature of the worm gear is abandoned, must certainly act upon the worm-wheel shaft and may be operated electrically in a similar manner to the smaller brake on the motor coupling. The type of brake suggested by Mr. Crews would be in every way suitable and probably less costly than one of the shoe type, for large capacity. I am not in the independent position necessary to give the authoritative figures asked for regarding the prime cost and costs of maintenance and energy consumption of lifts of various types. I suggest that Mr. Crews himself should follow up his excellent contribution to the subject with another, bringing these figures up to date.

In reply to Mr. Raeburn, the further investigation now in hand is not sufficiently advanced to allow of my saying anything further upon the subject of acceleration, but I hope to do so as soon as the experiments are completed. I certainly was not aware that winders were in operation at 4 000 ft. per min., although I have examined and can testify to the excellence of the acceleration attained with machines running up to 2 000 ft. per minute. In view of the probability that 600 ft. per minute will for long remain the maximum economic speed for passenger lifts in this country, it is doubtful if the Ward-Leonard system of control will be adopted to any considerable extent, as the stand-by losses would be likely to outweigh any control economy effected.

Mr. Mallinson fears that acceleration to full speed in a short time and distance will mean an increase in the maximum demand. This need not be so if the acceleration is achieved, as it should be, upon a perfectly smooth curve; indeed, the result would be a distinct improvement upon the usual conditions. In any case, the energy consumption of an electric lift is principally confined to the starting period.

Mr. Sills has called attention to the absurdity of installing lifting machinery of insufficient capacity to raise the car when it is only comfortably full of passengers. This condition is pressed upon lift makers daily by purchasers who insist upon the car being of a size to fill a certain definite space and upon the machine being only large enough to lift a specified load which it is believed will be the maximum and which is less than the capacity of the car. A good allowance for the floor space of the car in a city lift is 2½ sq. ft. per person, and a rather greater allowance, say 3 sq. ft.

per person, for lifts in West End establishments. The machine should always be of sufficient capacity to lift the car so loaded, with a margin to spare.

There is no doubt that Mr. Peck is right in attributing partly to elasticity of the ropes the periodic form of the acceleration curves shown, but I believe that other factors are also involved. I may say that the rope makers are extremely interested and have asked to be kept posted with the results of further experiments, towards which they have made some valuable suggestions.

A number of accidents have occurred in the way described by Mr. Herbert. The true solution of this difficulty is the mid-bar gate, which is so constructed as to make it impossible for the attendant or any other person to put his hand through the bars of the gate for any purpose. On existing gates of ordinary construction a protection may be provided by covering the space around the locking gear, or where one is likely to be tempted to put a hand through, with leather. This will collapse with the gate when it is opened.

SOUTH MIDLAND CENTRE, AT BIRMINGHAM, 20 FEBRUARY, 1924.

Mr. W. F. Higgs: In many instances the author refers to American practice; it is a pity that our engineers are becoming copyists rather than maintaining their tradition of originality. The author refers to escalator and other types of lifts, but he has omitted to comment upon the continuous cage type. Although it travels slowly, it carries a large number of people. I have seen a number of these working satisfactorily on the Continent. The author does not say what was the result of switching the 21-h.p. motor straight on to the line. If this can be done, why not adapt series-parallel control to series motors without starting resistance? I should like to ask the author why preference has so often been given in the past to marine thrust bearings rather than to ball thrust bearings; and what are the possibilities of using magnetic clutches in conjunction with a flywheel on the motor. Complications would no doubt arise, as two clutches and reduction gears would be necessary to obtain the reverse; on the other hand, the consumption of power would be less, the motor smaller, and the control more simple. The author rightly emphasizes the importance of "Safety First," and if there is one class of machinery that requires this consideration, it is lifting and hoisting tackle of all descriptions.

Mr. F. H. Mann: Difficulty has occasionally been experienced in obtaining a suitable friction material for the brakes. The chief troubles in this connection have apparently been due to variations in the coefficient of friction, leading to uncertainty in locating the cage. Chattering has also occurred, with consequent discomfort to the passengers. The former trouble is most pronounced in the case of push-button control, frequent adjustment of brake-spring tension being required to cause the lift to stop at the required point. Chattering is probably due to the same cause that accounts for the violent surges recorded by the author as occurring during acceleration, viz. the elastic nature of the suspensory system. In the case of lifts running on alternating current, single-phase solenoids have sometimes been used, usually with poor results. Three-phase solenoids are satisfactory, but it would be interesting to hear whether any device has been introduced to enable the simplicity of the single-phase solenoid to be retained, without losing reliability of operation.

Mr. F. O. Harber: Referring to the remarks that have been made in regard to copying American practice, it should be borne in mind that engineers must obviously be influenced by general conditions prevailing outside their control. This applies particularly to lift engineers. Whereas American lift engineers have had very great advantages over British engineers owing to the rapid progress that has been made in the design of buildings, this rapid progress has caused the lift industry to assume large proportions and consequently more time is expended on design. It is true that conditions vary in the different countries, but surely if we can learn anything from another country it would be a short-sighted policy not to do so. The lift engineer is, unfortunately, not usually called in for consultation until the last moment, and the architect, more often than not, relegates the lifts to some obscure corner which he cannot otherwise utilize, with the result that the ideal aimed at is often impossible. This is evident from the last lantern slide shown by the author. From the author's statement that the maximum lift speeds in this country are 400 ft. per min., and from the correspondence in the *Electrical Review* on this point, the inference might be drawn that higher lift speeds cannot be attained. This is, of course, erroneous, as any speed within reason can be provided for by British lift engineers, the point being that high-speed lifts are not required in this country, as the average service is for 4 floors, and about 10 floors is exceptional. Even in the latter case, however, it would not be necessary to exceed 400 ft. per min. In regard to acceleration, if the rate of acceleration is constant no discomfort should be felt by the passengers. The number of steps of starting resistance may not be directly responsible for the periodic leaps in the curve, but the time interval between each step will have an effect in this respect. I should be glad if the author would say if he has tried cutting out the series field in steps at starting and, if so, what results were obtained. The author gives a regenerative circuit for accurate floor stopping, but this is only applicable to d.c. supplies. Can this difficulty be overcome in the case of a.c. supplies? In push-button operation, what method is used for eliminating interference from the landings during the period between the closing of the car gate and the time of pressing the car push? If a landing push is being pressed, immediately the car gate is closed the car will obviously go to the floor corresponding to the landing push. I cannot agree that the over-driven gear appears to be the sounder engineering job. In my opinion, if the machine and motor are properly designed the under-driven type

makes an entirely compact and substantial job, although a little efficiency may be sacrified due to the churning of the oil.

Mr. H. Marryat (*in reply*): Mr. Higgs has referred to the continuous running lift which I have dealt with in answering Mr. Rawlings in the London discussion. With regard to the experiment in switching on the 21-h.p. motor without starting resistance, the motor did not suffer in any way and the commutator was not damaged as we rather expected it would be, but the contactor switchgear was put out of action. Of course there was a certain amount of main cabling in circuit, and a 300-ampere fuse was not blown. I think that marine thrust bearings were only preferred to ball bearings at a time when the latter were neither so well designed nor made as at present. The question regarding magnetic clutches seems to suggest a continuously running motor. This would be expensive, as the actual running time of a lift is small compared with the standing time. At one time we developed a system of control in which the field of the motor was kept constantly excited, but it was found that the energy consumption of the field with this system exceeded the total consumption of the motor with the usual form of control, in which there is no current passing when the motor is standing.

The chattering referred to by Mr. Mann is more usually the result of bad guide alignment than of brake trouble, and the necessity for frequent adjustment of brake-spring tension indicates that the brake is of insufficient capacity. I would sooner have a large brake with plain wood blocks than a small brake with any patent lining. Where a lining is employed, "Ferodo" or something of a similar nature is most suitable. With regard to single-phase solenoids, when properly designed these may now be relied upon to give good results.

I am in entire agreement with Mr. Harber in his remarks upon American practice. Certainly we should learn all we can of their greater experience, but, bearing in mind that conditions are in many respects different here, I am anxious that we should not continue to accept American figures without query and that we ourselves should make such investigations as are necessary to the design of lifts specially suited for this country. In an endeavour to obtain a more constant rate of acceleration I have tried cutting out the series field in steps, but without any very definite result, or none that I have recorded scientifically. The number of combinations of starting conditions is almost infinite, commencing with the great number of different windings which may be designed for a motor of definite capacity. The regenerative method of control cannot be applied to alternating-current circuits. For high-speed and varying loads upon an a.c. circuit a two- or three-speed motor must be employed and the mechanical brake relied upon to bring the car to floor-level from the low speed. In reply to the question regarding push-button control, when the passenger places his foot upon the floor of the car the landing pushes are cut out of circuit by means of a contact in the car floor, and the car remains under the control of the passenger until he steps out.

ANNUAL DINNER, 1924.

The Annual Dinner of the Institution was held on Thursday, 21st February, 1924, at the Hotel Cecil, when the President, Dr. Alexander Russell, presided over a gathering numbering about 500 persons. Among those present were: The Rt. Hon. the Viscount Chelmsford, P.C., G.C.M.G., G.M.S.I., G.M.I.E., G.B.E. (*First Lord of the Admiralty*), The Rt. Hon. Lord Southborough, P.C., G.C.B., G.C.M.G., G.C.V.O., K.C.S.I. (*Honorary Member*), The Rt. Rev. Bishop H. E. Ryle, K.C.V.O., D.D. (*Dean of Westminster*), The Rt. Hon. Sir Henry Norman, Bart., P.C., Sir George Sutton, Bart., Sir Archibald Denny, Bart., LL.D. (*Chairman, British Engineering Standards Association*), Sir Charles Sherrington, G.B.E., D.Sc. (*President, Royal Society*), Sir Frank Heath, K.C.B. (*Secretary, Department of Scientific and Industrial Research*), Sir Evelyn Murray, K.C.B. (*Secretary, General Post Office*), The Hon. Sir Charles Parsons, K.C.B., F.R.S. (*Hon. Member I.E.E.*, and *President, Institute of Physics*), Sir William Clark, K.C.S.I., C.M.G. (*Comptroller, Overseas Trade Department*), Sir Thomas Holland, K.C.S.I., K.C.I.E., F.R.S. (*Rector, Imperial College of Science and Technology*), Sir John Cadman, K.C.M.G., D.Sc. (*President, Institution of Mining Engineers*), Sir Westcott Abell, K.B.E. (*Chief Ship Surveyor, Lloyd's Register of Shipping*), Sir Arthur Colefax, K.B.E., K.C., Sir James Devonshire, K.B.E. (*Vice-President*), Sir John Dewrance, K.B.E. (*President, Institution of Mechanical Engineers*), Sir Arnold Gridley, K.B.E., Sir William Hale-White, K.B.E., M.D. (*President, Royal Society of Medicine*), Sir Joseph Petavel, K.B.E., D.Sc., F.R.S. (*Director, National Physical Laboratory*), Sir Robert Robertson, K.B.E., F.R.S. (*President, Faraday Society*), Sir Arthur Durrant, C.B.E., M.V.O., (*H.M. Office of Works*), Sir Hugh Thomas, C.B.E., Sir Joseph Broodbank (*President, Institute of Transport*), Sir Harry Haward (*Vice-Chairman, Electricity Commission*), Sir James Kemnal, Sir William Noble, Sir Ernest Rutherford, F.R.S. (*President, British Association*), C. T. Allan (*Chairman, Western Centre*), R. L. Barclay, C.B.E. (*Chairman of Council, London Chamber of Commerce*), J. W. Beauchamp (*Member of Council*), H. Booth, O.B.E. (*Electricity Commissioner*), A. C. Chapman, F.R.S. (*President, Institute of Chemistry*), Commander F. J. Cleary, U.S.N. (*Assistant Naval Attaché, American Embassy*), F. W. Crawter (*Member of Council*), Colonel R. E. B. Crompton, C.B. (*Past President* and *Honorary Member*), R. A. Dalzell, C.B.E. (*Director of Telegraphs and Telephones, G.P.O.*), W. R. Davies, C.B. (*Principal Assistant Secretary, Technical Branch, Board of Education*), Robert W. Dibdin (*President, Incorporated Law Society*), Captain J. M. Donaldson, M.C. (*Member of Council*), D. N. Dunlop (*Member of Council*), Lieut.-Col. K. Edgcumbe (*Member of Council*), Dr. S. Z. de Ferranti (*Past President* and *Faraday Medallist*), Rear-Admiral C. T. M. Fuller, C.B., C.M.G., D.S.O. (*Controller of the Admiralty*), F. Gill (*Past President*), J. A. Gotch (*President, Royal Institute of British Architects*), J. Grosselin (*Past President, Société Française des Electriciens*, and *I.E.E. Local Hon. Secretary for France*), A. F. Harmer (*Member of Council*), A. F. Harrison (*President, Chartered Institute of Secretaries*), J. S. Highfield (*Past President*), H. Hooper (*Hon. Secretary, South Midland Centre*), J. H. Jeans, D.Sc., F.R.S. (*Secretary, Royal Society*), H. H. Jeffcott, Sc.D. (*Secretary, Institution of Civil Engineers*), J. E. Kingsbury, Lieut.-Col. F. A. Cortez Leigh, T.D., R.E. (*Member of Council*), C. D. le Maistre, C.B.E. (*Local Hon. Secretary, American I.E.E.*), B. Longbottom (*Chairman, British Electrical and Allied Manufacturers' Association*), A. B. Mallinson (*Hon. Secretary, North-Western Centre*), C. W. Matthews (*Chairman of Highways Committee, L.C.C.*), S. W. Melsom (*Member of Council*), Lieut.-Col. J. Mitchell Moncrieff, C.B.E. (*Chairman, Association of Consulting Engineers*), W. M. Mordey (*Past President*), J. D. Morgan (*Chairman, South Midland Centre*), A. Page (*Member of Council, I.E.E.*, and *Electricity Commissioner*), G. W. Partridge (*Member of Council*), C. C. Paterson, O.B.E. (*Vice-President*), Colonel T. F. Purves, O.B.E. (*Member of Council, I.E.E.*, and *Engineer-in-Chief, G.P.O.*), W. R. Rawlings (*Member of Councils, I.E.E.* and *Illuminating Engineering Society*), P. Rosling (*Member of Council*), P. F. Rowell (*Secretary*), E. H. Shaughnessy, O.B.E. (*Chairman, Wireless Section*), F. E. Smith, C.B.E., F.R.S. (*President, Physical Society of London*), Roger T. Smith (*Past President*), C. P. Sparks, C.B.E. (*Past President*), A. A. Campbell Swinton, F.R.S. (*Vice-President*), W. J. Turrell, M.D. (*President, Electro-therapeutic Section, Royal Society of Medicine*), O. C. Waygood [*Hon. Secretary, Mersey and North Wales (Liverpool) Centre*], and W. B. Woodhouse (*President, British Electrical Development Association*).

After the usual loyal toasts, the President read the following messages from other societies:

From the French Society of Electricians.

"The French Society of Electricians send most hearty greetings to President Russell, to the Members of Council and to the members of the Institution of Electrical Engineers on the occasion of their Annual Dinner. They are most gratified at the ever-increasing cordial relations between the two Institutions.—ESCHWÈGE, *President.*"

From the American Institute of Electrical Engineers.

"Kindly convey to President and members Institution of Electrical Engineers on occasion their Annual Dinner hearty greetings and best wishes from officers and members.—HARRIS J. RYAN, *President.*"

From the Italian Electrotechnical Association.

"Prof. Ing. G. Sartori, President of the Italian Electrotechnical Association, regrets that, owing to a prior engagement, he is unable to accept Dr. Alexander Russell's kind invitation to the Annual Dinner of the Institution of Electrical Engineers, to be held on the 21st February. He is, however, glad to express his cordial feelings towards the Institution which, in unison with the Italian sister Society, is making noble efforts to achieve scientific results which will do honour to both countries. We send our best wishes to the eminent Institution of Electrical Engineers."

The Rt. Hon. Viscount Chelmsford, P.C., G.C.M.G., G.M.S.I., G.M.I.E., G.B.E. (First Lord of the Admiralty), in proposing the toast of "The Institution of Electrical Engineers," said: "The toast which I have to propose is coupled with the name of the President, a short biographical sketch of whom was sent to me about a week ago, containing the following passage: 'He was born at Ayr in the year 1861, but without this fact being stated anyone who has met him would realize he is of Scotch extraction.' I have been wondering why one would realize that he is of Scotch extraction, and the only thing which has convinced me is that he is sitting in the President's chair. It will be found that Scotsmen generally manage to get into the big offices and the big positions. During my conversation with the President during dinner I have realized how small matters sometimes influence large events. The President tells me that 40 years ago he was competing for a scholarship at Oxford with the present Archbishop of York. While they were at the examination a telegram reached him to the effect that he had been elected to a scholarship at Cambridge. The consequence was that he went to Cambridge instead of to Oxford. One would like to speculate whether, if he had got the scholarship at Oxford, he would have been Archbishop of York? I can say quite confidently that he would not have been President of this Institution. Before I leave the subject of the President, may I add that he has been nominated to-day for a Fellowship of the Royal Society, which is, I suppose, one of the greatest distinctions to which any Englishman can aspire. Now let me turn for a few moments to the toast which I have to propose. I have been long enough at the Admiralty to realize that a modern ship, especially a modern warship, without electricity is almost inconceivable. In every sphere of activity in that ship electricity almost invariably comes in. We must have light; it is electric light. We must have ventilation; it is through electric fans that we get it. We must have communication; again it must be electrical. The control of gunnery, and the firing of modern guns, we can only get by using electricity. There is one other matter to which I should like to allude, because it happens to have been my lot during the short time I have been at the Admiralty to have been engaged in what seems to be that perennial controversy between the Air Ministry and the Admiralty. There is a point in that controversy which is not generally known, I think, but which is very interesting from the point of view of electricity. It is sometimes forgotten that when the Admiralty say that they would like wireless apparatus of their own on the aircraft which are going to play a part in the Fleet air arm, such wireless apparatus in connection with naval operations is of primary importance—of far greater importance than the aeroplane itself—because upon the wireless apparatus depends whether the Fleet Commander is going to get the information that he is expecting from his aircraft. It stands in absolute contradistinction to what happens on land, because the pilot who is working with land forces is always able to land behind his lines and take his messages. No such thing is possible to the naval wireless operator. He has to send his message by wireless or it is not delivered at all. Then, again, take submarines. Unless a submarine had large secondary batteries it would be useless. During the last month I have discovered that there is a development of the potentialities of submarines; there is an anti-submarine department; and as the submarines get ahead in one direction the anti-submarine department gets to know of that direction and immediately proceeds to devise something by which the submarine can be countered. In both departments electricity plays an important part. I could go on, but I think that I have said sufficient to show that the Navy is deeply indebted to electrical engineers for much of its efficiency. At the same time, however, I think that electrical engineers have some cause for indebtedness to the Navy. It is through the increasing requirements and demands of the Navy that electrical engineers are provided, as a profession, with a stimulus to fresh invention and to fresh developments. I ask you to rise and drink with me the toast of 'The Institution of Electrical Engineers,' coupled with the name of your President."

The President, in responding, said: "I am grateful to Lord Chelmsford for having spoken so kindly of our Institution and of our industry, and for having referred so kindly to myself. In Lord Chelmsford we have a Minister who has filled the highest offices of State with distinction and universal acceptance. The activities of the Research Department of the Admiralty are reflected in the equipment of their latest vessels. They have proved that science is a weapon of greater potential value than weight of broadsides. Some of the activities of that Department will prove of value to the mercantile marine; for example, the radio-acoustic method of locating the position of a ship at sea and communicating the result to the ship in a few minutes. This can be done in rough and foggy weather and in all seasons of the year. The method can doubtless be improved. I hope that some of our younger radio engineers will turn their attention from devising new methods of receiving broadcasting to navigation problems which are in urgent need of solution. I feel that it is within our power to devise means whereby a seaman in a cargo boat, or even in a fishing smack, would be enabled to determine his position at sea quickly and easily. Radio first proved its value in navigation. Let us develop it further to lessen the risks of those that go down to the sea in ships, that do business in great waters. The work of our Institution overlaps that of many other Institutions. We cherish feelings of lively gratitude to the Institution of Civil Engineers for their help when we were a young

and struggling society. Now when we are prosperous we are always willing to help and co-operate with other societies. To me it is an especial pleasure that on the 21st March next the Physical Society of London will celebrate its Jubilee in our building. We congratulate it on the excellent work that it is doing for science and, incidentally, for industry. We hope that it will prosper in the future even more than it has done in the past. As electricians we remember that the first polyphase motor was shown in action at a meeting of this Society in June 1879. The crude toy then shown was the forerunner of those large and economic machines which are toiling endlessly for our benefit in coal-pits and factories. We gladly welcome the valuable help which both the Physical Society of London and the American Physical Society are giving us in the production of the Physics Section of *Science Abstracts*, and we are looking forward to greatly extending the usefulness of this well-known publication. We are at the beginning of an almost miraculous linking up of the whole world by the electrical reproduction of sound. The simplicity of this new scientific development is the aspect of it which seems most astounding to the older electricians. The United States of America are brought very close to us when we can listen to speeches being broadcast from New York. Several English amateurs have already succeeded in establishing occasional two-way communication with several American and Canadian amateurs. We are on the eve of many practical applications of radio broadcasting in our schools. The time is rapidly approaching when our railways will be electrified. Amongst our members are many traction engineers and inventors. The transverter of Mr. W. E. Highfield should prove of great value in long-distance electric traction. At the present moment our railways are consuming unnecessarily some 6 million tons of coal per annum. The past year can be looked at with complacency by the supply industry. We have made steady progress. The price of electricity has been reduced. There has been an increase in the demand and a consequent increase in the work of the associated industries. I was pleased to learn last week that the National Association of Supervising Electricians has the names of only three unemployed members in its books. Luckily for manufacturers, existing plant is always depreciating. They recognize, too, that new inventions are continually being made, and they are always on the look-out for improvements. Assuming that this country is to maintain its place in the front rank of civilized nations, new inventions must always be forthcoming. It is of vital importance to the nation that every schoolboy who shows an inventive turn of mind should be encouraged to follow his bent, even if this involve very early specialization. William Thomson (Lord Kelvin) when he was 15 gained a university medal for an essay on the figure of the earth. Dr. Ferranti invented the Ferranti alternator when he was 18. Many have been prevented from specializing at an early age by the necessity of passing many examinations. In my opinion the training requisite for passing examinations does not encourage the inventive faculty. The loss to the nation when an inventive genius is prevented from developing is a grievous one. We are looking forward with lively interest to the World Power Conference at the British Empire Exhibition this year. It will bring together engineers from every civilized country in the world. We are certain that it will work for a better understanding between the nations. Engineering is truly international. The invention of the telephone by Alexander Graham Bell, for instance, was a boon to the whole world. On the 10th and 11th July next we are uniting with the Royal Society and with practically every other scientific and engineering Society in the kingdom in celebrating the centenary of the birth of Lord Kelvin, who was three times our President. To many of the coming generation of engineers he is merely a name. It is right, therefore, that they should be reminded of the great work which he did in advancing science and industry—pioneering work that has proved of such great value in so many different fields. The advance of engineering is never finished; it can never rest; it can never be perfect. This Institution gives us opportunities of service. We strive to carry out the injunction of our Founders to do our utmost to advance electrical science. We are proud of our Institution. We are glad that our work tends to ameliorate the lot of labour in every country. We are ever looking out for ways of making Nature more and more a servant of humanity."

Mr. F. Gill (Past President) then proposed the toast of "Our Guests," to which **Sir William Clark, K.C.S.I., C.M.G.** (Comptroller, Overseas Trade Department), and **Sir Ernest Rutherford, F.R.S.** (President, British Association), responded.

At the invitation of the President, **Colonel R. E. B. Crompton, C.B.** (Past President and Honorary Member), and **Dr. S. Z. de Ferranti** (Past President and Faraday Medallist) also spoke.

A reunion was then held in the Victoria Hall of the hotel.

ATMOSPHERICS AND THEIR EFFECT ON WIRELESS RECEIVERS.

By E. B. Moullin, M.A., Associate Member.

(*Paper first received* 2nd *July, and in final form* 18th *December*, 1923; *read before the* Wireless Section 6th *February*, 1924.

Summary.

The paper contains a mathematical analysis of the effect of an atmospheric upon a wireless receiver. The choice of functions representing the atmospheric has been governed by information contained in *Proceedings of the Royal Society*, A, vol. 103. The effect of each of several wave-forms is calculated and the results are compared. The effect is calculated of an atmospheric acting respectively on a tuned antenna, on an aperiodic antenna, on a tuned loop aerial, and also the combination of each of these with a selective amplifier. In each case a formula is derived which gives the ratio of signal to atmospheric, and it is shown that for a given wave-length these formulæ are identical. The possible advantage to be got from the use of an aperiodic antenna or of a slightly distuned periodic circuit is considered in detail. Finally, the rectified current produced by the atmospheric is compared with that produced by the signal, and it is shown that the decrement of the aerial should always be reduced to the point where ringing or bad shaping of signals commences.

Table of Contents.

Index to the Formulæ Derived in the Paper.

1. Introduction.

The paper on the "Nature of Atmospherics" which has been published recently by the Royal Society* contains information which makes it possible to analyse mathematically the effect of an atmospheric on a wireless receiver.† The authors of that paper used a cathode-ray oscillograph of the pattern made by the Western Electric Company; they have recorded many oscillograms of atmospherics and have measured both their amplitude and duration. The oscillograms show that the average duration of an atmospheric is about 1/500th second and that the period of growth usually equals, and is seldom less than half, the time of decay. The average value of the maximum field strength of the atmospherics observed was about 0·1 V per metre, which is about 5 000 times the field strength of average wireless signals.

In the past it has been assumed that an atmospheric rises to its maximum in an indefinitely short period of time and decays at a rate such that it has sensibly died out in a time which is short compared with the duration of a Morse dot (at 25 words per minute a Morse dot lasts about 1/20th second).

* See R. A. Watson Watt and E. V. Appleton: *Proceedings of the Royal Society*, A, 1923, vol. 103.

† So far as the author is aware, no analysis has been made of the effect of an atmospheric, except an incorrect one by M. Abraham. (See *Jahrbuch der Drahtlose Telegraphie*, 1919, vol. 14, p. 259, and a correction by Friis and Sivian, *Wireless World and Radio Review*, 1921, vol. 2, p. 526.)

The mathematical analysis to be described in this paper has been made in order to discover if disturbance by atmospherics can be reduced appreciably by suitable design of ordinary receiving circuits. The analysis shows where and when it is advisable to reduce the decrement of a circuit by the use of retroaction; it also shows that an atmospheric is relatively ineffectual in setting up oscillations in the receiver, and so helps to explain why signals have been able to hold their own against atmospherics that are several thousand times as strong. The use of special devices such as balanced aerials or current limiters is not considered.

2. Wave-form of the Atmospheric.

Watt and Appleton found that the commonest wave-forms were approximately those shown in Fig. 1 (*a*),

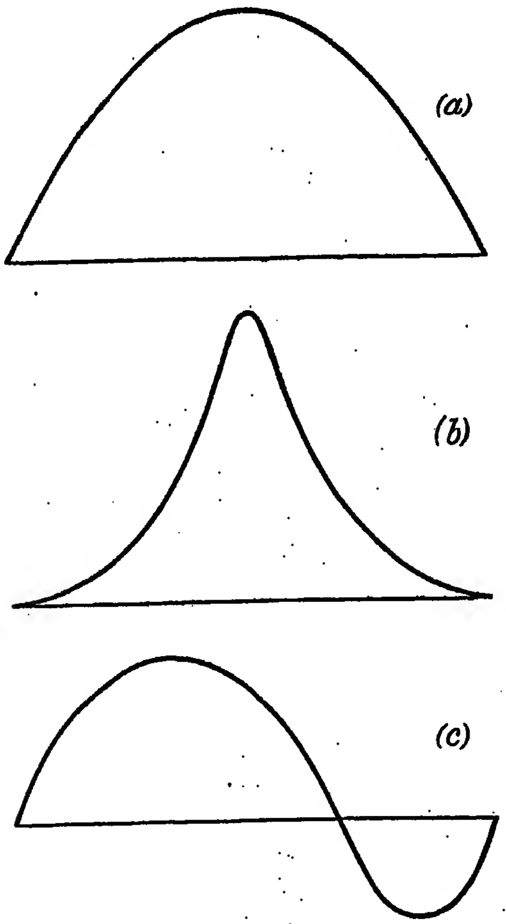

Fig. 1.

(*b*) and (*c*). About one-third of the observed wave-forms closely resembled type (*a*), and about one-third type (*c*). The remaining third resembled type (*b*) or a modification of type (*c*) in which one half-wave was peaked and the second half-wave rounded. Two-thirds of those resembling (*a*) were accurately symmetrical, and 90 per cent had a time of growth which was not less than half the time of decay. Type (*b*) were less markedly symmetrical than type (*a*). The atmospherics of type (*c*), which roughly resemble a heavily damped sine wave, are normally characterized by the half-wave of greater amplitude lasting about $1\frac{3}{4}$ times as long as the smaller half-wave. The majority of type (*c*) showed two half-waves only, but about 8 per cent showed three, and 2 per cent showed eight, half-waves. The authors point out that since successive half-waves seldom occupy the same time, and since succeeding half-waves may differ appreciably in form, it is a very poor approximation to represent an atmospheric by any simple function such as $A\epsilon^{-bt}\sin pt$.

If we were investigating the rate of change of the electric moment of the thundercloud from which the disturbance originates, no doubt that would be so, but for investigating the effect that the discharge has on a wireless receiver we shall show that the simple approximation represents the problem very closely. The mathematical analysis shows that the harmful effect depends mainly on the time of duration of the first half-wave and its initial rate of increase. Various functions are taken to represent the atmospheric, and it is shown that in each case the effect produced is approximately the same as would have been produced by a simple heavily-damped sine wave of the same initial maximum value.

Having established the fact that the simple expression $A\epsilon^{-bt}\sin pt$ represents the actual conditions with considerable accuracy, the function $e = A\epsilon^{-\frac{1}{2}pt}\sin pt$ has been chosen to represent the standard atmospheric. This function is delineated in Fig. 2, and it is seen that the maximum of the third half-wave is only about 4 per cent of the first wave. The damped sine curve has been adopted because it is the function which leads to the simplest mathematical treatment; also, if an atmospheric was of that form it would produce rather greater disturbance than any of the actual forms observed by Watt and Appleton.

By measurement of the period of duration of the

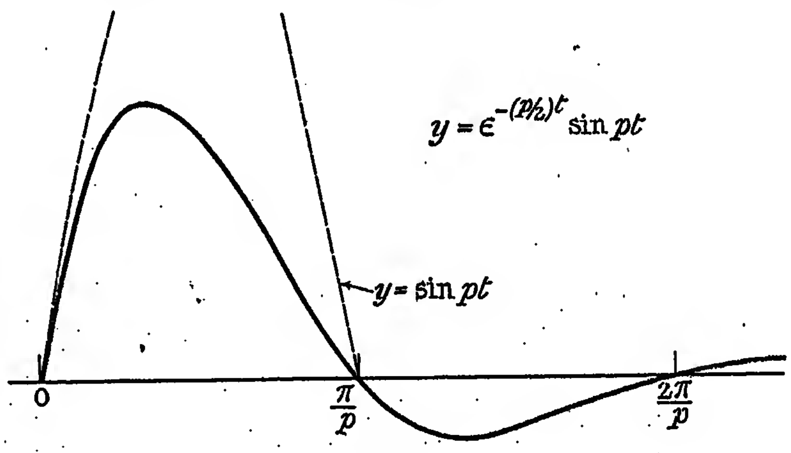

Fig. 2.

longer half-wave Watt and Appleton state (*ibid.*) that the mean value of p is about $3 \cdot 6 \times 10^3$. Representing a steady continuous-wave signal by the function $e = E\sin\omega t$, the appropriate value of ω corresponding to a wave-length of 6 000 m is $3 \cdot 1 \times 10^5$ and corresponding to 600 m is $3 \cdot 1 \times 10^6$. For the band of wave-lengths included between 600 m and 6 000 m we have a value for ω/p which lies between, say, 100 and 1 000.

3. Functions used to Approximate to the Form of Atmospherics.

As stated previously, the most frequent form of aperiodic atmospheric is the symmetrical rounded hump. To represent this it has been assumed that the form of the atmospheric was $e = A\sin pt$, starting at time $t = 0$ and ending abruptly at time $t = \pi/p$. To represent the type shown in Fig. 1 (*b*) it has been assumed that

the atmospheric was of the form $e = A \sin pt - B \sin 3pt$, starting at time $t = 0$ and ending abruptly at time $t = \pi/p$. It may be noted that if this function is used to represent type (b), then the greatest value that the coefficient B can have is $A/3$. If B exceeds $A/3$ then a negative loop is formed within the span of a half-wave of the fundamental, as shown in Fig. 3, which depicts the function $e = A (\sin pt - \sin 3pt)$.

If we imagine that an atmospheric having the form of this function does not affect the receiver until after time $t = \pi/4p$, and ends abruptly at time $t = \pi/p$, we have a close approximation to type (c), for the larger half-wave lasts twice as long as the second half-wave.

The concept of a single half sine wave of E.M.F.

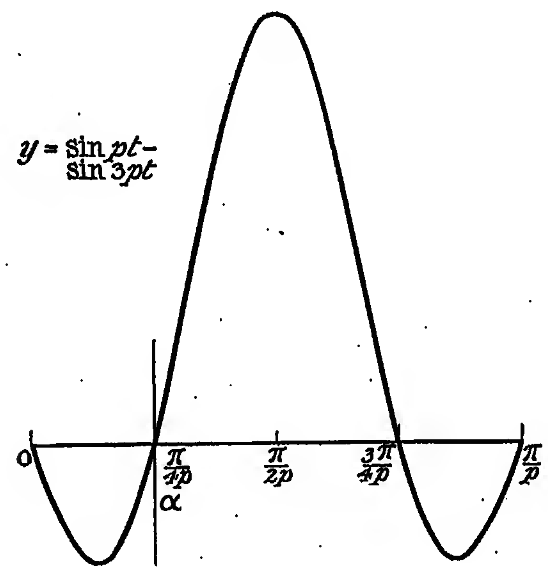

FIG. 3.

acting on a receiver could be realized, for we can imagine that it emanates from a spark transmitter in which the spark gap, placed direct in the antenna circuit, is arranged to quench the oscillation at the instant when the current falls to zero for the first time.

4. Current produced by an Atmospheric Acting on an Open Antenna.

If a receiver is actuated by an open antenna the E.M.F. induced in it will have the same wave-form as the atmospheric. If reception is by means of a coil aerial then the E.M.F. induced in it will not have the same wave-form as the atmospheric, for the E.M.F. depends on the rate of change of flux through the coil. At present, consideration is limited to the open antenna, and the coil is considered in Section 7 below.

Let the antenna of capacity C have an inductance L placed in series with it, the value of L being such as to tune the antenna to a frequency which is considerably less than its natural frequency when unloaded. Let the total effective resistance of the circuit be R, and let the logarithmic decrement of the circuit at that frequency be δ.

It is convenient to resolve the current produced by the atmospheric into two components, one having the same frequency and wave-form as the atmospheric and corresponding to the particular integral of the differential equation, and the other corresponding to the complementary function of the differential equation. The latter component is a simple damped sine wave having the same frequency as that to which the antenna is tuned. Since the particular integral has the same form as the atmospheric it has a period which is much greater than the complementary function, for (see Section 2) ω/p has some value which lies between, say, 100 and 1 000. For convenience we shall call the particular integral the low-frequency portion of the current, and the complementary function the high-frequency portion of the current. In Section 5 we shall see that the low-frequency portion is important only because it fixes the size of the high-frequency portion.

The P.D. (applied to the amplifier or rectifier) produced by the low-frequency portion is always negligible in comparison with that produced by the high-frequency portion.

It will be assumed that the appropriate circuit representing the loaded antenna is as shown in Fig. 4. Consequently, the differential equations representing the flow of current are :—

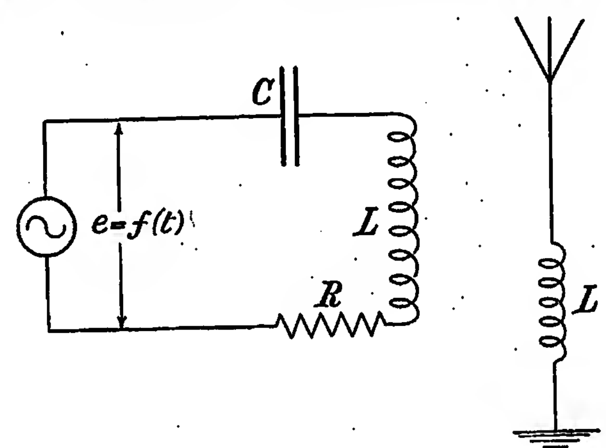

FIG. 4.

$[D^2 + (R/L)D + \omega^2]i = 0$ for times less than zero.
$[D^2 + (R/L)D + \omega^2]i = 1/L\, f'(t)$ for times between 0 and t'.
$[D^2 + (R/L)D + \omega^2]i = 0$ for all times greater than t'.

The third equation is required only when we are considering an atmospheric which ends abruptly at time t', as, for instance, a single half sine curve. If the atmospheric is represented by a simple heavily-damped sine curve then t' is infinite, and the third equation is not required. For an open antenna, $f(t)$ is of the same form as the atmospheric. If the atmospheric is represented by a function such as $e = E\epsilon^{-bt} \sin pt$, where E is expressed in terms of the potential gradient of the electric field, then $f(t)$ is given by $e = hE\epsilon^{-bt} \sin pt$, where h is the effective height of the receiving antenna. It is inconvenient to separate h and E, and this product will be written A, so that the E.M.F. set up in the antenna is given by $e = A\epsilon^{-bt} \sin pt$ or $e = A \sin pt$ or $e = A \sin pt - B \sin 3pt$, according to circumstances.

First we will determine the low-frequency current produced by the atmospheric of the form $e = A\epsilon^{-bt} \sin pt$, where $b \doteq p/2$. We have

$$\left(D^2 + \frac{R}{L}D + \omega^2\right)i = \frac{A}{L}\epsilon^{-bt}(-b \sin pt + p \cos pt)$$

whence

$$i = \frac{A\epsilon^{-bt}}{L} \times \frac{(-b\sin pt + p\cos pt)}{D(R/L - 2b) + (b^2 - p^2 - bR/L + \omega^2)}$$
(with $D^2 = -p^2$)

$$\doteqdot \frac{A\epsilon^{-bt}}{L} \times \frac{(-b\sin pt + p\cos pt)}{D(R/L - 2b) + \omega^2} \quad \text{because } \omega >>> p$$

$$\doteqdot -\frac{AC\epsilon^{-bt}}{\omega^2}\left\{\left(\omega^2 b - p^2\frac{R}{L} - 2b\right)\sin pt - \left(\omega^2 p + bp\frac{R}{L} - 2b\right)\cos pt\right\}$$

$$\doteqdot ACp\epsilon^{-bt}[\cos pt - (b/p)\sin pt]$$

Hence, as might be expected, to the low frequency of the atmospheric the circuit behaves as if it were simply a capacity C.

Similarly, if the atmospheric is $e = A\sin pt - B\sin 3pt$, the low-frequency current is given by

$$i \doteqdot pC(A\cos pt - 3B\cos 3pt)$$

To approximate to the type of atmospheric shown in Fig. 1 (c), the value of B lies between zero and $\frac{1}{3}A$, and to represent the type shown in Fig. 1(b) the appropriate value of B lies between $\frac{1}{3}A$ and A. For values of B between these limits we shall imagine that the atmospheric begins to act on the antenna at the instant when it passes through the value zero after having passed its first maximum (see point a in Fig. 3).

In every case the high-frequency portion of the current produced by the atmospheric will be of the form

$$i = K\epsilon^{-mt}\sin\omega t + M\epsilon^{-mt}\cos\omega t$$

where m is the damping factor proper to the circuit LRC; K and M are arbitrary constants.

The complete solution of the differential equation is obtained by adding together the high-frequency and low-frequency terms. The appropriate values of K and M are determined from the condition that in the complete solution both i and di/dt are zero when t is zero.

Thus in the case of an atmospheric of the form $e = A\epsilon^{-bt}\sin pt$ we have

$$i = K\epsilon^{-mt}\sin\omega t + M\epsilon^{-mt}\cos\omega t + ApC\epsilon^{-bt}[\cos pt - (b/p)\sin pt] \quad (1)$$

$$\text{and } \frac{di}{dt} = K\epsilon^{-mt}(-m\sin\omega t + \omega\cos\omega t) + M\epsilon^{-mt}(-m\cos\omega t - \omega\sin\omega t) + ApC\epsilon^{-bt}[-b\cos pt - p\sin pt + (b^2/p)\sin pt - b\cos pt]$$

Now, when $t = 0$, both i and $\frac{di}{dt}$ are zero.

Therefore $M = -ApC$ and $\omega K - mM - 2ApCb = 0$
Therefore $K = M/\omega(m - 2b)$

$$\doteqdot (p/\omega)M\left(-1 + \frac{\omega}{p} \times \frac{\delta}{2\pi}\right) \text{ since } b \doteqdot p/2$$

where δ is the decrement of the LRC circuit.

It will be seen later that it is important to reduce δ to the lowest possible value consistent with stability or signalling speed. Suppose, for example, that $\delta = 0\cdot01$ and that $\omega/p = 100$. Then

$$K \doteqdot (p/\omega)M \doteqdot 0\cdot01M, \text{ and hence } M >>> K$$

Thus to a very close approximation the high-frequency current may be represented by the expression:

$$i = -ApC\epsilon^{-mt}\cos\omega t$$

With atmospherics taking the form of undamped sinusoids, ending abruptly, we must consider two high-frequency terms, commencing at the start and at the abrupt end respectively of the atmospheric. For the initial high-frequency term we have

$$i = K\epsilon^{-mt}\sin\omega t + M\epsilon^{-mt}\cos\omega t + ApC\cos pt - 3BpC\cos 3pt$$

If B is less than $\frac{1}{3}A$ we consider that $i = 0$ when $t = 0$, and if B is equal to A we shall consider that the atmospheric begins to act when $t = \pi/(4p)$.

Hence $M = -pC(A - 3B)$ (if $i = 0$ when $t = 0$)
or $M = -pCA \times 2\sqrt{2}$ [if $i = 0$ when $t = \pi/(4p)$]

It can be shown that in either case $M >>> K$.

The high-frequency currents set up by the various forms of atmospheric are readily compared by means of Table 1.

TABLE 1.

Form of atmospheric	High-frequency current set up
$e = A\epsilon^{-bt}\sin pt$	$i = -ApC\epsilon^{-mt}\cos\omega t$
$e = A\sin pt$	$i = -ApC\epsilon^{-mt}\cos\omega t$
$e = A\sin pt - (A/3)\sin 3pt$	$i = 0$
$e = A\sin pt - A\sin 3pt$	$i = -2\sqrt{2}ApC\epsilon^{-mt}\cos\omega t$

It is interesting to note that should the atmospheric be of the form $A\sin pt - \frac{A}{3}\sin 3pt$, no high-frequency current is set up, and consequently such an atmospheric would be sensibly innocuous.

Now on reference to the above table it will be seen that in each case the high-frequency current is proportional to the initial rate of increase of the atmospheric E.M.F. An atmospheric having initial and final slopes equal to zero will not create any sensible disturbance in a lightly damped LRC circuit.

Table 1 must not be used to estimate which form of atmospheric will create the greatest disturbance; such a comparison must be made between atmospherics which actually attain the same maximum value.

Table 2 has been arranged to facilitate this comparison.

Hence, so far as the initial high-frequency current is concerned, that produced by the damped sinusoid has the greatest value, because such an atmospheric has the same initial slope as an undamped sine curve of about twice the amplitude.

If the atmospheric is represented by an undamped sinusoidal function ending abruptly at time $t = \pi/p$, we have another current set up at the abrupt ending.

Hence, if $t > 0 < \pi/p$

$$i_1 = ApC[-\epsilon^{-mt}\cos\omega t + \cos pt - (3B/A)\cos 3pt]$$

and for values of t greater than π/p

$$i_2 = \alpha\epsilon^{-mt}\cos\omega t + \beta\epsilon^{-mt}\sin\omega t$$

α and β are determined by making the values of i_1 and di_1/dt obtaining at time $t = \pi/p$ agree with the values of i_2 and di_2/dt when $t = 0$.

If we assume that the value of δ is such that $\omega\delta/p \doteqdot 1$, and if $\cos(\omega\pi/p) = -1$, then it is easy to show that

$$i_2 = -1\cdot 6ApC\epsilon^{-mt}\cos(\omega t + \lambda)$$

If $\cos(\omega\pi/p)$ has any value other than 1 the resulting current will be smaller than the value given above.

Hence, in comparison with a damped sinusoid which gives a current $-\frac{1}{2}DpC\epsilon^{-mt}\cos\omega t$, a single half sine curve gives a current $-\frac{1}{2}DpC\epsilon^{-mt}\cos\omega t$, which, if $\delta = 0\cdot 01$, will persist until its amplitude has fallen by about 40 per cent, and is then followed by another current which may have a value equal to $i_2 = 0\cdot 4DpC\epsilon^{-mt}\cos\omega t$ in the worst possible case. Hence it appears that for a given maximum value either form of atmospheric just considered will have approximately the same effect, and it seems possible that the simple heavily-damped sine curve may represent the worst case.

Hence it seems reasonable to adopt the form $e = A\epsilon^{-bt}\sin pt$ (where $b \doteqdot \frac{1}{2}p$) as the standard atmospheric for purposes of investigation. This function leads to the simplest analysis, since only one train of oscillations has to be considered.

5. The Effect of the Atmospheric on Apparatus or Circuits Coupled to the Antenna.

In the following section it is presumed that a triode valve is coupled directly across the aerial tuning inductance; and this valve is presumed to be either a rectifier, or the first valve of a chain of selective amplifiers actuating a rectifier. It is supposed that it is possible, by means of retroaction, to reduce the decrement of the antenna to any required degree, and if necessary that of all of the selective amplifiers also.

The P.D. impressed upon the first valve is the P.D. developed across the ends of the aerial tuning inductance by the passage through it of the current set up by the atmospheric. Thus if the current in the aerial be i at any instant, then at any instant the P.D. applied to the first valve is $L\frac{di}{dt}$.

It follows from formula (1) that

$$L\frac{di}{dt} = LApC\Big\{\epsilon^{-\frac{1}{2}pt}\Big(-\frac{p}{2}\cos pt - p\sin pt + \tfrac{1}{4}p\sin pt - \tfrac{1}{2}p\cos pt\Big) - \epsilon^{-mt}(-\omega\sin\omega t - m\cos\omega t)\Big\}$$

$$\doteqdot -1\cdot 12A\frac{p^2}{\omega^2}\epsilon^{-\frac{1}{2}pt}\sin(pt+\lambda) + A\frac{p}{\omega}\epsilon^{-mt}\sin\omega t \quad (2)$$

when $b \doteqdot \frac{p}{2}$ and $\omega >> p$.

It is interesting to notice that neither L nor C appears explicitly in either the low-frequency or the high-frequency component of this expression. Hence for antennæ of the same effective height and decrement and tuned to the same wave-length the P.D. produced by the atmospheric is independent of the capacity of the antenna and depends only on the ratio of the signal frequency to the atmospheric frequency.

The ratio of the high-frequency component to the low-frequency component is given by

$$\frac{\text{High-frequency P.D.}}{\text{Low-frequency P.D.}} = \frac{(\omega/p)\epsilon^{-mt}\sin\omega t}{1\cdot 2\,\epsilon^{-\frac{1}{2}pt}\sin(pt+\lambda)}$$

The minimum value of this ratio is approximately equal to $(\omega/p)\sin\omega t$; when $\frac{\omega}{p} >> 1$ and $\delta << 1$.

Hence the low-frequency P.D. is vastly smaller than the high-frequency P.D. and is negligible in comparison. If the combined P.D. is applied to a selective amplifier the high-frequency component will be amplified and the low-frequency component will be diminished, so that each successive stage of high-frequency amplification makes the low-frequency component of less and less importance.

At this stage it may be of interest to consider probable numerical values for these two components. We shall suppose that an antenna, which is tuned to a wave-length of 6 000 m, has an effective height of 30 m. The field strength of the atmospheric is 0·1 volt per metre at its maximum, so that the maximum E.M.F. in the antenna is 3 V, and the appropriate value of A in formula (2) will be about 6 V. Since p/ω is about 1/100, the initial amplitude of the high-frequency component will be about 60 mV and the maximum of the low-frequency component will be about 0·8 mV.

Table 2.

Form of atmospheric	Maximum amplitude attained	High-frequency current set up by atmospherics each of which rises to the same maximum, D
$e = A\epsilon^{-\frac{1}{2}pt}\sin pt$	$\frac{1}{2}A$	$i = -\frac{1}{2}DpC\epsilon^{-mt}\cos\omega t$
$e = A\sin pt$	A	$i = -\frac{1}{2}DpC\epsilon^{-mt}\cos\omega t$
$e = A\sin pt - (A/3)\sin 3pt$	$\frac{4}{3}A$	$i = 0$
$e = A\sin pt - A\sin 3pt$	$2A$	$i = -\frac{1}{2\sqrt{2}}DpC\epsilon^{-mt}\cos\omega t$

The important point to consider, however, is not the absolute value of the P.D. set up by the atmospheric, but the ratio between the atmospheric and the signal. The P.D. produced by a sustained continuous-wave signal $e = E \sin \omega t$ to which the antenna is tuned is given by the expression

$$v = E\frac{\pi}{\delta} \cos \omega t$$

So that the ratio of signal to atmospheric is given by

$$\frac{\text{Signal P.D.}}{\text{Atmospheric P.D.}} = \frac{E\pi \cos \omega t}{\delta(p/\omega)A\epsilon^{mt} \sin \omega t} \quad . \quad (3)$$

Consequently the ratio of signal P.D. to initial maximum P.D. of atmospheric is equal to $\frac{E\pi\omega}{A\delta p}$. It is seen that for fixed conditions of signal strength and wave-length this ratio increases in direct proportion as the aerial decrement is reduced; hence to minimize the disturbances caused by atmospherics the aerial decrement should be reduced to the lowest value compatible with stability and speed of signalling. The physical explanation is that whereas the signal P.D. increases in inverse proportion to the aerial decrement, the initial maximum of the atmospheric P.D. is sensibly independent of the aerial decrement, see formula (2). It will be seen in Section 8 that it is not equally effective to apply the retroaction in the amplifier circuit; in fact it is deleterious to reduce the decrement of the amplifier below that of the aerial. So it seems important to apply the retroaction in the first oscillatory circuit.

It is interesting to investigate the relative value of the field strength of the signal and atmospheric which will give the same maximum P.D. across the aerial tuning inductance. Suppose that for various reasons δ is limited to about 0·003, then if $E\pi\omega$ is to be equal to $A\delta p$, E will be approximately equal to $(\omega A/100p)$. If the signal wave-length is 6 000 m, then p/ω is about 0·01, and consequently for equality of maximum P.D. we have $A = 10^6 E$. Now, as pointed out in Table 2, the maximum value of the field strength of the atmospheric is about $\frac{1}{2}A$, and (as stated in Section 1) Watt and Appleton find that the average value of $\frac{1}{2}A$ is about 0·1 volt per metre. Hence by sufficient reduction of the antenna decrement it would appear that E may be reduced to a few microvolts per metre and yet be sufficiently strong to hold its own against the atmospherics ordinarily to be expected in this country. That comparatively strong atmospherics are relatively very ineffectual in causing a disturbance is, after all, a matter of common experience rather than of surprise, for had it been otherwise it is improbable that wireless telegraphy would ever have emerged from its experimental stages, and continuous long-distance services would have been impossible.

6. Current produced by an Atmospheric in an Aperiodic Antenna.

At the present time it is fairly common to use aperiodic antennæ for reception. The term "aperiodic antenna" is used to describe an aerial circuit which contains no added inductance and the resistance of which is at least of such a value as to render a discharge non-oscillatory. With such a circuit the necessary resistance is usually added at the base of the antenna, and its ends are connected to the terminals of a selective amplifier. All necessary tuning is then performed in the circuits of the amplifiers. Such a circuit is shown in Fig. 5. This system of reception has been proposed* and used experimentally to make multiplex reception possible on a single antenna and has also been employed in the hope of minimizing atmospheric disturbances.

The effect of the standard atmospheric acting on the circuit of Fig. 5 will now be considered. It is clear that if the value of R is indefinitely great, the P.D. applied between the terminals of the amplifier will be sensible equal to the E.M.F. of both signal and atmospheric. However, since the frequency of the signal is likely to be at least a hundred times as great as the frequency of the atmospheric, it is possible to arrange the value of R so that while the P.D. developed across

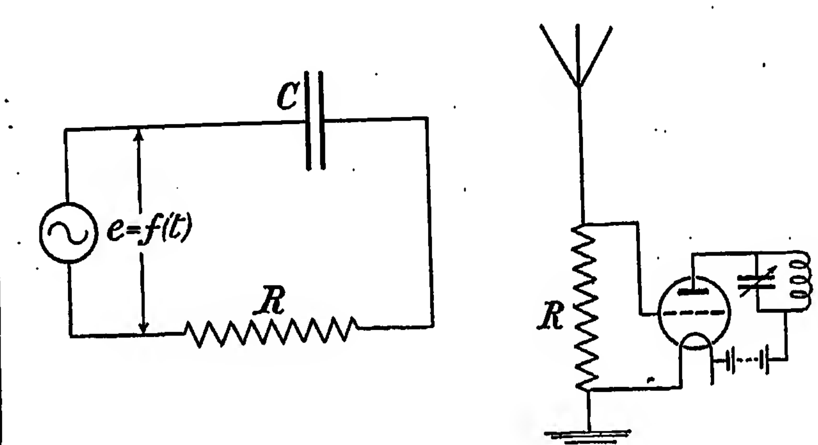

Fig. 5.

it by the signal is sensibly equal to the signal E.M.F., the P.D. developed by the atmospheric is only a small portion of the atmospheric E.M.F. In this way some degree of discrimination between signals and atmospherics can be obtained. In short, for an atmospheric the antenna acts like a simple capacity, and to the signal like a simple resistance.

The differential equation expressing the current produced by the atmospheric $e = A\epsilon^{-bt} \sin pt$ (where b is approximately equal to $\frac{1}{2}p$) is

$$\left(D + \frac{1}{RC}\right)i = \frac{A}{R}\epsilon^{-bt}(-b \sin pt + p \cos pt)$$

The approximate solution of this equation for the case where $1/(RC)$ is much greater than p is given by

$$i = -ApC\left\{\epsilon^{-\frac{1}{RC}t} - \epsilon^{-bt}[\cos pt - (b/p) \sin pt]\right\} \quad (4)$$

Writing $RC = x/\omega$ (where x is, say, not less than about 3), the P.D. developed across R is given by

$$v = -\frac{xAp}{\omega}\left\{\epsilon^{-\frac{\omega}{x}t} - \epsilon^{-bt}[\cos pt - (b/p) \sin pt]\right\} \quad (5)$$

* See L. B. Turner, British Specification No. 189 693.

The P.D. across R produced by the signal $e = E \sin \omega t$, is given by the expression

$$v \doteq E\left(1 - \frac{1}{2x^2} + \frac{1}{8x^4}\right) \sin \omega t$$

Now, so long as x is greater than, say, 3, the signal P.D. is nearly independent of x, but the atmospheric P.D. increases greatly with x. If x has the value 3, and if $\omega = 100p$, then about 1/30th part of the atmospheric E.M.F. is applied to the amplifier.

But using the expression given in formula (5) it can be shown that the initial rate of increase is independent of the value of RC, and, as has been already pointed out (see Section 4), the amplitude of the high-frequency current set up in the first oscillatory circuit depends on this initial rate of increase. Hence so long as the value of R is small enough to make the antenna behave to the atmospheric in sensibly the same manner as if it was a simple capacity, then the exact value of R is unimportant. This subject will be dealt with more fully in Section 10.

It is of interest to calculate a suitable value for R in a specific numerical case. Suppose, for example, that the capacity of the antenna is 1 000 $\mu\mu$F, and that the wave-length of the signals to be received is 6 000 m. If we choose R so that $1/(RC)$ is equal to $\frac{1}{3}\omega$, then its value will be about 10 000 ohms; probably any value of R between, say, 5 000 and 50 000 ohms would be equally suitable. In practice it is common to use values of R which are very much greater than those just calculated, but for minimizing atmospheric disturbances this practice does not seem to be a good one.

7. Current produced by an Atmospheric acting on a Tuned Loop Aerial.

It is commonly believed that where atmospheric disturbance is considerable it is advantageous to receive on a loop rather than on an open antenna. No doubt the advantage can be partly explained by the directional properties of a loop, but analysis shows that quite apart from this a loop has an advantage over an antenna.

In calculating the E.M.F. set up in a loop it is simpler to consider the rate of change of magnetic flux through the loop rather than the line integral round it of the electric field. If at any specified point the electric field set up by the atmospheric is represented by $e = E\epsilon^{-bt} \sin pt$, then the magnetic field can be represented by $h = H\epsilon^{-bt} \sin pt$. If the electric field is measured in volts per cm and the magnetic field in C.G.S. units, then E and H are connected by the relation $E = 300H$.

Let the loop, the dimensions of which are very small compared with the wave-length of the atmospheric, have N turns each of area A, then at any instant the magnetic flux through the loop is given by the expression $\phi = ANh$.

Hence the E.M.F. round the loop is given by the equation

$$e = -\frac{d\phi}{dt} = -NA\frac{dh}{dt} = -ANH\epsilon^{-bt}(-b \sin pt + p \cos pt) \quad (6)$$

Let the loop have inductance L and resistance R, and let it be joined in series with a condenser of capacity C. It is supposed that the value of C has been adjusted so that the circuit is in resonance with a signal E.M.F. $e = E \sin \omega t$.

The differential equation expressing the current set up in the loop is

$$\left(D^2 + \frac{R}{L}D + \omega^2\right)i$$
$$= -\frac{ANH}{L}\epsilon^{-bt}\left\{(b^2 - p^2) \sin pt - 2bp \cos pt\right\}$$

For the case where b and p are both much smaller than ω the approximate solution is given by

$$i = -ANHC\epsilon^{-bt}\left\{(b^2 - p^2) \sin pt - 2bp \cos pt\right\}$$

Thus, as in the case of the antenna, to the low frequency of the atmospheric the loop behaves as a simple capacity C.

The complete solution of the equation will consequently be of the form

$$i = B\epsilon^{-mt} \sin \omega t + D\epsilon^{-mt} \cos \omega t$$
$$- ANHC\epsilon^{-bt}\left\{(b^2 - p^2) \sin pt - 2bp \cos pt\right\}$$

where the constants B and D are determined by the condition that both i and di/dt are zero when t is zero.

Applying these conditions it is readily shown that $D = -2bpCANH$, and that $B \doteq (p/\omega)(D/4)$.

The approximate solution of the high-frequency portion of the current set up in the loop is accordingly given by the expression

$$i = -2bpCANH\epsilon^{-mt} \cos \omega t \quad . \quad . \quad . \quad (7)$$

and the P.D. across the terminals of the loop is given by

$$L\frac{di}{dt} = -2bpCLANH\epsilon^{-mt}(-m \cos \omega t - \omega \sin \omega t)$$
$$\doteq 2b\frac{p}{\omega}ANH\epsilon^{-mt} \sin \omega t \quad . \quad (8)$$

If the magnetic field of a signal is $h' = H' \sin \omega t$, the P.D. between the terminals of the loop is given by

$$L\frac{di}{dt} = ANH'\frac{\pi\omega}{\delta} \sin \omega t$$

Consequently the ratio of signal to atmospheric is given by

$$\frac{\text{Signal}}{\text{Atmospheric}} = \frac{H'\pi\omega^2}{H2\delta bp}$$
$$\doteq \frac{H'\pi\omega^2}{H\delta p^2} \quad (\text{since } b \doteq \tfrac{1}{2}p) \quad . \quad (9)$$

It is instructive to compare this expression with the corresponding one for a tuned antenna [see Section 4, formula (3)] which is

$$\frac{\text{Signal}}{\text{Atmospheric}} = \frac{E\pi\omega}{A\delta p}$$

It is seen that both expressions vary inversely as the decrement of the circuit (loop or antenna), but in the case of the loop the ratio depends on ω^2/p^2 instead of

ω/p for the antenna, and it is evidently from this factor that the loop gains its superiority.

8. Effect of an Atmospheric on a Selective Amplifier Coupled to the Aerial.

The term "selective amplifier" is used to denote an amplifier in which the anode circuit presents an appreciable impedance to currents of one frequency only. One example of such an amplifier may be obtained by placing a lightly-damped tuned stopper circuit between plate and filament. Such an amplifier, connected to the antenna, is shown in Fig. 6. The P.D. developed across

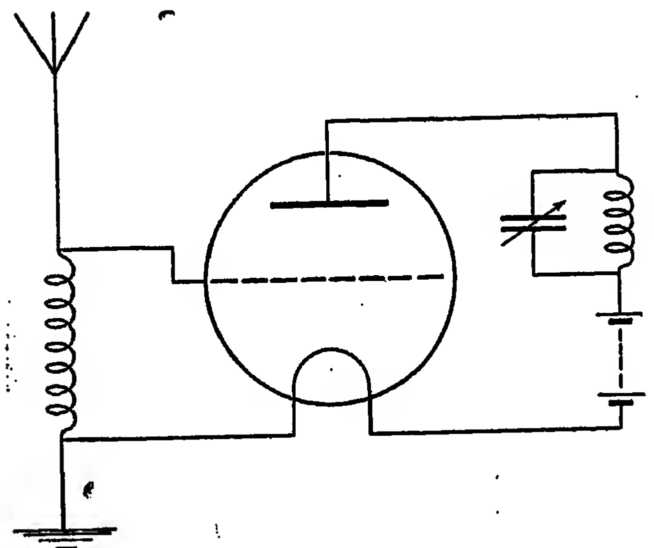

Fig. 6.

the terminals of the anode-circuit impedance is supposed to be handed on in the usual manner to the next triode, which may be another amplifier or a rectifier.

The P.D. applied to the input terminals of the first valve consists of a high-frequency and low-frequency component [see Section 5, formula (2)]. This P.D. will produce a current in the anode-circuit inductance L which will consist of three components, one low-

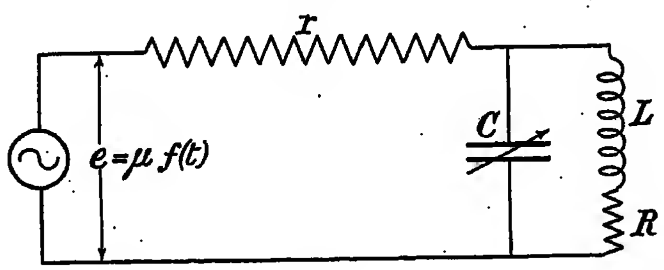

Fig. 7.

frequency and two high-frequency. The two high-frequency components will have the same frequency, since the amplifier is supposed to be tuned to the same frequency as the aerial; one component will have the decrement of the aerial and the other the decrement of the LRC circuit of the amplifier together with the conductance of the valve.

The circuit of the amplifier can be replaced by the equivalent circuit shown in Fig. 7. The input voltage to the equivalent circuit must be represented by μ times the input voltage to the amplifier, where μ is the amplification factor of the valve. The resistance r represents the apparent resistance of the valve and is numerically equal to $1/a$, where a is the anode slope conductance. For ordinary receiving triodes will be between, say, 30 000 and 40 000 ohms.

It is obvious that to the low-frequency component of the applied P.D. the circuit of Fig. 7 will behave in sensibly the same manner as a simple resistance r; that such is actually the case can readily be shown. Hence the low-frequency component of the applied P.D. will produce a current in L which is given by

$$i = -\frac{\mu A p^2}{r\omega^2}\epsilon^{-bt}\left(\tfrac{3}{4}\sin pt + \cos pt\right) \quad . \quad . \quad (10)$$

and the P.D. developed across L by this current is given by

$$L\frac{di}{dt} = -\frac{\mu A p^2}{r\omega^2}pL\epsilon^{-bt}\left(-\tfrac{11}{8}\sin pt + \tfrac{1}{4}\cos pt\right)$$

$$\doteqdot \frac{\mu A p^2}{r\omega^2}pL\epsilon^{-bt}\sin pt \quad . \quad . \quad . \quad . \quad . \quad . \quad (11)$$

Now if $p/\omega \doteqdot 1/100$, $\mu = 10$ and $L \doteqdot 4 \times 10^3 \mu H$.

Then $$L\frac{di}{dt} \doteqdot \frac{A}{10^6}\epsilon^{-bt}\sin pt$$

Hence of the E.M.F. in the aerial about one-millionth part will be applied to the second valve. In the numerical case considered in Section 5 this would be about $0{\cdot}8\ \mu V$.

It is now necessary to consider the current produced in L by the high-frequency P.D., $e = \frac{\mu A p}{\omega}\epsilon^{-mt}\sin \omega t$, applied at the terminals of the equivalent circuit.

It is readily shown that the appropriate differential equation expressing this current is given by

$$\left\{D^2 + \left(\frac{R}{L} + \frac{1}{rC}\right)D + \omega^2\right\}i = \frac{\mu A p \omega}{r}\epsilon^{-mt}\sin \omega t$$
$$\equiv K'\epsilon^{-mt}\sin \omega t$$

whence it follows that

$$i = K'\epsilon^{-mt}\frac{\sin \omega t}{\left(2m' - 2m + \frac{1}{rC}\right)D + m\left(m - 2m' - \frac{1}{rC}\right)}$$

where m' is the damping exponent of the LRC circuit in the anode circuit of the valve.*

Now to a steady continuous-wave signal the impedance of the stopper circuit is ω^2L^2/R, and the amplification of such a signal is $\frac{\omega^2L^2}{R(r + \omega^2L^2/R)}\mu$. Hence in order that the valve shall amplify satisfactorily it is probable that $\omega^2L^2/(Rr)$ will lie between, say, 1 and 5. To simplify the analysis we must take some value for $\omega^2L^2/(rR)$. We shall suppose first of all that it is 5, so that the valve will be giving an amplification of $0{\cdot}83\mu$.

Then $$\frac{\omega^2 L}{r} = \frac{5R}{L}$$

$$\frac{1}{rC} = \frac{5R}{L} = 10m'$$

* m' does not include the damping added by the anode conductance of the valve, but is the damping exponent of the LRC circuit by itself.

Hence it follows that

$$i = K'\frac{\epsilon^{-mt}\sin\omega t}{m\left\{(12x-2)D + m(1-12x)\right\}} \text{ where } m' = xm$$

$$= K'\frac{\epsilon^{-mt}\left\{(12x-2)D - m(1-12x)\right\}\sin\omega t}{m\left\{-(12x-2)^2\omega^2 - m^2(1-12x)^2\right\}}$$

$$\doteqdot -K'\frac{\epsilon^{-mt}\left\{2\omega(6x-1)\cos\omega t - m(1-12x)\sin\omega t\right\}}{4m\omega^2(36x^2-12x+1)}$$

$$\doteqdot -\frac{\mu A p\epsilon^{-mt}\cos\omega t}{2rm(6x-1)} \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad (12)$$

$$\therefore L\frac{di}{dt} \doteqdot \frac{\mu A p\omega L\epsilon^{-mt}\sin\omega t}{2mr(6x-1)}$$

$$= \frac{\mu A p 5m'\epsilon^{-mt}\sin\omega t}{\omega m(6x-1)}, \text{ since } \frac{\omega L}{r} = \frac{10m'}{\omega}$$

$$= \frac{5x\mu A p\epsilon^{-mt}\sin\omega t}{(6x-1)\omega} \quad . \quad . \quad . \quad . \quad . \quad . \quad (13)$$

Hence it is seen that the amplifier amplifies the P.D. applied to it in the ratio $\frac{5x\mu}{(6x-1)}$.

Should x have the value 1/6 this factor appears to be infinite; but this is not so, because in the analysis m has been neglected in comparison with ω, and also the applied P.D. has been assumed to be $\epsilon^{-mt}\sin\omega t$, when actually it is $\epsilon^{-mt}\,t\,\sin\sqrt{(\omega^2-m^2)}t$.

The condition when x equals 1/6 corresponds to the case when the decrement of the aerial is the same as the decrement of the stopper circuit together with the valve resistance in parallel. If this case is worked out without approximations, the complete expression for the current is

$$I \doteqdot -\frac{\mu A p}{2r}\epsilon^{-mt}\left\{t\cos\omega t - \frac{1}{\omega}\sin\omega t\right\}$$

The P.D. across the stopper circuit is therefore given by

$$L\frac{di}{dt} = \frac{\mu A p\omega L}{2r}t\epsilon^{-mt}\sin\omega t \doteqdot \frac{\mu A p m}{\omega}t\epsilon^{-mt}\sin\omega t$$

This expression represents a sine curve the maxima of which gradually grow to a maximum and then gradually die away to zero. The greatest maximum occurs at time $t = 1/m$ approximately, and this maximum is approximately equal to $0 \cdot 4\ (\mu A p/\omega)\sin\omega t$.

It is interesting to consider the values of the amplifications that obtain for various values of x.

If x is much greater than unity, $\frac{5x}{6x-1}$ approaches 5/6.

If x is equal to unity, $\frac{5x}{6x-1}$ is unity.

If x is equal to 1/6 the amplification may be considered to be $0 \cdot 4$.

If x is equal to 1/10, $\frac{5x}{6x-1}$ is equal to $1 \cdot 25$.

If x is equal to 1/20, $\frac{5x}{6x-1}$ is equal to $0 \cdot 3$.

But in addition to the component of current already considered there is the component due to the free oscillation of the stopper circuit. It is readily shown that the approximate expression for this is given by

$$L \doteqdot \frac{p\mu A}{2mr(6x-1)}\epsilon^{-6m't}\cos\omega t$$

and the complete expression for the P.D. applied to the next valve is

$$L\frac{di}{dt} \doteqdot \frac{5\mu x}{6x-1} \times \frac{Ap}{\omega}(\epsilon^{-mt} - \epsilon^{-6m't})\sin\omega t$$

It can be seen from this expression that if m' is much less than m, then the free oscillation is much the most persistent and consequently the most important in causing disturbances. Hence, although great reduction of the decrement may reduce the amplitude some 50 per cent. it is at the expense of increased persistence.

The critical adjustment which makes the resultant amplifier decrement equal to that of the aerial is no doubt to some extent advantageous, but it is difficult in practice to attain. The safest plan appears to be to keep the stopper circuit decrement much greater than that of the aerial. It would appear that the best procedure in practice is to reduce the stopper circuit decrement until further reduction increases the signal very little; when this has been done the aerial decrement should be reduced to the limit imposed by stability or speed of signalling. Probably the most satisfactory method is to build the stopper circuit so that its inherent decrement is low enough to get the required degrees of amplification without resorting to retroaction, and to apply retroaction in the aerial circuit and there only.

9. Effect of Slightly Distuning the Aerial.

It is often considered that atmospheric disturbances are somewhat reduced if the aerial is slightly distuned from the signal. Since the frequency of the atmospheric and the signal are widely separated, a slight alteration of the aerial tuning cannot sensibly alter the magnitude of the high-frequency current set up by the atmospheric; but it will make the frequency of this current appreciably different from that of the signal to which the stopper circuit is tuned.

Consequently the amplifier, which is supposed to be highly selective, will not function as efficiently at the frequency of the current set up by the atmospheric as it does at the signal frequency. Distuning the aerial, however, has not only the desired effect of throwing the atmospheric out of tune with the amplifier but it has also the undesired effect of weakening the signal. In order to benefit by the method it is evidently necessary to choose the decrements of the circuits in such a way that the advantage gained by reducing the atmospheric is not more than counterbalanced by the weakened signal; in fact the system is admissible only when the aerial has a relatively high decrement.

The P.D. produced by the atmospheric between the terminals of the aerial tuning inductance is given (see Section 5) by

$$L\frac{di}{dt} = A\frac{p}{\omega}\epsilon^{-mt}\sin\omega' t$$

where ω' is 2π times the frequency of the slightly distuned aerial. The initial amplitude of this P.D. is sensibly independent of the extent of distuning and of aerial decrement. We may then consider that the atmospheric P.D. applied to the amplifier is independent of circuit conditions, while the signal P.D. depends greatly on decrement and the amount of distuning.

The P.D. produced by the signal $e = E \sin \omega t$ is given by

$$L\frac{di}{dt} = \frac{E \sin \omega t}{\sqrt{\left[\frac{\delta^2}{\pi^2} + 4\left(\frac{\delta\omega}{\omega}\right)^2\right]}}$$

where $\delta\omega$ is the amount by which the aerial is distuned.

We shall consider an amplifier the circuits of which are arranged to give an output P.D. $\frac{4}{5}\mu$ times as great as the input P.D.; then the output voltage due to the signal will be given by

$$v = \tfrac{4}{5}\mu \frac{E \sin \omega t}{\sqrt{\left[\frac{\delta^2}{\pi^2} + 4\left(\frac{\delta\omega}{\omega}\right)^2\right]}} \quad . \quad . \quad . \quad (14)$$

Considering now the output voltage due to the atmospheric, we have, as previously,

$$\left\{D^2 + \left(\frac{R}{L} + \frac{1}{RC}\right)D + \omega^2\right\} i = \frac{\mu A}{rCL} \times \frac{p}{\omega} \epsilon^{-mt} \sin \omega' t$$

whence

$$i = \frac{10\mu A m'}{L} \cdot \frac{p}{\omega} \cdot \frac{\epsilon^{-mt} \sin \omega' t}{D^2 + D(12m' - 2m) + \omega^2 + m^2 - 12mm'}$$

$$\doteq \frac{10\mu A\omega\delta'}{4\pi L} \cdot \frac{p}{\omega} \cdot \frac{\epsilon^{-mt} \sin \omega' t}{\left(\frac{\delta\omega}{\omega}\right)^2 + \frac{1}{2\pi\omega}(6\delta' - \delta)D}$$

$$= -\frac{10\mu A}{L} \cdot \frac{\delta'}{4\pi\omega} \cdot \frac{p}{\omega} \cdot \frac{\epsilon^{-mt} \sin (\omega' t + \lambda)}{\sqrt{\left[\left(\frac{\delta\omega}{\omega}\right)^2 + \left(\frac{6\delta' - \delta}{2\pi}\right)^2\right]}}$$

$$L\frac{di}{dt} = \frac{10\mu A\delta'}{4\pi} \cdot \frac{p}{\omega} \cdot \frac{\epsilon^{-mt} \sin (\omega' t + \lambda)}{\sqrt{\left[\left(\frac{\delta\omega}{\omega}\right)^2 + \left(\frac{6\delta' - \delta}{2\pi}\right)^2\right]}}$$

$$\equiv 0 \cdot 8K\mu\delta' \frac{\epsilon^{-mt} \sin (\omega' t + \lambda)}{\sqrt{\left[\left(\frac{\delta\omega}{\omega}\right)^2 + \left(\frac{6\delta' - \delta}{2\pi}\right)^2\right]}} \quad . \quad . \quad (15)$$

To compare the signal with the atmospheric it is best to give numerical values to the decrements δ and δ'.

The values of the expressions (14) and (15) have been worked out for various amounts of distuning up to 5 per cent in the two cases where $\delta = 0 \cdot 1$ and $\delta' = 0 \cdot 01$ and when $\delta = 0 \cdot 01$ and $\delta' = 0 \cdot 01$ respectively. The results are collected in Tables 3 and 4.

Figs. 8 and 9 exhibit two curves plotted from the results of these tables and show the relation between the ratio of signal to atmospheric for various amounts of distuning.

It is clear that the distuning system is a very distinct advantage in the case when the aerial decrement is somewhat high, but is very disadvantageous when the aerial decrement is reduced by retroaction to a low value. It can be seen that the distuning method cannot give as good results as if the two circuits are kept dead in tune and the aerial decrement reduced to the lowest possible limit.

It must not be overlooked that the free oscillation has not been considered in the results of Tables 3 and 4.

TABLE 3.

$\delta = 0 \cdot 1, \quad \delta' = 0 \cdot 01.$

Amount of distuning	0·00	0·01	0·02	0·03	0·04	0·05
Amplified signal	$26\mu E$	$22\mu E$	$19 \cdot 5\mu E$	$17 \cdot 5\mu E$	$16 \cdot 3\mu E$	$15 \cdot 4\mu E$
Amplified atmospheric	$1 \cdot 3\mu K$	$0 \cdot 67\mu K$	$0 \cdot 51\mu K$	$0 \cdot 43\mu K$	$0 \cdot 38\mu K$	$0 \cdot 37\mu K$
Signal atmospheric	$20\frac{E}{K}$	$33\frac{E}{K}$	$38\frac{E}{K}$	$40\frac{E}{K}$	$43\frac{E}{K}$	$45\frac{E}{K}$

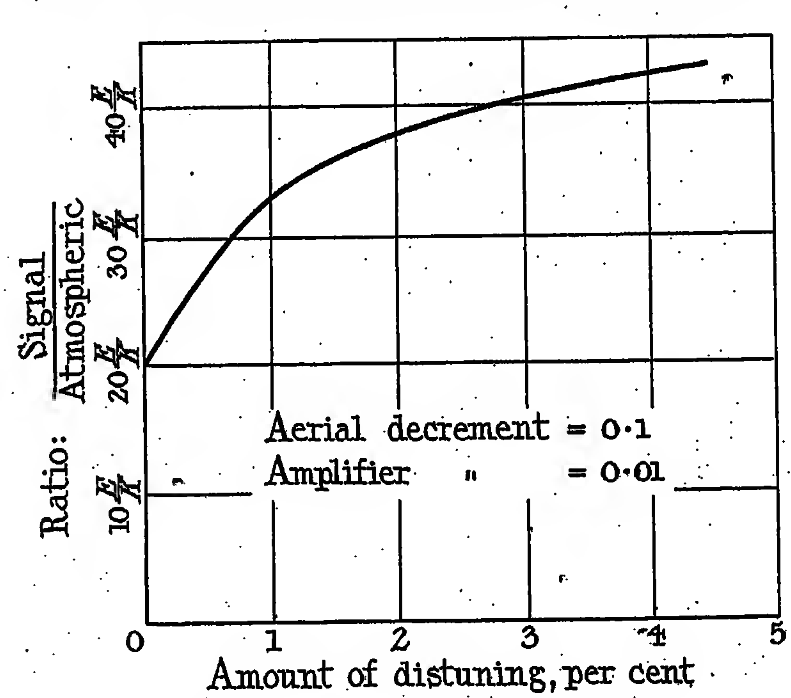

FIG. 8.—Effect of distuning aerial.

Aerial decrement = 0·1.
Amplifier decrement = 0·01.

This free oscillation is in tune with the next amplifier of the chain, and consequently it is important that its amplitude should be kept small and its decrement high. Indefinite reduction of the amplifier decrement will

merely serve to increase the importance of this term and thereby make the net advantage of distuning consider-

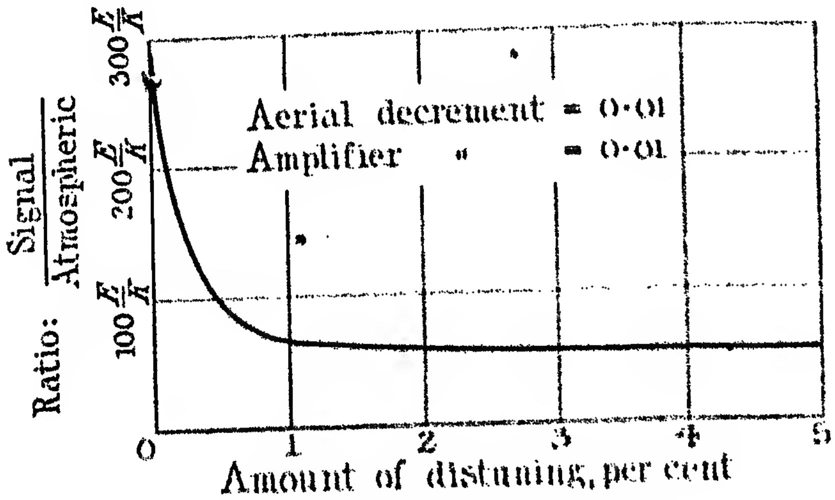

FIG. 9.—Effect of distuning aerial.
Aerial decrement = 0·01.
Amplifier decrement = 0·01.

ably less than would appear from calculations based on formulæ (14) and (15).

10. RATIO OF SIGNAL TO ATMOSPHERIC WITH APERIODIC ANTENNA AND SELECTIVE AMPLIFIER.

The correct design of antenna circuit for working with an aperiodic aerial has been considered in Section 6.

whence it follows that

$$i = -\frac{\mu A x}{r}\frac{p}{\omega}\left[\frac{\epsilon^{-\frac{\omega}{x}t}}{1+1/x^2} - \epsilon^{-bt}\left(\cos pt - \frac{b}{p}\sin pt\right)\right]$$

when t is equal to 0

$$\frac{di}{dt} = \frac{\mu A x}{r}\cdot\frac{p}{\omega}\left[\frac{\omega}{x(1+1/x^2)} - 2b\right]$$

The complete solution is given by

$$i = B\epsilon^{-Mt}\sin\omega t + C'\epsilon^{-Mt}\cos\omega t$$
$$-\frac{\mu A x}{r}\cdot\frac{p}{\omega}\left[\frac{\epsilon^{-\frac{\omega}{x}t}}{1+1/x^2} - \epsilon^{-bt}\left(\cos pt - \frac{b}{p}\sin pt\right)\right]$$

When $t = 0$, $i = 0$ and $\frac{di}{dt} = 0$

$$\therefore C' = \frac{\mu A x}{r}\times\frac{p}{\omega}\left[\frac{1}{1+1/x^2} - 1\right]$$

and $$\omega B = -\frac{\mu A x}{r}\times\frac{p}{\omega}\left[\frac{\omega}{x(1+1/x^2)} - 2b\right]$$

Suppose $x = 1$

then $$C' = \frac{\mu A}{r}\times\frac{p}{\omega}\times\frac{1}{2}$$

and $$B = -\frac{\mu A}{r}\times\frac{p}{\omega}\times\frac{1}{2}$$

TABLE 4.

$\delta = 0·01, \quad \delta' = 0·01.$

Amount of distuning	0·00	0·01	0·02	0·03	0·04	0·05
Amplified signal	$260\mu E$	$42\mu E$	$29\mu E$	$24\mu E$	$21\mu E$	$19\mu E$
Amplified atmospheric ..	$0·9\mu K$	$0·61\mu K$	$0·48\mu K$	$0·41\mu K$	$0·37\mu K$	$0·31\mu K$
Signal atmospheric	$290\frac{E}{K}$	$69\frac{E}{K}$	$60\frac{E}{K}$	$59\frac{E}{K}$	$58\frac{E}{K}$	$57\frac{E}{K}$

We are now in a position to consider how the combination of an aperiodic aerial and selective amplifier compares with the combination of tuned aerial and selective amplifier. If the signal E.M.F. in the aperiodic aerial is $e = E\sin\omega t$, then the P.D. across the resistance inserted in the aerial is also sensibly equal to $v = E\sin\omega t$, and hence the output voltage from the amplifier will be sensibly equal to $v = \frac{1}{2}\mu E\sin\omega t$.

The input P.D. due to the atmospheric is given [see Section 6, formula (5)] by

$$v = -xA\frac{p}{\omega}\left\{\epsilon^{-\frac{\omega}{x}t} - \epsilon^{-bt}\left(\cos pt - \frac{b}{p}\sin pt\right)\right\}$$

Hence the differential equation representing the current through the stopper circuit inductance is

$$\left\{D^2 + \left(\frac{R}{L} + \frac{1}{rC}\right)D + \omega^2\right\}i$$
$$= \frac{\mu A p\omega x}{r}\left\{\epsilon^{-\frac{\omega}{x}t} - \epsilon^{-bt}\left(\cos pt - \frac{b}{p}\sin pt\right)\right\}$$

If now $x > 5$, say

$$C' \doteq 0$$
$$B \doteq -\frac{\mu A}{r}\times\frac{p}{\omega}$$

Hence if $x = 1$, the resulting high-frequency current is

$$i = 0·7\frac{\mu A}{r}\times\frac{p}{\omega}\epsilon^{-Mt}\sin(\omega t + \lambda)$$

and if $x > 5$

$$i \doteq \frac{\mu A}{r}\times\frac{p}{\omega}\epsilon^{-Mt}\sin\omega t$$

Hence the value of $1/(CR)$ makes very little difference to the magnitude of the high-frequency disturbance set up. It was pointed out in Section 6 that, if the atmospheric was truly of the form assumed, then the initial rate of rise of atmospheric P.D. applied to the amplifier is independent of $1/(RC)$ and equals Ap. Hence this is merely another example of the fact that if a low-

frequency P.D. is applied to a high-frequency circuit of low decrement, the resulting disturbance depends not on the amplitude of the low-frequency P.D. but on its initial rate of increase.

The output P.D. from the amplifier is given by

$$L\frac{di}{dt} \doteqdot \frac{\mu A p L}{r}\epsilon^{-Mt}\cos\omega t$$

and if $$\frac{L}{r} \doteqdot \frac{5R}{\omega^2 L} = \frac{5}{\pi}\cdot\frac{\delta'}{\omega}$$

then $$L\frac{di}{dt} \doteqdot \frac{5\mu A p \delta'}{\pi\omega}\epsilon^{-Mt}\cos\omega t$$

and the ratio $$\frac{\text{Signal}}{\text{Atmospheric}} = \frac{E\pi\omega}{A6p\delta'} \quad . \quad . \quad . \quad (16)$$

The corresponding ratio for a tuned aerial is [see Section 5, formula (3)]

$$\frac{\text{Signal}}{\text{Atmospheric}} = \frac{E\omega\pi}{Ap\delta}$$

Expressions (3) and (16) are seen to be very similar in form, and it is possible to make them numerically equal. Since δ' represents the decrement of the stopper circuit alone without the decrement produced by the valve inductance, δ' can be very much smaller than δ. With the amplifier adjustment considered when $\delta = 6\delta'$ the tuned aerial circuit and the whole amplifier circuit would have the same decrement, and in that case also $M = m$ so that the tuned aerial and aperiodic aerial would be identical.

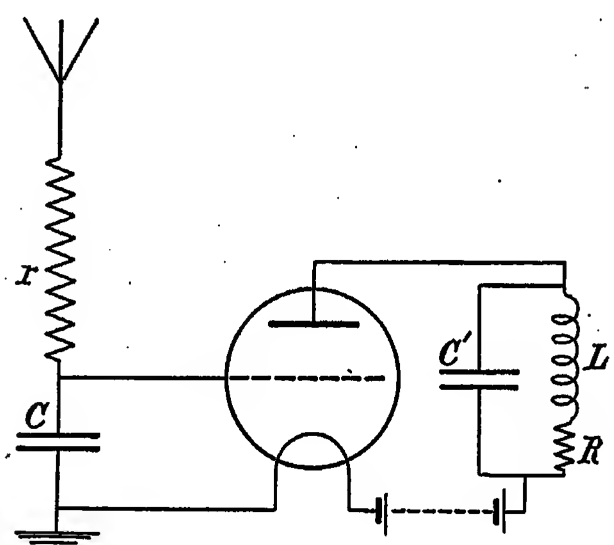

FIG. 10.

Hence if an aperiodic antenna is required for multiplex reception it may be used without fear of increasing the atmospheric disturbance.

Instead of using an aperiodic antenna in the way just described, we may place a condenser in series with it and apply the P.D. across this condenser to a selective amplifier (see Fig. 10). This method appears to be advantageous because the initial rate of change of the P.D. applied to the amplifier is zero for all forms of atmospheric; but since the signal P.D. applied to the amplifier is now only a small fraction of the signal E.M.F., the signal is reduced as much as the atmospheric and a net gain does not result. If K is the capacity and r the resistance of the antenna, and C the capacity of the series condenser, it may be shown that an atmospheric $e = A \sin pt$ will produce a potential difference V across the condenser C which is given by

$$V = \frac{pAr}{C(p^2r^2+\gamma^2)}\left\{-\cos pt + \frac{\gamma}{rp}\sin pt + \epsilon^{-\frac{\gamma}{r}t}\right\}$$

where $\gamma \equiv \dfrac{K+C}{KC}$.

It can be shown that V will produce a high-frequency P.D. across the stopper circuit inductance L which is given by

$$V' \doteqdot \frac{Ap}{\omega}\cdot\frac{Lg}{Cr}\epsilon^{-mt}\cos\omega t \quad \text{if} \quad \frac{\gamma}{r} << \omega$$

where g is the anode-grid conductance of the valve and m is the damping exponent of the stopper circuit together with the valve. The signal potential difference V_s is given by

$$V_s \doteqdot -\frac{E\cos\omega t}{r\omega C}\times\frac{y}{y+1}\mu$$

where $\dfrac{y}{y+1}\mu$ is the amplification factor of the valve.

It follows that the ratio

$$\frac{\text{Signal}}{\text{Atmospheric}} = \frac{E\omega\pi}{Ap\delta}\times\frac{y}{y+1} \quad . \quad . \quad (17)$$

where δ is the decrement of the stopper circuit by itself. If, as in Sections 10 and 8, we give y the value 5, formula (17) becomes identical with formula (16). If $\gamma/r \doteqdot \omega$ it may be shown that the ratio is still given by formula (17). Hence it appears that a tuned aerial or the combination of any form of aperiodic antenna with a selective amplifier can always be made to give an identical ratio of signal to atmospheric by simply adjusting the decrement of the first oscillatory circuit of the chain. It is possible that with a given selective amplifier the ratio of signal to atmospheric can be improved by replacing the tuned aerial by an aperiodic one, but it cannot be improved beyond the point which could have been attained if the decrement of the tuned antenna had been reduced to the lowest possible limit.

11. Practical Limitations of Decrement.

In the previous portion of this paper it was tacitly assumed that signals and atmospherics did not occur simultaneously, and that a signal lasted long enough to allow the current in the oscillatory circuit to build up to its final value; but if these conditions obtained in practice, stability would be the only limitation imposed on the decrement of circuits. For signals which last for a time T only, it may be shown that formula (3) becomes

$$\frac{\text{Signal}}{\text{Atmospheric}} \equiv \frac{E\omega\pi(1-\epsilon^{-n\delta T})}{Ap\delta} \equiv Z\frac{(1-\epsilon^{-n\delta T})}{\delta}$$

For a given wave-length and speed of signalling n and T are fixed. Let their product be denoted by K. For a

given value of K, Table 5 illustrates how the ratio depends on $n\delta T$.

TABLE 5.

$n\delta T$	Ratio : $\frac{\text{Signal}}{\text{Atmospheric}}$
2	$0 \cdot 43KZ$
1	$0 \cdot 63KZ$
1/2	$0 \cdot 8KZ$
0	$1 \cdot 0KZ$

Table 5 shows that there is little to be gained by reducing δ below the point at which $n\delta T = \frac{1}{2}$, but it is probable that considerations of shaping make it impossible to reduce $n\delta T$ much below 2.* But even with low-speed signalling we cannot reduce the decrement indefinitely without blurring the signals and making them unreadable. Some experiments have been made by Mr. F. P. Best at the Engineering Laboratory, Cambridge, who finds that $n\delta$ cannot be reduced much below 100 without causing troublesome ringing. If we make $n\delta$ equal to 100, formula (3) becomes

$$\frac{\text{Signal}}{\text{Atmospheric}} \equiv \frac{E\omega^2 1}{Ap \times 200} \doteq \frac{E}{A} \times 10^5 \text{ if } \frac{\omega}{p} = 100 \text{ and } \lambda = 6\,000m$$

$$\text{or } \doteq \frac{E}{A} \times 10^7 \text{ if } \frac{\omega}{p} = 1\,000 \text{ and } \lambda = 600m$$

This ratio should be compared with that given at the end of Section 5.

12. Effect of the Atmospheric on the Rectifier and the Low-Frequency Amplifiers.

Having traced the course of the atmospheric through the successive stages of the aerial and the high-frequency amplifiers, we must now consider its effect on the rectifier and low-frequency amplifiers.

The P.D. applied to the rectifier consists of a small low-frequency component and a relatively large high-frequency component. It follows from formula (11) that the low-frequency output P.D. from the first amplifier is about $\frac{5\mu}{\pi}\delta' \frac{p^3}{\omega^3}A$, and from the second amplifier is approximately $\frac{25\mu^2}{\pi^2}\delta'\delta'' \frac{p^4}{\omega^4}$. If p/ω is of the order of 1/100, this P.D. will be about one hundred-millionth of the atmospheric E.M.F., or less than a microvolt in value. But the high-frequency P.D. applied to the rectifier will be (with two high-frequency amplifiers) $\mu^2 \frac{p}{\omega}$ of the atmospheric E.M.F., and will be of the order of a volt or two. Hence, although the rectifier, together with its low-frequency transformer, forms an amplifier suitable for the low-frequency portion of the atmospheric, the P.D. handed on to the first low-frequency transformer by this means will be negligible in comparison with that due to the rectified current produced by the high-frequency portion. The low-frequency component may now be finally dismissed from consideration.

Although we can increase the ratio of the signal P.D. to the initial P.D. of the atmospheric by decreasing the decrement of the circuit, we thereby increase the persistence of the atmospheric. Before finally recommending low decrements we must estimate the quantity of electricity that the atmospheric will cause to flow through the rectifier. A powerful heterodyne generator makes the quantity rectified per cycle of applied P.D. sensibly proportional to the area of the positive half-cycle of applied P.D. Let it be K times this area, where K is a constant depending on the rectifier.* If the applied P.D. is of the form $e = B\epsilon^{-n\delta t} \sin \omega t$, it can readily be shown that, if δ is small, the total area of all the positive half-waves is $2B/(\omega\delta)$. Hence the quantity Q_A rectified by the atmospheric $e = A\frac{p}{\omega}\epsilon^{-mt} \sin \omega t$ is given by

$$Q_A = \frac{Ap}{\omega} \times \frac{2K}{\omega\delta}$$

Let the duration of a Morse dot be T seconds. We shall suppose that the signal P.D. reaches its full value in a time that is appreciably less than T. Then the quantity Q_S rectified by the signal $v = \frac{E\pi}{\delta} \cos \omega t$ will consist of a quantity $\frac{E\pi}{\delta} \times \frac{2KTn}{\omega}$ produced during the transmitted dot, and a quantity $\frac{E\pi}{\delta} \times \frac{2K}{\omega\delta}$ produced after the transmitter key has been raised.

$$\text{Hence } Q_S/Q_A = \frac{E}{A} \times \frac{\pi}{\delta} \times \frac{\omega}{p} \times \frac{\left(\frac{Tn}{\omega} + \frac{1}{\omega\delta}\right)}{1/(\omega\delta)}$$

$$= \frac{E}{A} \times \frac{\pi}{\delta} \times \frac{\omega}{p} \times (1 + n\delta T) \quad . \quad . \quad (18)$$

If T is long enough for the signal to reach its full P.D., then formula (18) shows that the final ratio of signal to atmospheric is always greater than the ratio given by formula (3). If audible reception requires that $n\delta$ shall not be less than 100, then $n\delta T$ must not be less than 4 for 30 words per minute, or 8 for 15 words per minute. Imposing that limitation on equation (18) we have

$$\frac{Q_S}{Q_A} \doteq \frac{E\pi\omega}{A\delta p} \times 6$$

$$= \frac{E\omega^2}{Ap} \times \frac{1}{30} \text{ if } n\delta \doteq 100$$

If we allow for the gradual rise of signal P.D. it may be shown that in the limiting case when δ is zero

$$\frac{Q_S}{Q_A} = \frac{E\omega^2}{Ap} \times \frac{T}{2}$$

The rectifier will impose a limiting action on very strong atmospherics if its anode potential is chosen suitably with respect to the strength of the heterodyne.

* See paper by L. B. Turner: "The Relation between Damping and Speed in Wireless Reception," *Journal I.E.E.*, 1924, vol. 62, p. 192.

* E. B. Moullin and L. B. Turner: "Thermionic Triode as Rectifier," *Journal I.E.E.*, 1922, vol. 60, pp. 711 and 717.

Also, if we make the second acoustic amplifier selective to the beat note between signal and heterodyne, and make the natural frequency of the first amplifier very different from that beat note, we can obtain some degree of discrimination between signals and atmospherics.

13. Conclusion.

Common experience has shown that the difficulty of combating atmospherics is greater than the mathematical analysis contained in this paper would suggest, for to cause great disturbance it seems that atmospherics would have to be at least 10 times as strong as those measured by Watt and Appleton. There are at least two reasons why the analysis makes the problem easier to solve than it is. First, the atmospherics delineated by Watt and Appleton are necessarily single discharges which produce a click in the receiver, but it often happens that a series of discharges occur in rapid succession and will cause much more disturbance than a single click. Also, Watt and Appleton observe that high-frequency ripples are often superposed on the main atmospheric and it is possible that they are the main cause of disturbance. Thus a superposed ripple having one-tenth the amplitude and 10 times the frequency of the main atmospheric will at least double the disturbance caused by the discharge. Hence, although it cannot be hoped that the analysis represents the whole problem, it is probably a close approximation to it. The analysis shows that the direct effect of the low-frequency component of current is always negligible, and that the disturbance is caused by the high-frequency oscillation produced by the atmospheric. It also shows that an aperiodic antenna cannot in itself be any protection against atmospherics, and that a tuned loop aerial is more selective than a tuned antenna. For a given wave-length it appears that the disturbance does not depend in any way on the ratio of inductance to capacity, but only on the decrement of the first oscillatory circuit. It is shown that for audible reception the decrement of the first oscillatory circuit should be reduced until the phenomenon of "ringing" becomes troublesome; the receiver is then in the best condition to battle with atmospherics, and further protection can be obtained only by use of special apparatus such as current limiters or directional devices.

Discussion before the Wireless Section, 6 February, 1924.

Dr. E. V. Appleton: It was natural that we should make calculations similar to those described by the author as soon as we had seen the wave-forms on the oscillographic screen. In work of this type I used the well-known mathematical expressions for pulses $E = Ate^{-\lambda t}$ and $E = A(e^{-\lambda t} - e^{-2\lambda t})$. The net results were similar to those of the author in that they showed that the effect of an atmospheric pulse increases with increase of amplitude and also with decrease of duration, but no attempt was made to discuss the effect on various circuits in the comprehensive way the author has done. At first I thought that the author's work was a little premature in that it was based on a preliminary report of our experiments. In that report we were mainly concerned with trying to prove that it was possible to devise an apparatus which would show atmospheric wave-forms, and the analysis of the 600 wave-forms in that report is not to be considered final. During the year many improvements have been made in the experimental gear. Also something like 8 000 wave-forms have been observed, mainly by Mr. J. F. Herd, a full account of which will be published shortly. But it appears that wave-form, apart from ripples, is not of much importance in the analysis and so the author's work is independent of our later results. The interesting outcome of Mr. Best's experiments is that the relief we can get from atmospheric interference by feebly damped circuits is limited by "ringing," and it seems certain that the main solution at present lies in short-wave working and in directional reception. We therefore have to ask ourselves the question: Where do atmospherics come from in the first place? Much has been written in answer to this question and many theories have been proposed. To these theories I wish to add another, and that is, that atmospherics are caused by lightning flashes or discharges from thunder-clouds. It is, of course, well known that lightning flashes do cause atmospherics, but this theory differs from the older ones in that we are to regard discharges from thunder-clouds as the major source of atmospherics, instead of, as previously, a very minor source. Some years ago (see *Year-book of Wireless Telegraphy and Telephony*, 1921, p. 1114) I pointed out that Mr. C. T. R. Wilson's observations on the electric field of thunder-clouds might be used in deducing the order of magnitude of the electromagnetic disturbance arising from lightning flashes. From these measurements we may deduce that a lightning flash is an aerial with an effective height only to be measured in kilometres and with a rapidly changing current of the order of 20 000 amperes. There seems no doubt that thunder-cloud discharges can be of sufficient magnitude to account for the radiation fields observed. It has often been argued that it is difficult to imagine sufficient lightning flashes on the earth's surface to account for the number of atmospherics observed, but I do not think that this is the case, as the following considerations show. It is known that the earth as a whole remains negatively charged in spite of the positive atmospheric current flowing into it, which is of sufficient magnitude to neutralize the charge in 10 minutes. The chief problem of atmospheric electricity is to determine how this negative charge is maintained. Mr. Wilson's theory is that the negative charge is replenished by the electricity from thunder-clouds either in the form of lightning flashes or intense ionization currents. According to one version of this theory we must regard the thunderstorm regions of the earth's surface as sending positive charges to the Heaviside layer and negative to the ground, either in the form of lightning flashes or ionization currents, and thus maintaining the Heaviside layer at a million volts positive with respect to the earth. In accounting for the maintenance of the earth's charge in this way it may be estimated that at least 1 000 thunder-clouds

are in action at any one time. I have tried to link up this theory of the thunderstorm origin of atmospherics with the directional observations of Hoyt-Taylor, Round, Watson, Watt and Schindelhauer on atmospherics, and it appears possible to get satisfactory correlation if we assume that the thundery regions are situated mainly on a wide equatorial belt (and in particular South Africa and South America) which acts as a permanent source of atmospherics. If we accept the theory the next point is to consider what general rules it gives as to the average direction of arrival of atmospherics at any point on the earth's surface, and what form the diurnal variation will take. It is a well-known fact (and one which I have noted particularly in Cambridge during the past 5 years) that there is a correlation between local time and thunderstorm frequency. Thunderstorms occur most frequently during the afternoon, and thus at that time we may expect places having the same longitude as the point in question to act as sources of atmospherics. So far as this point is concerned, the source of atmospherics should follow the sun. Secondly, there is the question of the proximity of a particularly thundery district either on or off the equatorial belt (e.g. a land area as opposed to a sea area). This region will be a marked source of atmospherics when its local time is afternoon. And thirdly, we have to consider the question of the ease of transmission of electric waves through the atmosphere between the point of origin and the point of observation, and the diurnal variation of the transmission factor. In this connection we may further note the possibility of the atmosphere's being aelotropic due to the conductivity of ionized gas being greater in the direction of the earth's magnetic field than in the direction at right angles. According to Mr. Wilson's theory the earth should possess its maximum negative charge when the maximum number of thunderstorms are in action at any part of the day. Now Mauchly has shown that the charge on the earth reaches a maximum about 18 G.M.T., and if we examine Schindelhauer's results we find that the atmospheric disturbances coming from the south and southwest reach a maximum at about the same time. This points to the conclusion that South Africa and South America may be regarded as the centres of gravity of the earth's thunderstorm and atmospheric-producing regions. It has often been argued that atmospherics come from places where lightning is not seen, but I think that many discharges take place from the top of a thunder-cloud (10 to 15 km up) to the Heaviside layer, in which case lightning may not be seen through the dark thunder-cloud. The general streaming of electricity from the thundery regions near the equator to the remainder of the earth may have on the magnetic declination an effect which is perhaps not negligible. It seems quite certain that the high-frequency ripples mentioned in the recent paper by Mr. Watt and myself are one of the chief causes of trouble in dealing with atmospherics, and more will be said of this in our second paper. Such high-frequency ripples will show a diurnal variation as compared with the low-frequency form due to atmospheric absorption, and thus will be especially pronounced near the source and at night.

Major A. G. Lee: I should like to mention another way of looking at this problem. Lord Rayleigh many years ago showed that an aperiodic pulse could be resolved into a number of sustained sinusoidal components forming an infinite spectrum. As an atmospheric can be resolved into these sustained sinusoids, it follows that, so far as our wireless receiving circuits are concerned, it is impossible to eliminate those sinusoidal components of the atmospheric which lie within the frequency curve of the apparatus. One result of this way of looking at the problem is that it does not matter where the low decrement in a circuit is placed, so long as there is a low decrement. Present wireless practice rather points to having the low-decrement effect at the low-frequency end of the wireless system, largely because it is more easily attained there. General experience agrees with the author's conclusion in so far as the reduction of atmospherics depends upon the decrement, but it does not quite agree with the analysis in the paper in regard to the position of that decrement. On page 358, taking the figures of Watt and Appleton of 0·1 volt per metre, the author says: "It would appear that E may be reduced to a few microvolts per metre and yet be sufficiently strong to hold its own against the atmospheric ordinarily to be expected in this country." This led me to think that Watt and Appleton's value of 0·1 volt per metre (which was taken in the winter time) did not apply to the average summer atmospheric, as practical experience shows that E must be much more than a few microvolts per metre in order to hold its own against the ordinary atmospheric. In Section 7, which deals with the effects of atmospherics on a tuned loop aerial, the ratio of signal to atmospheric on the frame and on the vertical antenna is given as ω/p. This means that the frame is 100 times better than the vertical antenna at 6 000 metres wave-length. That is not in accordance with practical experience. My own experience indicates that a frame is only better than a vertical antenna as regards its directive effect. Friis, in the *Radio Review* a few years ago, came to the conclusion that a frame and a vertical antenna were equal in effect. He took a different form of atmospheric, but he showed—and I think that is probably the fault in this particular analysis—that with a frame antenna there is a short interval of time during which the atmospheric acts in one leg of the frame only. At a later stage the atmospheric acts in both legs, the net E.M.F. being due only to the phase difference between the equal E.M.F.'s in each leg. The author in his analysis has taken that later stage as the commencement of his atmospheric. Actually the atmospheric would cause a strong, uncompensated E.M.F. to act in the loop on one leg for a short period before it reached the other leg. That is possibly the cause of the departure from what we know to be practical experience in this ratio of loop to vertical antenna. The author quotes from Mr. Best's experiments. I believe that Mr. Best used retroaction to obtain the low figure of $n\delta = 100$ in his experiments. Below that point he was troubled with what is known as "ringing" on the circuit. I am not quite clear what effect retroaction has on such ringing: without retroaction I have got as low as 80 on the low-frequency portion of the circuit without any sign of ringing what-

ever. There is one limitation on the use of low decrements which has not been discussed so far. That is, it is possible to reduce the decrement to such a point that satisfactory signals are obtained, either aurally or by relay, in the absence of atmospherics. In the presence of atmospherics, however, the operator prefers a high decrement to a low decrement for *aural* reception. The explanation, I think, is that so long as the atmospheric is represented in the telephones by a noise, the signal, which is a musical note, can be distinguished through a noise which is considerably stronger than itself. When a very low decrement is employed, the circuit filters out the side components of the noise, leaving only the centre components which produce a more or less musical tone of the same pitch as the signal. It now becomes impossible to distinguish aurally the signal from the atmospheric.

Mr. J. F. Herd: I should like to comment on the fact that the wave-forms by which these conclusions have been reached were only in the way of a preliminary report from the Radio Research Board Station at Aldershot. The continuation of the work has revealed a greater variety of shapes of atmospherics than was apparent when the smaller numbers in the first report were dealt with. The author's analysis shows that the actual shape is not so important. A new form of time base, which we are now using, gives a linear movement of the cathode-ray spot, and enables us to say with accuracy the order in which the various voltages occur. Actually the greater voltage or steeper slope does not always occur first. A type of atmospheric that would seem to have a far more serious effect on wireless receivers than any mentioned in the paper is in the form of a quasi-periodic single cycle, the half cycles being of sensibly equal voltage and of a sharp structure. These constitute 5 per cent of about 6 000 wave-forms taken, and are characterized by a greater field strength than all the other types, that is to say, a mean of about 0·2 volt per metre, which is considerably greater than the mean field strength of other atmospherics, except when there is comparatively local lightning. Even in Aldershot it is frequently observed that the disturbance is in the form of a background of considerable numerical frequency but of small individual amplitude, with disturbances of much smaller numerical frequency but of greater amplitude superimposed. Even the steady disturbance of small amplitude is, of course, still very large compared with a signal, and where considerable interference is experienced it is due to a large extent to the much greater number. It is quite possible that many atmospherics of apparently simple wave-form may be accompanied by minute ripples, which, although small in comparison with the fundamental form, may be large compared with a signal. There is no doubt that the effect of such ripples would be very important.

Mr. C. E. Horton: The general conclusions of the author agree with the observations of most wireless engineers who have had experience of atmospherics. I have examined the most important anti-atmospheric devices that have been published, and I certainly agree with the author that "the difficulty of combating atmospherics is greater than the mathematical analysis contained in this paper would suggest." The reason is, of course, that the full nature of the problem is not expressed in the original equations. The results are therefore true in themselves, but they are not the whole truth. It might perhaps have been wise to direct attention more to the quantities of electricity involved than to the potential differences, because the interference produced by atmospherics is not simply a question of amplitudes; it depends very largely upon the rapidity with which the impulses follow each other. For this reason the total quantity of electricity set in motion per second by the disturbing forces seems to be a better measure of their damaging effect than the mean or the maximum amplitude of the free oscillation. For instance, it is possible by using suitable limiting valves to arrange that the atmospherics have an amplitude in the telephones not greater than that of the signal. In some experiments on this matter I have examined the nature of the current through the telephones by means of a cathode-ray oscillograph, and I have satisfied myself that this state of limitation was actually obtaining. It might be thought that with a 1 : 1 ratio of signal to atmospheric, a signal of good strength would always be readable. But this is not so; it all depends on how frequent the atmospherics are. At the southern end of the Red Sea there are times when even Nauen is not readable, although the limitation of atmospheric amplitude may at the same time be perfect. In common with Major Lee, I should like to ask the author to explain a little more fully the equations which appear to show that the signal atmospheric ratio for a loop is ω/p times that of an aerial of the same decrement. I take it that the advantage of loop reception is now doubted by no one. It is the one anti-atmospheric device that always works; but is it as much superior to the ordinary aerial as this formula seems to hint? It has been held that the signal atmospheric ratio for a loop is two or three times that for an ordinary aerial. I have sometimes felt that that estimate is a little optimistic, but a superiority of several hundred times is suggested here. The discrepancy is so great as to warrant some explantion. Possibly a direct examination by cathode rays of the form of the E.M.F. induced by an atmospheric in a loop would throw light on the matter.

Mr. J. E. Taylor: The author points out that one of the limitations in decreasing the antenna decrement in order to obviate or reduce the effect of atmospherics is the phenomenon of ringing. No doubt that is true, but is it not in effect a recommendation for the use of shorter waves for signalling? I was much interested in the view which Dr. Appleton expressed, viz. that all atmospherics are due to lightning flashes. His definition of a lightning flash is rather broad. In his view, apparently, all electric disturbances of whatever kind that may occur in the course of a thunderstorm are lightning flashes. It appears to me, however, that it is likely that the flash itself is only the full development of an electrical disturbance, and that full development only occurs very occasionally, the initial disturbances which do not mature into a flash proper being much more frequent. I am not inclined to agree with Dr. Appleton's view because, for one reason, a wireless antenna

probably only picks up a very small proportion of the total atmospherics existing. This will be realized if an isolated earthed telephone line is used instead of a wireless antenna for picking up atmospherics. They can then be frequently heard in great profusion and with their various sound characteristics faithfully reproduced, so that numerous different types can be picked out which repeat themselves at irregular intervals. Individual lightning flashes can also be readily recognized on such a circuit, though doubtless certain high-frequency atmospherics may be ignored by the simple telephone receiver. Some of the types heard are palpably not lightning flashes, whatever else they may be.

Mr. R. H. Barfield: To me the most interesting point in the paper is the great superiority which the author's analysis gives to the loop over the antenna from the point of view of freedom from atmospherics. If his view were correct, the use of the antenna for reception purposes would be likely to disappear. He admits, however, that there is no experimental confirmation of this conclusion. One possible explanation of this discrepancy between theory and the observed fact is that the loop in picking up the atmospherics may be acting as an antenna. That is to say, it may be the "antenna effect" of the loop which is responsible for the greater part of the atmospheric disturbances obtained in practice. When receiving signals on a loop the antenna effect may easily be of the order of 10 per cent of the loop effect, but for atmospherics the ratio of the former to the latter might conceivably be very much greater than 100 per cent, since the loop acting as an antenna would have a high decrement and this circumstance has been shown by the author to favour greatly the atmospheric as opposed to the signal. Even if the loop were compensated for antenna effect as regards signals, it is probable that this compensation would not hold good for atmospherics.

Mr. W. J. Brown: In the recent Westinghouse Metropolitan-Vickers tests on 100-m transatlantic transmissions, the ratios of signals to atmospherics were carefully estimated, using a frame aerial and an open vertical antenna, and it was found that very little improvement indeed resulted from using a frame aerial. In this case, the wave-length being 100 m, $\omega/p = 6\,000$, so that even if 10 per cent were allowed for antenna effect on the frame aerial, a ratio of 600 could still be expected. The fact that on these very short wave-lengths there is no real advantage in using a frame aerial, seems to bear out the idea that there must be something not accounted for in these formulæ.

Mr. C. F. Phillips: The author mentions that the only hope he has of combating atmospherics lies in the use of some type of frame. One type of antenna does seem to show a higher ratio of signal to static than any other form at present known. I refer to the Beveridge antenna—a long, low wire perhaps only a few feet off the ground, of at least half a wave-length and preferably several wave-lengths in dimension. The previous speaker referred to the transmissions on 100 m from the United States. I have not tried to receive them on a frame aerial, but I have done a good deal of reception on a high antenna normally subject to very considerable interference. On these short waves, the conclusions shown in Equation (3) seem to be very fully justified, as what most people take to be atmospherics I think are valve noises or noises that occur in the set. There is a very great disparity between the opinions of the author and those of Major Lee regarding the position in which retroaction might introduce negative resistance. I have always held the opinion that a more selective circuit can be obtained by introducing negative resistance as close to the aerial as possible, and personally I prefer that way of working. Reaction or retroaction, when applied to what the author has termed a "stopper" circuit, does not seem to be particularly valuable unless the decrement of the aerial circuit is quite low.

Major H. P. T. Lefroy: The author, in dealing with the reduction of atmospherics, appears to assume that their complete elimination is so improbable that this point does not need consideration. In this we should probably all be inclined to agree with him; the following remarks may, however, be of interest in this connection. At Cairo, in September 1917, I was experimenting on a four-wire aerial suspended from the top of the Great Pyramid to the Nile River level, i.e. a vertical height of about 600 ft. Atmospherics were, of course, extremely strong, and, as they hindered our work, I was constantly experimenting with a view to the reduction of their effect. On the occasion under consideration I was using a modified Marconi No. 16 tuner, arranged for combined high- and low-frequency magnification on a "Round" soft valve, with a carborundum detector, as usual, but instead of connecting the grid and filament direct to the aerial they were connected to a closed grid circuit which was not directly coupled to the aerial. The aerial was coupled magnetically to a tuned plate-circuit, and the latter was coupled also to the tuned grid circuit, so that the plate circuit acted as a filter to the grid circuit, and the arrangement was practically the same as that of a continuous-wave transmitter. I observed that when there was a certain intensity and direction of coupling between these three circuits, I could receive signals well with reduced filament current, and that the effect of atmospherics was then considerably reduced. On further reducing the filament current and then making these couplings tighter, and also slightly retuning the grid and plate circuits, I found that atmospherics became still weaker, and finally I completely eliminated them. I was adjusted to a wave-length of 600 m, and soon after obtaining this result I received exceptionally loud spark signals from Alexandria on this wave-length, thus proving that my apparatus was still very sensitive for the reception of desired signals. Unfortunately I had to leave Cairo for Baghdad two days later, and I can now find no detailed record of my circuits, nor have I since been able to reconstruct the exact arrangement necessary; perhaps some other experimenter may yet find this arrangement, or another one giving similar results.

Mr. J. Hollingworth (*communicated*): In a paper of this nature consisting chiefly of mathematical analysis the two points most suitable for discussion are the premises on which the fundamental formulæ are based, and the generalized conclusions drawn from the results. In the first of these categories falls the formula assumed for the shape of the atmospheric. Pending the develop-

ment of a photographic method of recording these traces, the scheme of hand reproduction of a visual trace seems to be hardly one on which a critical analysis can be based. In addition, the author refers to the importance of the ripples in the atmospheric wave-form in determining the initial rate of growth. I believe that the size of the spot in the oscillograph is comparable with its maximum amplitude, and it seems that under such conditions superimposed ripples of considerable amplitude might be present without being detected. I should like to ask the author how far the important statement—that the determining factor in the disturbance produced is determined by the initial rate of rise—holds for ripples whose frequency approaches that of the tuned circuits, and when it would require modification. Also, how far do the results of Section 5 hold for the ordinary case of a secondary circuit coupled to the aerial with the valve in the usual position; as the reduction of aerial resistance by retroaction appears to involve a considerable risk of throwing the whole aerial circuit into a condition of oscillation and consequently of interference? Two small points arise with regard to the very low decrements advocated by the author. One is that retroaction pushed to the limit cannot be regarded as a mere reduction of effective resistance only, but is also accompanied by modification of the other constants of the circuit; and the other that in a practical case the frequency of transmission is liable to swing considerably about its mean position. If the decrement be too low these swings will be accompanied by very large variations in signal intensity. The author is to be congratulated on grasping the fact, appreciated by far too few mathematicians, that, in a subject like this where conditions cannot be rigidly specified, the prime object is to indicate general conditions of behaviour rather than to give numerical results.

Dr. N. W. McLachlan (*communicated*): Equation (7) is in error, due to the assumption that di/dt is zero when t is zero. Taking the author's equation to the atmospheric, viz. $h = He^{-bt} \sin pt$, where h is the instantaneous value of the magnetic field, the value of $L \cdot di/dt$ is equal to $d(ANh)/dt = -pANH$ when $t = 0$, since there is then no ohmic voltage-drop in the circuit, the current being zero. In other words $L \cdot di/dt$ is equal to the voltage induced in the loop due to the variation in the magnetic field. Putting this value in the expression for i, and using the author's approximations, we find that $i \doteq (-p/\omega)\, ANHe^{-mt} \sin \omega t$. The ratio (maximum steady signal)/(maximum atmospheric) is then $(H'\pi\omega)/(H\delta p)$, which is similar to that for a tuned open aerial. It follows, therefore, that for the type of atmospheric under consideration, a tuned frame or loop has no advantage over a tuned open aerial, excepting that possessed in virtue of its directional properties. This only holds, of course, when the signal current in the loop has attained a sensibly steady value. With a circuit of very low decrement the initial and final transients would have to be taken into consideration. Apart from the analytical viewpoint, it is clear that Equation (7) does not truly represent the physical aspect of the matter, since the current in the loop cannot increase with increase in decrement of the atmospheric. Also from the equation immediately preceding (9) we can see that the presence of b in the denominator indicates something which is opposed to an accurate physical concept of the problem. In Section (12) it is shown that, except for the effect of the decay period at the termination of a Morse character, the ratio Q_S/Q_A is independent of the damping of the receiver circuit. The result of the analysis *expressed in this form* is apt to lead to the erroneous impression that no advantage is gained by using circuits of low decrement. Although the quantity of electricity rectified, due to either signal or atmospheric, increases with decrease in decrement, the vector sum or difference of the signal and atmospheric, prior to rectification, increases in favour of the signal. It is this resultant voltage with which we are concerned in reception. Moreover, it can be seen—on this voltage basis—that after rectification the lesser atmospherics become innocuous when the decrement is sufficiently low, for the voltage of the atmospheric—even when it is initially in opposite phase to the signal in the receiving circuit—is never large enough to cause any material alteration in signal

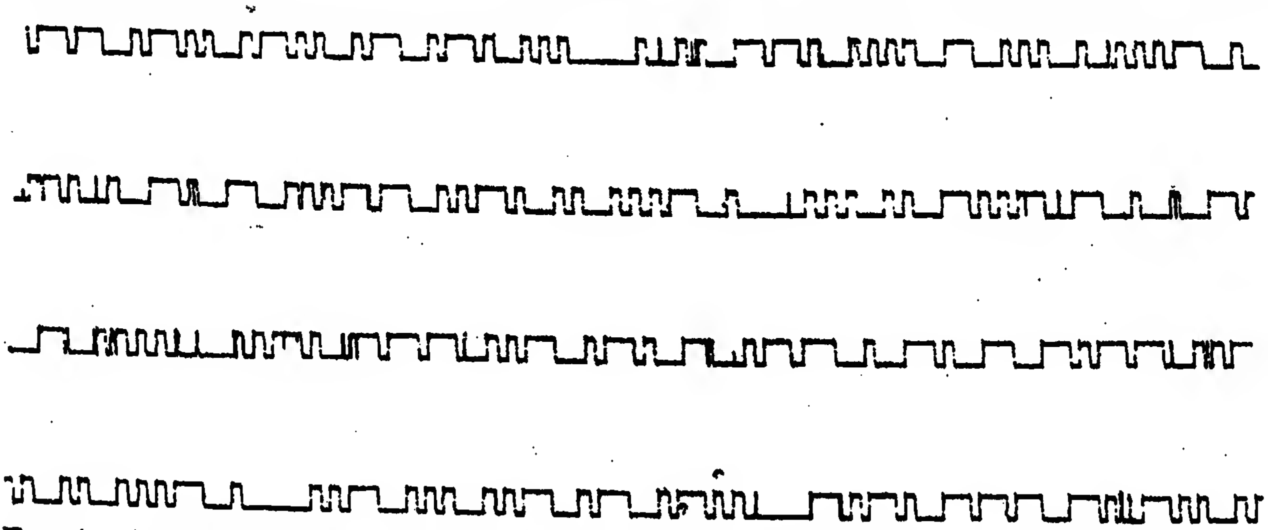

FIG. A.—Portion of message from New Brunswick, U.S.A. (WII), received at Chelmsford with a magnetic drum recorder on the 2nd July, 1923, using a frame aerial 3 ft. 9 in. square. Automatic transmission at 25 words per minute.

Atmospherics are clearly shown as thin upright strokes, which on the actual tape are quite straight. Owing to the rapidity of action of the instrument, the tape is not rendered illegible.

strength. So far as the recording of signals is concerned, the following remarks may be of interest. With strong atmospherics, provided they do not occur too frequently and the speed of transmission is not too high, it is possible, by using a suitable receiving circuit and a recording instrument which responds very quickly, to obtain a legible record. Fig. A shows a record of signals from New Brunswick (WII) taken at Chelmsford about 7 p.m. on the 2nd July, 1923, with my Magnetic Drum Recorder.* Despite atmospherics the tape is quite legible, since the duration of the impulses in the recorder circuit is much less than that of a dot. To secure this condition the circuit must be properly adjusted as regards damping; also as regards signal strength at the recorder. It should be observed that an oval, or chisel-pointed, siphon giving thin up and down strokes is essential to secure optimum legibility. When the record was obtained, the strength of the atmospherics was such that an open aerial accompanied by a receiving circuit comprising high-frequency retroaction and three low-frequency filter units of low decrement gave unreadable tape. For satisfactory recording, a frame 3 ft. 9 in. square having seven turns of stranded wire was used.† Stabilized retroaction was employed on the frame, and after suitable high-frequency amplification and heterodyning, the signals were rectified, working on the curvature of the anode-grid characteristic. The retroactive circuit was adjusted so that signals from the rectifier were clear-cut. Following the rectifier was a three-stage inter-valve tuned note filter (2 000 periods) with air-core coils of variable coupling, whose selectivity characteristic could be varied. The signals from the third valve were just "ringing," so that aural reception was not unpleasant. The voltage variation on the plate of the valve was applied to a d.c. converter unit of the type devised for the recorder.‡ The anode voltage on the note filters and converter unit was 240, so that substantial negative potentials could be applied to the grids of the amplifying valves to reduce the possibility of grid current or of the rectification or saturation limits being reached due to high-voltage atmospherics. There was no limiting valve device in the circuit, since sensibly linear amplification was desired.

Professor E. W. Marchant (*communicated*): The paper is open to the objection that must apply to all purely mathematical papers, namely, that the premises on which the mathematical analysis is based are incomplete. The paper by Messrs. Appleton and Watt recording the actual wave-shape of atmospherics has thrown a great deal of light on their true nature, but the records that they have published include only a relatively small number of atmospherics which have been observed at one time of the year only. An analysis such as that which has been made by the present author, although useful in throwing light on the factors which are of importance in reducing atmospheric disturbances, deals with only one or two forms of atmospherics, and one would like to see a more complete record of the actual wave-forms of atmospherics before coming to any conclusion as to the effectiveness or ineffectiveness of any particular method of reducing their effect. During the past year we have been making a number of experiments at Liverpool on methods of reducing disturbances due to atmospherics, and other causes, mostly on short wave-lengths. The disturbances which were found to be most troublesome were those due to electrical currents which produce effects not unlike the atmospherics recorded by Messrs. Appleton and Watt, and we have found experimentally that the use of an aperiodic aerial has considerably improved the signals received, i.e. it has reduced the ratio between the "atmospheric" and the signal. The reason for the improvement is, I think, that in the author's words, "the high-frequency part" of the solution of his differential equation has been cut down. On page 361 he refers to the method of slightly distuning the aerial from the received signal. As he says, such a distuning can have very little effect on the magnitude of the high-frequency current set up by the atmospheric, but will make the frequency of this current appreciably different from that of the signal for which the amplifier is tuned. The method, which was proposed many years ago by Marconi, of using two secondary circuits, both coupled to the antenna, one tuned and the other slightly distuned from the received signal, and balancing these circuits so that when they have equal currents flowing in them they will produce no effect on the receiver, is an illustration of the application of this method. In practice, however, it is stated by those who have used the method that the effect of slightly distuning one of the circuits is to alter very appreciably the currents due to atmospherics flowing round it, with the result that the two circuits no longer remain balanced for atmospheric disturbances, and considerable noise is produced in the receiver. I have suggested elsewhere that this effect may be due to the production by the atmospherics of oscillations in the aerial—what the author calls the "high-frequency current"—due to the complementary function in the solution of his differential equation. The use of the balanced system with an aperiodic aerial would, I believe, be much more beneficial and I hope it may be tried under conditions where atmospherics are very severe. On page 364 it is stated that the tuned aerial or the combination of any form of aperiodic antenna with a selective amplifier can always be made to give an identical ratio of signal to atmospheric by adjusting the decrement of the first oscillatory circuit of the chain. There is, of course, a fairly high "lower limit" to the decrement which can be obtained on an ordinary aerial for the reception of broadcast messages. For example, in order to reduce disturbance in buildings, it is often beneficial to use an "earth mat" instead of connecting to water pipes, although the effective resistance of the aerial circuit with this arrangement is increased and the signal strength diminished. The signal strength is, of course, cut down by the insertion of extra resistance in the aerial, and the signal is therefore correspondingly weakened, but the signal strength can usually be increased again as much as is necessary by using amplifiers. We have found in practice that the ratio of signal strength to noise due to disturbance or atmospherics can be appreciably increased by inserting

* *Journal I.E.E.*, 1923, vol. 61, p. 910.
† In this case the superiority of the frame, due to its directional properties, was clearly shown.
‡ *Loc. cit.*, Fig. 11.

resistance in the aerial. In his "Conclusion" the author points out what must be evident to everyone, viz. that the mathematical analysis contained in the paper does not correspond very closely to practical results. As he says, the mathematical analysis suggests that, to cause serious disturbance, atmospherics would have to be at least 10 times as strong as those measured by Watt and Appleton. The paper is of interest in showing the way in which the effect of certain types of atmospherics, such as have been recorded by Messrs. Watt and Appleton, can be reduced, but it will require a very much more elaborate analysis if the effect of the almost innumerable combination of disturbances that are met with in a wireless receiving set can be discussed mathematically. The only method which can lead to a practical solution of this problem is that of observation and experiment.

Mr. E. B. Moullin (*in reply*): Some speakers have suggested that a mathematical analysis is of little practical use since it does not include all the factors in the problem. I cannot agree with this. I think that finally the problem can be studied only experimentally, but unless the programme of such experiments is directed by analysis there cannot be, in my opinion, much hope of success. In this problem we have at least eight independent and controllable variables, as well as several independent variables not under control which arise from the atmospheric itself. Should an optimum combination of these many circuit variables exist, the chance of happening on it experimentally is very small. Had my analysis depended on an exact wave-form for the atmospheric it would indeed have been useless, but it shows that all atmospherics having the same initial rate of increase will produce sensibly the same result whatever their subsequent shape. I made this analysis preparatory to starting on experimental work, and I hope that it may be of use as a rough guide to other experimenters and show which are the most suitable avenues of attack.

Mr. Hollingworth asks if the analysis is valid for ripples of which the frequency approaches that of the tuned circuit. This question can be answered by means of the analysis in Section (4) leading up to formula (1). If the main atmospheric is accompanied by a slightly damped ripple of one-tenth its amplitude and having a frequency one-quarter that of the tuned circuit, the resulting current would be about 4 per cent greater than if it had been calculated from the true initial slope, but the presence of the ripple would increase the current about four times. Hence I think we may say that the disturbance is always sensibly proportional to the initial slope, but it is probable that the apparent initial slope as shown by the oscillograph as constructed at present may be quite different from the true value. As pointed out in Section (10), I think that this is the chief reason why the numerical part of this analysis appears to underestimate the difficulties of the problem. The analysis is valid for ripples, and to obtain correct numerical results we must doubtless take some other value for ω/p, say 6 or 7, and a reduced value for A, and add the result to the figures given in the paper. The results of Section (5) do not apply directly to the case of an intermediate tuned circuit between the antenna and the amplifier. This case is easily worked out because the low-frequency current can be ignored. The problem is therefore the same as that of spark reception with a double tuned circuit; and I think that the modifying factor to be applied to formula (3) would be negligible. With present conditions I agree that the unsteadiness of transmitter frequency is likely to impose a limit on the decrement, but I do not think that modification by retroaction of the circuit constants will affect the results, for the circuit will simply be retuned to suit those conditions.

Major Lee suggests that the atmospheric be represented by a Fourier integral. I did not do this because the analysis is more complex and less readily reduced to a generalized form. We must argue with care from the spectrum analysis of a pulse, because we must remember that the pulse is represented by the net effect of the simultaneous presence of every frequency. I do not think that we can necessarily ignore the presence of an infinite number of finite terms the frequency of which lies outside the resonance band. An aperiodic pulse can scarcely have the same effect as sustained and uninterrupted sinusoids having a frequency lying within an indefinitely narrow band. The sum of the infinite number of terms which lie outside that band must evidently produce a finite effect. Also the effect of those acoustic frequencies which lie within the band of the low-frequency amplifier, and which are vastly diminished by their passage through the high-frequency amplifiers [see Section (12)], may not produce the same effect as the high-frequency band which is amplified. Hence, although his argument for putting the low decrement anywhere in the chain may be correct, I do not think that it can be proved without detailed analysis.

Major Lee and Dr. McLachlan have both pointed out an error in the treatment of the loop aerial. I agree with Dr. McLachlan that I was in error in taking the initial value of di/dt to be zero, though if the loop be treated properly, in the way Major Lee suggests, the initial value of di/dt would be zero. I am grateful to those speakers for clearing up a point which common experience suggested was wrongly treated somewhere: their remarks answer the questions of several other speakers.

Mr. Horton suggests that the ratio which I have taken of signal to atmospheric does not represent the amount of disturbance produced, but since I have carried on my analysis to compare the quantities of electricity rectified [see formula (18)] I think that my ratio is a suitable measure of disturbance. If the effect of a succession of atmospherics is to be calculated it is necessary to consider the phase relation of one pulse to another.

If I understand Dr. McLachlan correctly, he suggests that an atmospheric which occurs during a Morse sign is not likely to produce as much disturbance as one which occurs during a space. If this be the case, my analysis, which does not consider the co-existence of signal and atmospheric, is more complete than I had supposed. The photographic records, however, do not seem to bear this out, for many atmospherics which occur during a sign bring the signal current down to zero. The signal current never seems to be increased by the atmospheric, but possibly this is due to a limit on the siphon.

DISCUSSION ON "LOUD-SPEAKERS FOR WIRELESS AND OTHER PURPOSES."

FURTHER COMMUNICATIONS TO THE DISCUSSION.*

Dr. W. A. Aikin (*communicated*): Without going too deeply into the science of phonology, which is a special branch of physiology for the study of the vocal organs and their functions, I think that some of its facts and principles might be useful in this discussion. We learn from the natural phenomenon known as the "resonator scale" that the resonation of vocal sound is two-fold. The upper, principally in the mouth, is a complex of high reinforcements with a definite resultant, giving vowel-character; whereas the lower, principally in the neck, expands for deeper reinforcements, giving "tone" or general quality to the sound. By this arrangement sonorous quality increases the amplitude of the sound waves by reinforcing deep harmonics, and the special characters of vowels may be represented by furrows of various designs upon the vibrations. Remembering that sound waves are in three dimensions, the delicacy of the sense which detects the shapes as well as the amplitude and frequency of the vibrations as they fall upon the drum of the ear, is wonderful indeed. In declamation we rely more upon deep resonation than upon force, and therefore the mechanical loud-speaker should be constructed with a view to preserving and even augmenting this function, if the natural "humanity" of speech is not to be impaired. I would therefore draw particular attention to the deeper effects of resonation in any experiments that are made; for the smaller vibrations of character will come through almost anything, whereas the deeper effects of tone are easily destroyed. Mentioning experiments reminds me that I sought for years in vain for a laboratory where acoustic experiments could be carried on. Then electricity and chemistry crowded out all else. Now, perhaps, someone will take up sound and make the best of mechanical voices on the same principles as the phonologist does of natural ones. Among the papers which I have written on the subject, I think that one read at the Society of Arts in 1906 and printed in their *Journal* would indicate to anyone the laws we follow. The subject of resonation is not yet fully investigated, and our greatest authority, Helmholtz, left behind him in his work on vowel sounds several unaccountable errors which have delayed our correct knowledge of the facts. His definition of the shape for the vowel AH, for instance, as "a funnel increasing with tolerable uniformity from the larynx to the lips," is anatomically impossible. Any loud-speaker made upon that pattern would, in my opinion, cut off much of the full quality or tone reinforced in the lower hollow and emitted through an open throat.

Mr. L. Miller (*communicated*): Prof. Rankine alludes to thermal receivers. Like many other useful inventions, these originated in this country and have been almost entirely dropped, while other nations have continued to develop them. Many patents have been taken out on the Continent and in America for heat-operated receivers, chiefly of the glow-lamp type, in which the air takes up the vibrations from a hot wire, no diaphragm being employed. Such receivers have been placed on the market, but it is obviously very difficult to compete with such a good and heavily-capitalized instrument as the ordinary electromagnetic telephone. I have had no experience with the thermal receivers in question, nor with the straight-wire kind with one end fixed to a diaphragm, but have made many experiments with the loose-contact receiving microphone type, which, in my opinion, is also actuated by expansion and contraction. I gave a demonstration with them in this hall, before the Wireless Society, in November 1921. They reproduce speech and music very clearly, but not at all loudly, as compared with the ordinary telephone. As claims have been made in the electrical Press (though not by me) that they can be used for loud-speaking purposes, I have recently tried at what distance from one of my receivers speech could be heard so as to be understood, and I found it to be about 3 ft. No horn was employed. One contact of fused marcasite was fixed in the centre of a large mica diaphragm, slightly pressed by another contact of hard synthetic galena. It seems very unlikely that the instrument has reached anything like finality in my hands alone, and I shall therefore conclude by endorsing the words of Prof. Fleming, in the last Kelvin Lecture,* that it is well worth further study.

Professor A. O. Rankine (*in reply*): The outstanding fact which emerges from this discussion is that apparently we cannot yet get sufficient loudness for loud-speaking purposes without relying to a considerable extent upon resonance. Perhaps in the future there will be developments on the practical side which will enable us to escape from this position, and I feel sure that this would lead to great improvement. For the present, however, we have to make the best of the actual situation, and this fact makes my opinion coincide with that of Mr. Nash, who has, I think, misinterpreted my remark about horns. I would advocate the elimination of these devices only if up to the point where their function begins the acoustic output has already suffered no distortion from resonance. If, on the contrary, as Captain Cohen has so clearly explained, present circumstances compel us to choose between pure quality and enough intensity, I agree with Mr. Nash as to the value of horns in that they may render resultant resonance less selective. They may, as I have already indicated in my introductory remarks, be used to provide additional resonances so as to balance other inevitable ones in other parts of the essential frequency scale. It would, however, be a rather fatal mistake to fashion them to suit any special vowel, as is half suggested at the end of Dr. Aikin's remarks.

* See page 265.

* *Journal I.E.E.*, 1923, vol. 61, p. 613.

Mr. Smith has suggested an arrangement suitable for visual observations on the quality of transmission. In this system the original sounds on the one hand, and the loud-speaker output on the other, are to be picked up respectively by two "as nearly as possible identical" telephone receivers, and the results recorded simultaneously on an oscillograph. I should prefer to impose the additional condition that the telephone receivers should be completely non-resonant; and I should not feel happy about the oscillograph itself unless it possessed the same negative attribute. It is a little surprising that Mr. Smith did not specify a cathode-ray oscillograph. Perhaps he recognizes no other! Mr. Sutherland in his introductory paper speaks of "desirable reverberation," more particularly in relation to music, but also as regards speech; but I still adhere to the opinion that reverberation is a thing which we have to put up with in order to hear loudly enough, and that we have virtually to learn several different languages, musical and otherwise, according to the conditions of listening. Does a speaker or a band, after all, sound so "dead" in the open air if we are close enough to hear? I disagree, however, rather reluctantly, for Mr. Sutherland's view seems to provide me with an excuse for inability to appreciate some modern music. If a correct amount of overlapping and blending by the agency of reverberation forms an essential part of the music, it might with some force be argued that I had not yet been fortunate enough to listen to the work of, let us say, Mr. Arnold Bax, in the right concert hall.

Mr. L. C. Pocock (*in reply*): Mr. Marris disagrees with the statement that a horn is the ideal form of coupling between the diaphragm and the air, and considers that one becomes tired of the horn resonance; further, he states that the presence of horn resonance can be proved by removing the horn. I should like to point out, however, that the use of a horn cannot be so lightly dismissed. It is easy to design a horn with strong resonance, and this is done in horn-type musical instruments; it is also possible, though less easy, to design a horn with much weaker resonance. The former is analogous to a resonance transformer or resonant transmission line, the latter to a transmission line in which the inductance and capacity vary continuously from end to end, and such an arrangement may, in principle, be a maximum energy coupling, although the application of the principle is restricted by the length of the horn. One may easily tire of the resonance of a bad horn, but a good horn has a far from evident fundamental, with many partials, and it can scarcely be claimed that the change of tone on removing a horn of this type proves anything, because the increased diaphragm resonance resulting from reduced damping introduces far more distortion than was caused by the horn.

Mr. Voigt endeavours to show that the efficiency of a loud-speaker is considerably greater than 1 per cent. In a reacting circuit of the kind which he describes, the oscillation point is conditioned by $\eta_1\eta_2\eta_3 = 1$, where η_1, η_2, are the loud-speaker efficiencies and η_3 is the amplifier power-efficiency. Mr. Voigt overlooks the fact that the power amplification is the square of the voltage amplification, so that if $\eta_1 = \eta_2$, and $\eta_3 = (25)^2$—using the lowest figure assumed—the loud-speaker efficiency at resonance is only 4 per cent, and the average efficiency a good deal lower. It is rather doubtful whether types of receivers having less-pronounced resonance peaks would sustain oscillations with so small an amount of amplification as that described. My own calculation of the efficiency as less than 1 per cent was based upon the estimate that normal speech represents an average emission of energy at the rate of 125 ergs per second (*Physical Review*, March 1922) and that the most efficient loud-speaker obtainable requires approximately 0·0005 watt to produce the same speech intensity. The efficiency is, therefore, about 2·5 per cent, and many loud-speakers have only one-tenth of the efficiency of the one quoted. The estimated input power of 0·0005 watt was calculated from experimental data on the R.M.S. current giving the required sound intensity, and on the impedance of the receiver at 800 periods per second.

Mr. H. L. Porter (*in reply*): One conclusion which may be drawn from this discussion is that electrical and acoustical resonance are mainly responsible for distortion in the loud-speaker. The introductory papers, however, were confined to a specialized consideration of one or other of the phenomena, but little attention has been paid to the need for their correlation. The discussion itself did not make this clear. For example, to manipulate the electrical circuit independently of the acoustic system could easily do more harm than good, for one might actually eliminate from the circuit resonances which might be permitted to play a very useful part in a suitably-chosen acoustic system. In our work on the gramophone, we found that the resonance of parts of the system which we anticipated might greatly add to the distortion proved to be very useful in arriving at our curve of uniform distribution of intensity. Again, we found that the greatest distortion did not arise from the separate resonance peaks but from their close acoustical proximity: the orderly arrangement of these peaks was most essential. It therefore seems reasonable to regard the problem of the loud-speaker in a similar manner. If an electrical circuit be used in conjunction with an acoustic system, the combination should be treated as a unit. The contribution of each part of that unit should be ascertained and, if possible, arranged for mutual assistance. In the past, work on the loud-speaker has been mostly concerned with the efficiency of the electrical circuit. There may now be the danger of investigations taking an acoustical bias. Since the final sound waves are determined both by the electrical circuit and by the acoustic system, further work should not be allowed to take what might easily be divergent paths. Our minds must be alert to both considerations.

Professor E. Mallett (*in reply*): In the original telephone receiver and in some loud-speakers the diaphragm performs a double function: it not only provides the necessary vibrating surface which moves the air particles about and so starts a sound wave, but also itself forms the mechanical system which is vibrated by the alternating speech current. In these cases resonance in the diaphragm is doubly important. In

other instruments the vibrating system is a reed or an armature with spring control, each of which will have its own peculiar resonance acting to modify the amplitude of the diaphragm at the point where it is fixed to the vibrating system, but leaving the resonances of the diaphragm still to control the distribution of amplitude over the surface of the diaphragm, and hence the emission of sound waves. In reply to Mr. Burnand, it is thought that these diaphragm resonances will occur whatever the form of the diaphragm, including the cases which he cites.

Many of the speakers have confined their attention to the resonances of the horn, and the various curves exhibited are ascribed to horn resonances. But they are in all cases to be ascribed rather to the combined mechanical resonance of reed (or other vibrator which may be a diaphragm), diaphragm and horn. One speaker, Mr. Nash, shows a curve purporting to separate these out, but the curve is admittedly a theoretical one, and none of the theory is given. But if Mr. Nash's figure for the permissible variation of power output with frequency for no appreciable distortion is correct, i.e. a variation from 100 to 850, or 750 per cent, one might be inclined to ask, "why all this fuss about resonance?" The answer seems to me to be this, that resonance may accentuate unduly a tone which was not originally transmitted. Consider, for instance, an ordinary receiver through the coils of which is flowing a current due to two simultaneously maintained notes at the transmitting end of frequencies $\omega_1/(2\pi)$ and $\omega_2/(2\pi)$. Now let the current be $i_1 \sin \omega_1 t + i_2 \sin \omega_2 t$. The pull on the diaphragm will be proportional to $(B_0 + b_1 \sin \omega_1 t + b_2 \sin \omega_2 t)^2$, where B_0 is the permanent flux, and b_1 and b_2 are the fluxes due to the currents i_1 and i_2. This expression

$$\begin{aligned} = B_0^2 + \tfrac{1}{2}b_1^2 + \tfrac{1}{2}b_2^2 + 2B_0 b_1 \sin \omega_1 t + 2B_0 b_2 \sin \omega_2 t \\ + b_1 b_2 \cos (\omega_1 - \omega_2)t - b_1 b_2 \cos (\omega_1 + \omega_2)t \\ - \tfrac{1}{2}b_1^2 \cos 2\omega_1 t - \tfrac{1}{2}b_2^2 \cos 2\omega_2 t \end{aligned}$$

Thus it is seen that alternating pulls of frequencies $2\omega_1/(2\pi)$, $2\omega_2/(2\pi)$, $(\omega_1 - \omega_2)/(2\pi)$ and $(\omega_1 + \omega_2)/(2\pi)$ are introduced as well as pulls of frequencies $\omega_1/(2\pi)$ and $\omega_2/(2\pi)$ of the original tones. It is true that the amplitudes of the additional pulls are small compared with those of the transmitted tones, provided B_0 is large compared with b_1 and b_2, but they will be appreciable if b_1 and b_2 are increased by overloading the receiver, and the amplitude of the resulting sound wave may be appreciable with quite ordinary loads if the frequency happens to be near a resonance point. With the harmonic tones $2\omega_1/(2\pi)$ and $2\omega_2/(2\pi)$ the resulting effect will probably not be unpleasant, but the summation and difference tones, $(\omega_1 + \omega_2)/(2\pi)$ and $(\omega_1 - \omega_2)/(2\pi)$, may well produce most unpleasant results. This will apply to all those loud-speakers in which there is a permanent magnetic pull on the vibrating system.

Similar considerations apply to the valve if the latter is overloaded, so that either the curved part of the characteristic is used or grid current is allowed to flow. The anode current from a double-frequency E.M.F. on the grid will then contain summation and difference terms which, if they happen to be those of resonance frequencies of the receiver may produce appreciable sound waves. It may also be that with very large sound amplitudes this effect may also appear in the throat of the horn. It would seem possible, therefore, that the question of distortion is more a matter of summation and difference tones than of the relative amplitudes of the transmitted tones. The above considerations would explain satisfactorily why telephone receivers and a loud-speaker worked to give a small sound output give really good reproduction, but that directly the output is increased distortion appears, and the greater the sound output the greater the distortion.

Captain P. P. Eckersley (*in reply*): Mr. Nash has raised the question of the horn. Briefly, the horn gives efficiency, whilst the large-diaphragm, hornless type is inefficient. If, however, the hornless type (for which I hold no brief whatsoever) gives sufficient volume with more faithful quality for an average drawing-room, it has at least served a useful purpose. The particular quality that pleased me in the type of loud-speaker which I demonstrated, was the warmth of bass tones, coupled with an extraordinary faithfulness even in the upper register. This quality might be manifest in a hornless or horn type, the low resonance being in no way intrinsic to the absence of a horn. I still reiterate that what I have called the "efficient" type of loud-speaker with resonances around 1 000 periods per second can never give faithful reproduction, and that lack of warmth in the bass, a minimization of higher harmonics, and a barking of vowel sounds in speech are all characteristic of this type of instrument. Our ears are most sensitive to this middle register, and are asking all the time for stronger extremes of the sound gamut. This must be the next great advance in loud-speaker design; whether the horn will be used or not is immaterial to the question of proper frequency recognition.

PROCEEDINGS OF THE INSTITUTION.

32ND MEETING OF THE WIRELESS SECTION, 7 NOVEMBER, 1923.

(Held in the Institution Lecture Theatre.)

Dr. A. Russell, President, took the chair at 6 p.m.

The minutes of the meeting of the Wireless Section held on the 6th June, 1923, were taken as read and were confirmed and signed.

A vote of thanks to Professor G. W. O. Howe for his services as Chairman of the Wireless Section during the past two Sessions was proposed by the President, seconded by Dr. W. H. Eccles, F.R.S., and carried with acclamation.

Mr. E. H. Shaughnessy, O.B.E., Chairman of the Wireless Section, then delivered his Inaugural Address (see page 51).

A vote of thanks to Mr. Shaughnessy for his Address, proposed by Admiral Sir Henry Jackson, G.C.B., K.C.V.O., F.R.S., and seconded by Mr. A. A. C. Swinton, F.R.S., was carried with acclamation, and the meeting terminated at 7.10 p.m.

33RD MEETING OF THE WIRELESS SECTION, 21 NOVEMBER, 1923.

(Held in the Institution Lecture Theatre.)

Mr. E. H. Shaughnessy, O.B.E., Chairman of the Section, took the chair at 6 p.m.

The minutes of the meeting of the Wireless Section held on the 7th November, 1923, were taken as read and were confirmed and signed.

A paper by Dr. E. V. Appleton, M.A., and Mr. F. S. Thompson, B.A., entitled "Periodical Trigger Reception" (see page 181), and a paper by Mr. R. C. Clinker, Member, entitled "A Dynamic Model of a Valve and Oscillating Circuit" (see page 125), were read and discussed. On the motion of the Chairman a vote of thanks to the authors was carried with acclamation, and the meeting terminated at 7.24 p.m.

704TH ORDINARY MEETING, 22 NOVEMBER, 1923.

[JOINT MEETING WITH THE SOCIÉTÉ DES INGÉNIEURS CIVILS DE FRANCE (BRITISH SECTION).]

(Held in the Institution Lecture Theatre.)

Dr. A. Russell, President, took the chair at 6 p.m.

The minutes of the Ordinary Meeting of the 1st November, 1923, were taken as read and were confirmed and signed.

The President announced that the French Government had awarded to Mr. C. H. Wordingham, C.B.E., and to Mr. Twelvetrees the Diploma of the Officer of Public Instruction, and he asked Monsieur Guéritte, who had obtained the Diplomas from the French Ambassador, to present one to Mr. Twelvetrees, Mr. Wordingham being unavoidably absent.

Monsieur Guéritte then presented the decoration to Mr. Twelvetrees.

A paper by Mr. A. Bachellery, entitled "The Electrification of the French Midi Railway" (see page 213), was read and discussed.

On the motion of the President a vote of thanks to the author was carried with acclamation. The meeting terminated at 7.50 p.m.

705TH ORDINARY MEETING, 29 NOVEMBER, 1923.

(JOINT MEETING WITH THE PHYSICAL SOCIETY OF LONDON.)

(Held in the Institution Lecture Theatre.)

Dr. A. Russell, President, took the chair at 5.30 p.m.

The minutes of the Ordinary Meeting of the 22nd November, 1923, were taken as read and were confirmed and signed.

A discussion took place on "Loud-Speakers for Wireless and other Purposes," in connection with which the following introductory papers were read (see pages 265 to 285):—

Prof. A. O. Rankine, D.Sc.: "General Principles involved in the Accurate Reproduction of Sound by means of a Loud-Speaker."

Mr. L. C. Pocock, B.Sc.: "Theory of Loud-Speaker Design."

Prof. C. L. Fortescue, M.A.: "The Sources of Distortion in the Amplifier."

Mr. H. L. Porter, B.Sc.: "The Acoustic Problems of the Gramophone."

Mr. E. K. Sandeman, B.Sc.: "The Relative Importance of each Frequency Region in the Audible Spectrum—Measurements on Loud-Speakers."

Prof. J. T. MacGregor-Morris and Prof. E. Mallett, M.Sc. (Eng.): "The Overtones of the Diaphragm of a Telephone Receiver."

Mr. G. A. Sutherland, M.A.: 'Auditorium Acoustics and the Loud-Speaker."

Mr. S. G. Brown, F.R.S.: "Some Directions of Improvement in the Loud-Speaking Telephone."

Captain P. P. Eckersley: "The Characteristics of a New Type of Loud-Speaker."

The discussion was adjourned and the meeting terminated at 9.40 p.m.

34TH MEETING OF THE WIRELESS SECTION, 5 DECEMBER, 1923.

(Held in the Institution Lecture Theatre.)

Mr. E. H. Shaughnessy, O.B.E., Chairman of the Section, took the chair at 6 p.m.

The minutes of the meeting of the Wireless Section held on the 21st November, 1923, were taken as read and were confirmed and signed.

A paper by Mr. L. B. Turner, M.A., Member, entitled "The Relations between Damping and Speed in Wireless Reception" (see page 192), was read and discussed. On the motion of the Chairman a vote of thanks to the author was carried with acclamation, and the meeting terminated at 7.40 p.m.

706TH ORDINARY MEETING, 13 DECEMBER, 1923.

(Held in the Institution Lecture Theatre.)

Professor E. W. Marchant, D.Sc., Vice-President, took the chair at 6 p.m., in the unavoidable absence of Dr. A. Russell, President.

The minutes of the meeting of the 29th November, 1923, were taken as read and were confirmed and signed.

A list of candidates for election and transfer approved by the Council for ballot was taken as read and was ordered to be suspended in the Hall.

A paper by Mr. D. Brownlie, B.Sc., entitled "Pulverized Fuel and Efficient Steam Generation," was read and discussed. On the motion of the Chairman a vote of thanks to the author was carried with acclamation, and the meeting terminated at 7.55 p.m.

35TH MEETING OF THE WIRELESS SECTION, 2 JANUARY, 1924.

(Held in the Institution Lecture Theatre.)

Mr. E. H. Shaughnessy, O.B.E., Chairman of the Section, took the chair at 6 p.m.

The minutes of the meeting of the Wireless Section held on the 5th December, 1923, were taken as read and were confirmed and signed.

A paper by Mr. R. H. Barfield, M.Sc., Student, entitled "Some Experiments on the Screening of Radio Receiving Apparatus" (see page 249), was read and discussed. On the motion of the Chairman a vote of thanks to the author was carried with acclamation, and the meeting terminated at 7.10 p.m.

707TH ORDINARY MEETING, 3 JANUARY, 1924.

(Held in the Institution Lecture Theatre.)

Dr. A. Russell, President, took the chair at 6 p.m.

The minutes of the Ordinary Meeting of the 13th December, 1923, were taken as read and were confirmed and signed.

A list of candidates for election and transfer approved by the Council for ballot was taken as read and was ordered to be suspended in the Hall.

The following list of donations was taken as read and the thanks of the meeting were accorded to the donors:

Benevolent Fund: W. H. Bottomley; R. V. Broberg; C. Cartmell; T. C. Christianson; E. T. Clifford-Jones; A. C. Coward; H. J. Finder; F. W. Geoghegan; P. H. Gwynn; Messrs. W. T. Henley's Telegraph Works; T. W. E. McKew; W. G. P. Mitchell; F. Riley; W. G. Smith; and The "Twenty-five" Club (per Mr. W. B. Esson).

Dr. S. P. Smith, Member, then delivered a lecture entitled "Railway Electrification in Foreign Countries" (see page 317), and the lecture was followed by a discussion (see page 322). On the motion of the President a vote of thanks to the lecturer was carried with acclamation, and the meeting terminated at 7.45 p.m.

708th ORDINARY MEETING, 10 JANUARY, 1924.

[Joint Meeting with the Société des Ingénieurs Civils de France (British Section).]

(Held in the Institution Lecture Theatre.)

Dr. A. Russell, President, took the chair at 6 p.m.

The minutes of the Ordinary Meeting of the 3rd January, 1924, were taken as read and were confirmed and signed.

The discussion on Mr. A. Bachellery's paper entitled "The Electrification of the French Midi Railway" (see page 213), was continued, and the meeting terminated at 7.25 p.m.

709th ORDINARY MEETING, 17 JANUARY, 1924.

(Held in the Institution Lecture Theatre.)

Dr. A. Russell, President, took the chair at 6 p.m.

The minutes of the Ordinary Meeting of the 10th January, 1924, were taken as read and were confirmed and signed.

Messrs. A. H. Allen and A. T. Dover were appointed scrutineers of the ballot for the election and transfer of members and, at the end of the meeting, the result of the ballot was declared as follows:—

Elections.

Members.

Aitken, Robert.
Cornfoot, Thomas.
Kennedy, Peter.
Kirkland, John Wilkinson.
Prince, Charles Edmond, Major.
Street, Charles Frederick.

Associate Members.

Adendorff, Gerald Victor.
Barnard, Frederick George.
Bowen, James Bevan, Wing-Commander R.A.F.
Brown, Cecil Norman.
Davies, Ralfe Davidson, Lieut. R.E.
Gage, Ernest Cecil.
Galliard, John Douglas.
Glanville, George Grosvenor.
Kendon, Donald Henry.
Lewtey, William Cruchley.
Mayral, Arthur Lawrence G.
Ohtsuki, Takashi.
Rawlinson, Rowland Henry.
Ricci, Ralph Elwyn.
Rissik, Jacob Willem, B.Sc. (Eng.).
Sheldrick, John Engledow, B.Sc. (Eng.).
Smith, Arthur Eric, B.Sc. (Eng.).
Smith, Ronald.
Struthers, George Alexander.
Tilley, Herbert Benjamin.
Toogood, Henry Featherston.
Varadachari, Perungavin.
Wilson, Herbert.
Workman, Eric Walter, B.Sc. (Eng.).

Graduates.

Ashton, William Thomas.
Atherton, John Francis.
Bickerstaff, Ernest.
Birkby, Harold.
Bliss, William Arthur.
Burn, Walter.
Carter, Arthur.
Close, Charles Victor.
de Burgh, Desmond, Herlouin, Flight Lieut. R.A.F.
Duce, George William, B.Sc. (Eng.).
Earle, Beresford Langston.
Eggins, Leonard George.
Forrester, James Shannan.
Garrett, Percival Theodore.
Ghosh, Surendra Nath.
Gill, Ernest William.
Glass, Francis.
Gould, Frank.

Graduates—continued.

Grainger, Oliver.
Groser, Stanley Rust.
Hall, John, B.Sc. (Eng.).
Hay, Andrew.
Henzell, George Peregrine.
Hewitson, Maynard.
Hounsell, Ernest Alfred.
Hughes, Lionel Jutson.
Kaempf, Emil.
Langlands, George Boyd.
Lucas, Leonard Hillyer.
Lundy, George Alfred.
McLaughlin, Bernard Alphonsus.
Mayo, Oswald James.
Mill, Harry.
Mitchell, George William.
Munro, John.
Nicholes, Samuel.
Nixon, Thomas Edgar B.
Osborn, Thomas Lester A.
Pearce, Reginald.
Pollack, Leonard Austin.
Pound-Corner, Harold Sinclair, B.A.
Procter, William Skirrow.
Scott, Alexander Theodore.
Sinclair, Harold.
Smith, Hubert Alfred, B.Sc.
Tozer, Robert James M.
Valentine, Arnot Stirling.
Verma, Panna Lal.
Wells, Charles Frederick.

Students.

Adbûtharaj, Rajiah.
Aiken, Leslie James.
Allcock, Frank Byard.
Anderson, Frank Cordue K.
Anderson, James Peter.
Anderson, Savile.
Andrews, Allan.
Archer, Leslie John.
Aria, Dadiba.
Atkins, James Walter.
Attlee, John Stuart.
Austen, Donald Edwin H.
Austin, Percy Ellis, B.Sc. (Eng.).
Azimuddin, Mohamed.
Bagnall, Maurice Arthur.
Bagshawe, Alexander Sinclair.
Baker, Ernest Edward.
Baldwin, Cecil Spence S.
Ball, William Barnard, B.Sc.
Banbury, Leonard Glanville.
Banks, Rowland Victor.
Bannatyne, Andrew Mansfield.
Bartlett, Cecil Vernon.
Batten, Ernest Richard.
Batty, Bernard.
Beer, Horace George.
Behrman, Boris.
Bell, Ian.
Bertone, John.
Bishop, John Montague, B.E.
Bogie, Andrew.
Bowden, George Herbert.
Boyne, John Grant.
Braid, Kenneth Edwin P.
Brailsford, Fred.
Brewer, Arthur Ernest.
Brierly, Richard Francis H.
Brown, Robert Redman.
Bull, Malcolm James.
Bush, Alfred John.
Cade, Sydney George.
Canning, Horace Reginald.
Carfrae, William John.
Carter, Murray Oliphant.
Catchatoor, George Eardley A.
Chapman, Geoffrey Tancock.
Chenevix-Trench, Lionel Geoffrey.

Students—continued.

Chisnall, Cecil Ernest.
Church, John William G.
Cleveland, George Robert E.
Cobb, Kenneth.
Cochran, Robert Jack.
Cokart, Petrus Isaac.
Cole, Frank Jaspar.
Colmar, Geoffrey Charles.
Connolly, Reginald Charles H.
Cook, Albert Edwin.
Cooke, Norton Robson.
Cooper, George Frederick.
Cox, Albert Rowland.
Crawshaw, Cyril John, B.Sc. (Eng.).
Crisp, Arthur Bright.
Cronwright, Roy Bazett, B.Sc.
Cullimore, Cedric Anthony.
Damant, George Edward.
Davidson, William Stewart.
Davoren, Lucius Andrew.
Dicks, William John H.
Dodd, John Hedley.
Dunbar, James Quentin.
Dupen, Vivian Cecil.
Easton, Nigel Tytherleigh.
Esther, Harry, B.Eng.
Field, James Frederick.
Fenton-Jones, Hugh.
Fletcher, Dudley Wilfred H.
Fox, Kenneth McLean.
Freeland, Arthur James.
Freeman, Charles Frederick.
Fricke, Henry Moger.
Frugtniet, Adalbert Vance.
Gardner, James Nielson.
George, Henry Hale.
Gibson, Robert.
Godden, William Fenwick.
Gomez, Jose Gomez.
Good, William Rexter.
Goubert, Arturo.
Graham, Douglas Ernest.
Graham, Harry.
Grant, Allan, B.Sc.
Green, Harry.
Griffith, Herbert Clewin.
Grove, George Richard P.
Hall, John Lawrence.
Hampshire, Harold William T.
Hancock, Harold Percy.
Hards, Richard Leo.
Harper, William George.
Harris, Francis Alfred.
Harris, Richard H.
Harrison, John Murray.
Harvey, Hector Gordon.
Haskard, John Leslie.
Heap, David, B.Sc.Tech.
Hedley, Hugh Hutton.
Hedley, Isaac Herdman.
Henry, Howard Francis.
Higgs, Thomas Ware.
Hinds, James Oliver.
Hinnawy, Abdul Magid.
Hodges, Leonard Allen.
Hogarth, John Russell.
Hogbin, Archibald.
Hollingshead, John.
Holmes, John Hardy.
Hughes, Alexander Russell M.
Hughes, Charles Wesley.
Hughes, Julio Reginald.
Hughes, Thomas Charles.
Hunking, Arthur Lancelot.
Hunter, Kenneth Kirkwood.
Hutchings, Eric Edward.
Jacques, John Rowland.
Jarvis, Arthur Porter.
Jehu, John William.
Jesty, Edgar Henry.
Jewsbury, Eric.
Jewsbury, William.
Johnston, Eric Montague.
Jones, Frank, B.Sc.
Kalle, Maurice L. F.
Kingshott, George William.
Kirkby, Norman Reginald.
Kirsten, Kenneth Haenert, B.Sc.
Knight, Arthur William.
Lamb, Henry Lincoln.
Lane, Francis John, B.Sc.
Latham, Tom.
Lawrence, Alan.
Lessel, Robert James.
Lightbown, John.
Linton, James.
Lloyd, John Austin H.
Long, Geoffrey.
Lower, John Henry.
McClean, Herbert George, B.Sc. (Eng.).
McClure, Charles Archibald.
McCracken, Stanley.
McFarlane, John.
Macfie, Duncan Brown.
McGavin, James.
Mackenzie, Evan John.
Mackenzie, William Alexander.

Students—continued.

McKie, David Gordon.
McLean, Francis Charles.
Manning, James Walter G.
March, Charles Edward M.
Matthews, Albert Dent.
Matthews, Harry James.
Maye, John Wintle.
Mayhew, Thomas Alfred.
Meares, Oswald Mapletoft.
Meneze, John Arthur.
Milne, Alexander James.
Mitchell, Alexander.
Mitchell, Ernest James W.
Moller, Herbert Cecil H.
Morton, Harold Christopherson.
Mosedale, Philip John.
Motha, Britto Raphael.
Moursi, Mostafa Riad.
Mullineux, James.
Nagel, Llewellyn.
Nahapiet, Ernest Owen.
Nash, Alfred James L.
Nind, Eric Arthur.
Nottingham, Edward Charles.
Ogden, Horace Chadwick, B.Sc. (Eng.).
Old, David.
Oldcorn, Eric Carlton T., B.Sc.
Olver, George Corden.
Osborn, Leroy Gordon.
Parish, William Joseph.
Parsons, Henry Harold.
Passmore, Charles Rivers.
Pattinson, Robert Raine.
Paul, Jack Heron.
Peakin, Cecil John.
Pearson, Frederick John.
Peasgood, Harold.
Peckett, Leslie James.
Perkins, Griffith Hugh, B.Sc.(Eng.).
Phillips, John Leslie.
Phillips, John Waldron.
Pilfold, Charles William.
Plumtree, Ian Stanley.
Porter, Andrew.
Price, Gilbert Watts.
Pritchett, Cyril George.
Pye, Frank Peveril.
Radford, John Samuel.
Ragunather, Arumugam.
Record, Charles Reuben.
Reid, William Alfred.
Renwick, William John.
Revell, Edward Walter M.
Ridsdale, Henry Arthur C.
Ritchie, Henry Wilfred.
Robertson, Gilbert.
Rogerson, Richard Wyndham.
Roseway, Walter Norman.
Rowell, Cecil Victor.

Simpson, George Francis.
Simpson, Norman George.
Skinner, Frederick George J.
Smith, David Hughes.
Smith, David Salmond.
Smith, Eustace Herbert.
Smith, Frank Jervis.
Smith, Ian Stewart.
Smith, Thomas Haworth.
Smythe, Francis Sydney.
Spindler, Arthur Hardman.
Squires, Frank Henri.
Starling, Benjamin.
Stewart, Ian Dunlop.
Storer, Robert Harrison.
Striem, Hubert Henry V.
Symes, George Leslie.
Tannett, Anthony.
Taylor, Samuel Mellor.
Tetley, Arthur Cyril.
Thomas, Arnold Harrison.
Thomas, Edgar Frank E.
Thornton, James Philip.
Tibbitts, Edgar Ernest.
Tidmus, Allan Hinds.
Todd, William George.
Trimmer, William Jack.
Tuck, William Douglas.
Tufnail, Maurice Edward.
Vallis, Leslie Cecil.
Verano, Ernest Augustus.
Vernier, Charles Leonard.
Vickers, Harold Edwin.
Villiers, William Amherst.
Walsh, Joseph Anthony.
Waterfield, Henry (Jnr.).
Watson, Robert Parker, B.A.
Watt, Warden Kennedy.
Webb, John Krauss.
Weston, Gordon.
Wheatley, Stanley James.
White, Jack.
Williams, Joseph.
Wills, David Hilary.

Students—continued.

Wilson, James.
Windred, George.
Witt, Stanley Reuben.
Wittrick, James Lewis.
Woodbridge, Arthur William.
Woodcock, Vincent.
Woodcock, Walter Leslie.
Woodforde, John.
Worthing, Cyril Evans.
Young, Albert Edward.
Young, Norman James.
Young, Richard Vincent.

Associates.

Atherton, Arthur.
Owles, Archibald Bewick.
Tansley, George Edward.

TRANSFERS.

Associate Member to Member.

Farrow, Alfred Edward.
French, Walter William E.
Gittins, George Edward, B.Sc.
Handley, Benjamin.
Harrison, Harry Hughes.
Lawson, Walter.
McLennan, Duncan.
Martin, Harold.
Mayes, Arthur Edward.
Naylor, William Slater.
Nelson, James.
Newberry, William George.
Phillips, Lewis Waight.
Stigant, Stanley Austen.
Thompson, Harry Sydney.
Waygood, Oscar Candish.
Wilcox, Walter Maitland, B.Sc.(Eng.).
Wilson, Henry.

Associate to Member.

Short, Frederick Martin.

Graduate to Associate Member.

Boyland, Harold John.
Bremner, Francis Donald H., B.A.
Brigg, John Ellwood.
Edwards, Leslie.
Farrell, James Fraser E.
Peasgood, Frank.
Searles, Harold Everard.
Smith, Esmond Wassell.
Smith, Harry Foster.
Stinchcomb, Ernest Arthur.
Swift, Bernard.
Vanneck, Richard Grant, M.C.
Waddicor, Harold, B.Sc.
West, Frederick William J.
Willson, Charles Schummelketel, B.Sc.(Eng.).

Student to Associate Member.

Benger, William Alan.
Buckman, Henry Leonard, B.Sc.
Chadwick, Samuel.
Champney, Laurence.
Hall, William Noel.
Hoyle, William Dickon.
Moir, Roy Adamson.
Morgan, Percy Davies.
Nicholson, Graham Franklin.
O'Neill, James Francis.
Perks, John Noel R.
Scott-Taggart, John, M.C.
Serner, Arthur.
Villiers, Algernon Edward, M.A.

Student to Graduate.

Beckett, Charles Murray.
Berry, John.
Booth, John Arthur.

Small, Allan Jamieson.
Snipe, Norman Victor.
Stansfield, Joshua Bertram, B.Sc.(Eng.).
Thompson, Cecil George.
Torrance, John.
Tucker, John Potterton.
Wade, John Charles.
Wilson, David MacArthur.

A paper by Mr. H. Marryat, Member, entitled "Electric Passenger Lifts" (see page 325), was read and discussed. On the motion of the President a vote of thanks to the author was carried with acclamation, and the meeting terminated at 7.47 p.m.

710TH ORDINARY MEETING, 31 JANUARY, 1924.

(Held in the Institution Lecture Theatre.)

Dr. A. Russell, President, took the chair at 6 p.m.

The minutes of the Ordinary Meeting of the 17th January, 1924, were taken as read and were confirmed and signed.

A list of candidates for election and transfer approved by the Council for ballot was taken as read and was ordered to be suspended in the Hall.

A list of donations to the Benevolent Fund (see pages 210 to 212) was taken as read and a vote of thanks was accorded to the donors.

The President announced that the third award of the Faraday Medal had been made to Dr. S. Z. de Ferranti, Past President.

A paper by Professor W. M. Thornton, O.B.E., D.Sc., Member, entitled "Some Researches on the Safe Use of Electricity in Coal Mines," was read and discussed. On the motion of the President a vote of thanks to the author was carried with acclamation and the meeting terminated at 7.52 p.m.

36TH MEETING OF THE WIRELESS SECTION, 6 FEBRUARY, 1924.

(Held in the Institution Lecture Theatre.)

Mr. E. H. Shaughnessy, O.B.E., Chairman of the Section, took the chair at 6 p.m.

The minutes of the meeting of the Wireless Section held on the 2nd January, 1924, were taken as read and were confirmed and signed.

A paper by Mr. E. B. Moullin, M.A., Member, entitled "Atmospherics and their Effect on Wireless Receivers" (see page 353), was read and discussed. A vote of thanks to the author was carried with acclamation and the meeting terminated at 7.50 p.m.

INSTITUTION NOTES.

Coopers' Hill War Memorial Prize.

The prize for the year 1922 (see *Journal I.E.E.*, 1921, vol. 59, p. 346) has been awarded to Mr. F. R. Combes for his monograph on "An Historical and Critical Survey of Atmospheric Electricity and Protection against Lightning."

"Chartered Electrical Engineer."

The following Bye-law of the Institution (in substitution for existing Bye-Law 9), which was adopted at a Special General Meeting of the Corporate Members held on the 28th February last, was allowed by the Lords of His Majesty's Most Honourable Privy Council on the 20th March, 1924:—

(*a*) An Honorary Member shall be entitled to the exclusive use after his name of the initials "Hon. M.I.E.E."; a Member of the initials "M.I.E.E."; an Associate Member of the initials "A.M.I.E.E."; an Associate of the initials "Associate I.E.E."; a Graduate of the initials "Graduate I.E.E."; and a Student of the initials "Student I.E.E."

(*b*) Every Member and Associate Member is, and is entitled to describe himself as, a Chartered Electrical Engineer, and in using that description after his name shall place it after the designation of the class in the Institution to which he belongs, stated in accordance with the following abbreviated forms, namely, M.I.E.E. or A.M.I.E.E., as the case may be.

(*c*) A Member or Associate Member practising
- (i) under the title of, or as an officer or employee of, a Limited Company authorized to carry on the business of an electrical engineer in all or any of its branches, or
- (ii) in partnership with any person who is not a Member or Associate Member of the Institution under the title of a Firm

shall not use or permit to be used after the title of any such Company or Firm the designation "Chartered Electrical Engineer" or "Chartered Electrical Engineers" or describe or permit the description of such Company or Firm in any way as "Chartered Electrical Engineer" or "Chartered Electrical Engineers."

(*d*) No person shall adopt or describe himself by any other description or abbreviation to indicate the class to which he belongs than is provided in this Bye-law for such class.

National Certificates and Diplomas in Electrical Engineering.

The following is a further list of schools and colleges approved for the award of the above [see *Institution Notes*, No. 39, page (18), July 1923, and *Journal I.E.E.*, 1924, vol. 62, page 209].

Approved for Ordinary Grade Certificates (*Senior Part-time Courses*).

Aston Technical School.
Bootle Municipal Technical School.
Darlington Technical College.
Dewsbury Technical School.
Doncaster Technical College.
Dudley Technical College.
Handsworth Technical School.
Hanley Technical School (Stoke-on-Trent).
Huddersfield Technical College.
Hull Municipal Technical School.
L.C.C. School of Engineering and Navigation.*
Leeds Central Technical School.
Manchester College of Technology.
Oldham Technical School.
Portsmouth Municipal College.
Sheerness Technical Institute.
Sheffield University.
Stoke-on-Trent Central School of Science.
Swansea Technical College.

Approved for Higher Grade Certificates (*Advanced Part-time Courses*).

Halifax Technical College.
L.C.C. School of Engineering and Navigation.*
Liverpool Central Technical School.
Manchester College of Technology.
Portsmouth Municipal College.

Approved for Ordinary Grade Diplomas (*Senior Full-time Courses*).

Leeds Central Technical School.

The Benevolent Fund.

The following is a list of the Donations and Annual Subscriptions received during the period 26 February to 25 March, and of those paid direct to the Institution bankers from 1 January to 25 March, 1924:—

	£	s.	d.
Alabaster, Bt.-Major E. O. (Gosport) ..		5	0*

PULVERIZED FUEL AND EFFICIENT STEAM GENERATION.

A DETAILED CONSIDERATION OF THE PERFORMANCE OF PULVERIZED FUEL AS COMPARED WITH MECHANICAL STOKING UNDER THE MOST MODERN CONDITIONS.

By David Brownlie, B.Sc.

[*Paper first received 29th November*, 1922, *and in final form 3rd October*, 1923; *read before* The Institution 13*th December, before the* Mersey and North Wales (Liverpool) Centre 10*th December, before the* Scottish Centre 11*th December, before the* North-Western Centre 18*th December, before the* Sheffield Sub-Centre 19*th December*, 1923, *before the* North-Eastern Centre 14*th January, before the* Irish Centre 17*th January, before the* East Midland Sub-Centre 29*th January, before the* South Midland Centre 30*th January, before the* Western Centre 4*th February, and before the* North Midland Centre 5*th February*, 1924.]

Summary.

The paper is a detailed consideration of the latest developments in the use of pulverized coal for steam generation, and a comparison of the advantages and disadvantages of this method of firing as compared with mechanical stoking, in each case under the latest improved conditions and more particularly as applied to very large power-station boiler plants. Since the starting up in December, 1920, of the pioneer large installation, Lakeside, Milwaukee (40 000 kW on Lopulco pulverized fuel), the progress made in the United States has been remarkable, and approximately 3 500 000 tons of pulverized coal per annum will shortly be burnt under water-tube boilers.

The paper contains a full account of the Lakeside station, particularly the exact working costs, whilst a description is also given of the River Rouge plant at Dearborn, Detroit, as representatives of modern pulverized-fuel practice. For comparison, a similar account is given of the Dalmarnock power station, Glasgow, characteristic of the best British mechanical stoker practice.

The author is of the opinion that the advantages in the aggregate of pulverized fuel are so great that they constitute almost a revolution in steam-boiler practice. The paper also contains a large amount of general statistical matter.

Introduction.

One of the most striking developments in the whole history of steam generation has been the rapid growth of the use of pulverized fuel in the United States during the past three or four years.

This progress is so remarkable, alike in the net working efficiency obtained, the size of the individual boilers made possible, and the use of the most modern methods of scientific control of the working of the boiler plant, practically from a distant switchboard, that something like a revolution in steam practice has undoubtedly been effected.

In view of the importance of efficient steam generation, both in power station work and from the national point of view, the most serious consideration in Great Britain of the whole question of pulverized fuel is, in the author's opinion, imperative.

In the present paper the author has endeavoured to give a survey of the latest developments in the use of pulverized fuel for steam generation. On account of the somewhat controversial nature of the whole question and the great difficulties in the way of comparing two entirely different systems of firing, i.e. pulverized fuel and mechanical stoking, because of almost endless complications due to load factor, price and quality of fuel, fluctuations in steam demand, and varying rates for labour, all of which cloud the issue, the author has based the paper on the performance of one definite pulverized-fuel plant, that of the Lakeside station, of the Milwaukee Electric Railway and Light Company, on Lake Michigan.

This plant is in the first place the pioneer modern large steam-generation plant fired with pulverized fuel, and it has the advantages—from the point of view of the power station engineer—that it is a generating station of very large size, viz. 40 000 kW, which has been running nearly three years, whilst the most elaborate records, almost unique in their thoroughness, have been taken of every detail of the performance. Also it is what would be termed to-day a "low-capacity" and "central" pulverized-fuel plant, which is to the advantage of mechanical stoking in the comparison, as distinct from high-capacity plants, such as those at Cahokia, Cleveland, Vitry, and Trenton Channel.

With regard to Lakeside, the author has been given the opportunity by Mr. John Anderson, the chief engineer, through the kindness of Mr. W. R. Wood, managing director of the Underfeed Stoker Co., Ltd., of studying the remarkable records obtained at this station. They include not only the efficiency of the plant and the exact cost of drying, pulverizing, and generally preparing the fuel, together with the wages bill and the repair and maintenance costs, but, in addition, even such difficult items as the actual amount of excess air required in the combustion. All these different figures have not hitherto been published under one head, and together they give reliable and extensive data on the performance of pulverized fuel (as applied to steam generation under given definite conditions) of a kind that has not before been easily available.

The author has not included any reference of importance to the so-called "unit" system of pulverized-fuel firing, in which each boiler has a separate self-contained pulverizer, separators and feeders in one machine, because in the first place this is more applicable to smaller boiler plants and not so much to large power station work, and secondly, authentic data as to prolonged performance do not appear to be available. Similarly he has not discussed the various different systems of pulverized fuel on the so-called "central" system (preparing the coal at some central position and supplying the different burners) because he feels that a better consideration will be obtained by

confining attention to what is actually being accomplished on certain large power-station boiler plants.

The paper gives first of all a sketch of the early history of pulverized fuel, followed by a brief account of the position to-day in the United States with regard to the use of pulverized fuel for steam generation. Since the whole position in this respect has been changed by the starting up of the Lakeside station in December 1920, the author has considered in some detail, after a brief mention of the general principles of pulverized-fuel firing, the general opinions of the relative advantages and disadvantages of pulverized fuel for steam generation held prior to 1920. Following this a detailed description of the actual plant at Lakeside, in addition to the mention of several other plants, is a convenient method of discussing the modern principles of pulverized fuel which have led to such an enormous development during the last three years.

The greater part of the paper is then taken up with a consideration, step by step, of the actual results obtained at Lakeside, and in a number of cases also on other large pulverized-fuel plants, as compared with modern mechanical-stoker practice, Dalmarnock power station, Glasgow, being taken as typical of the best class of British station. Such a consideration, of course, covers a very wide field, but the author trusts that the importance of the subject will be considered ample justification.

The History of Pulverized Fuel.

The idea of using coal in a finely pulverized condition for combustion as fuel, and also in carbonization and total gasification processes, is of very ancient origin. Pulverized coal was apparently first experimented with somewhere about 1820, but the work was kept secret and the results obtained are not known.

One of the earliest patents on the subject was that of J. D. Whelpley and J. J. Storer, both of Boston, Mass., U.S.A., whose British patent is 1471/1866, in which essentially pulverized coal was to be used by being fed into and over furnaces as an aid to hand-firing. The patent is entitled: "A novel application of fuel and of the fluxes or reducing agents used in metallurgic processes and consists in employing fuel and fluxes in a finely divided state and feeding them into the air blast of a furnace or fire box so that they may be floated on the blast during their consumption and thus generate their heat and perform their reactions at the working point by this means, giving great economy, more perfect results and better control over the operation in which the fuel is employed. The invention is equally applicable to furnaces for metallurgic operations and to fire boxes where the auxiliary blast is used."

Whelpley and Storer thoroughly understood the importance of the intimate contact of the fuel and the air, or the ore and the reducing agent, as obtained by pulverizing, and they used for the supply of pulverized fuel or other material a fan-blower arrangement, consisting essentially of a revolving cylindrical brush to supply both the fuel and the air at the same time. The process was intended to apply more to the reduction of ores, but pulverized-coal burning is also very specifically mentioned, although a later patent (1493/1866) relates to the use of pulverized ores only.

The first man, however, to investigate thoroughly the whole question of pulverized fuel from many aspects would appear to have been T. R. Crampton, of Westminster. Crampton took out a considerable number of patents on a great variety of subjects, such as special roadways and the construction of forts, and his first pulverized-fuel patent, a very long one, is 2539/1868. A portion of this patent covers the process of grinding coal in ordinary millstones but using a blast of air between the stones to remove the finely ground material as it is formed, whilst at the same time keeping the stones cool, and secondly, using the same fan to discharge into the furnace the pulverized coal mixed with air. The patent also includes the idea of burning a mixture of pulverized coal and air by passing them in a zigzag course between the extended surfaces of a heated firebrick furnace chamber, so as to aid the combustion, while another idea was to use in the bottom of the combustion chamber molten iron, molten slag or other molten material further to aid the combustion.

Crampton then took out another very voluminous patent (3504/1869) on pulverized-coal burning, consisting chiefly of numerous modifications of his previous patent 2539/1868, but especially from the point of view of causing different streams of pulverized coal and air to mix so as to ensure better combustion. The degree of grinding used was not very fine, the powder passing through a 30-mesh screen (30 holes per linear inch = 900 holes per square inch) for ordinary bituminous coal, but for anthracite or coke he suggested 40–80 mesh screens, and he also used in the most ingenious manner the principle of regenerating the heat, supplying for combustion air heated by coils in the hot exit gases.

Further remarkable ideas contained in Crampton's patents included a special bridge wall sloping in such a manner as to reflect the streams of air and burning fuel at an angle in order to secure still better mixing, and a highly ingenious arrangement of equal coal feed across the width of the furnace by means of air, including primary air to convey and mix with the coal and secondary air to complete the combustion. Various later patents of Crampton's in connection with the burning of pulverized coal were 2606/1870 and 931/1871, chiefly in connection with various special furnaces.

Crampton also took out a patent in 1872 for the continuous carbonization of coal in a pulverized condition, by grinding the coal to a fineness of all through a 30-mesh screen and allowing it to fall continuously down a very high vertical cylinder, the outside centre portion of which was heated by a gas-fired, encircling combustion chamber, so that the coal was carbonized almost instantaneously, the coke, in a fine powder, accumulating at the bottom and the gaseous and volatile products escaping at the top. Here again the details of the continuous coal feeder, the method of distributing the coal evenly throughout the fall, and the automatic removal of the coke dust "in step" with the admission of the coal, are all on the most ingenious principles. This idea of the carbonization

of pulverized coal has been allowed to lie dormant for over half a century and is only now occupying serious attention for low-temperature carbonization. It is evident that Crampton possessed an astonishing grasp of the whole of the principles and possibilities of pulverized fuel burning as applied not only to steam generation but also in connection with many types of furnace, especially such as are used in the glass and steel industries.

In spite, however, of this remarkable pioneer work and many other patents which followed, pulverized fuel made no headway at all, chiefly because the necessity of drying the coal was not realized, but also owing to the lack of modern types of grinding and pulverizing machinery, to the fact that the fuel was not pulverized to a sufficient extent, and to the difficulty of controlling the flame. The first commercial application of pulverized fuel was in the cement industry, and it is stated to have been used originally in this connection in Great Britain in 1884, although the evidence in support of this is not conclusive. In the United States, which may justly be stated to be the home of pulverized fuel, the first large-scale application in the cement industry was in 1894, when Hurry and Seaman used it at the works of the Atlas Portland Cement Co.

Shortly after this time pulverized fuel began to be used regularly in America for the manufacture of cement, and to-day approximately 90 per cent of the cement output of the United States is produced with the aid of such fuel. Also various other industries, especially in connection with iron, steel and glass, have adopted this method of firing for furnace work, and at the present time altogether probably over 30 000 000 tons of pulverized coal per annum are being used in America. As far as the British cement industry is concerned, the first rotary kiln with pulverized fuel seems to have been started up in 1901 at Swanscombe, and to-day also over 90 per cent of British cement is made with pulverized fuel.

With regard to steam generation, with which this paper is most directly concerned, pulverized fuel had made remarkably slow progress until a few years ago. It was first experimented with seriously for locomotive firing in about 1900 by the Manhattan Elevated Railroad in the United States, but the experiments were abandoned. Since then, however, various American railways have investigated the subject, several of them on quite a large scale. The work was stopped by the war but has since been resumed, and, as is well known, extensive developments in the application of pulverized-fuel firing to locomotives are now taking place in Brazil.

In stationary, land boiler plants the same slow progress obtained. Naturally, the use of pulverized coal in the cement industry led various cement works to experiment with this method of firing on their own boilers, and in 1901, for example, the Alpha Portland Co., and in 1902 the Lehigh Portland Cement Co., tried pulverized coal on water-tube boilers. The efficiencies obtained were generally extremely good, but for some reason or other, whether practical difficulties or merely lack of interest, the work was not followed up and practically nothing was done in the cement industry in the United States to use pulverized coal for steam generation until 1917 or 1918, when the Ashgrove Lime and Cement Co. adopted it on Heine water-tube boilers. Altogether there was little real application of pulverized fuel to steam generation in the United States before about 1913.

In Great Britain the principle has made practically no headway at all. It is believed that the British Admiralty have experimented with it, and for some years a few Bettington vertical boilers, fired with pulverized coal, were in operation. Even to-day there is, so far as the author is aware, only one large boiler plant in Great Britain—at Hammersmith electricity supply station—running on pulverized fuel, and he understands that 3 boilers, evaporating approximately 45 000 lb. of water per hour, are now in operation with very satisfactory results. There is also the new installation at Peterborough of "unit" pulverizers on two medium-sized boilers (25 000 lb. evaporation), and one or two small boilers have been equipped for experimental purposes, whilst general furnace work is also disappointing.

In the United States a fair amount of progress was made between, say, 1914 and 1920 with pulverized coal for steam generation on moderate-sized industrial plants. Thus some of the earliest American boiler plants to adopt pulverized fuel were the M.K. and T. Railroad boiler plant of a total of 84 250 h p. (American) at Parsons, Kansas; the Puget Sound Electric Light, Heat and Power Co. at the Western Avenue station with a 4 100-h.p. (American) installation; the American Locomotive Co. at Schenectady; the Sizer Forge Co. of Buffalo; the Susquehanna Collieries; and the Atlantic Steel Co.

Previous to 1918, as already stated, these plants were moderate-sized industrial installations and did not include any power stations. A list of prominent installations equipped from 1916 to 1918 showed boilers varying from 100 to 600 h.p. (American) mostly in plants of 1–10 boilers. The results obtained on some of these plants were very good, especially as regards efficiency.

Many engineers had also pointed out the advantages of pulverized coal, for example F. A. Scheffler and H. C. Barnhurst in their paper on "Pulverized Coal for Stationary Boilers," read in June 1919 before the American Society of Mechanical Engineers, but still the principle made slow progress, chiefly because of the difficulty of solving the problem of the maintenance of the furnaces. Much the same state of affairs existed in France and Germany, where a limited number of plants were at work.

The position as regards steam generation was, however, entirely altered by the final perfection of the Lopulco system of pulverized fuel and its successful adoption on a very large power-station plant, the Lakeside station of the Milwaukee Electric Railway and Power Co., the first section of 40 000 kW of which was started up in December 1920.

The remarkable success of the installation has quickly effected a revolution in the position of pulverized fuel for steam generation, and to-day, in the short space of three years, some of the largest and most noted power stations in the world have adopted it.

The Present Position of Steam Generation by Means of Pulverized Fuel.

The majority of power station engineers in Great Britain do not perhaps realize the extent of the application of pulverized fuel to steam generation in the United States, especially to power station work. In many cases, for example, the impression would appear to be that pulverized fuel is merely a fad, and in any case a matter for cautious experimenting for months on end with one boiler at a time, to test it and find out its faults. For this reason, therefore, a few facts as to the real situation will not be out of place.

The boiler-plant installations in America, in addition to Lakeside, now running on Lopulco pulverized fuel include the West Pennsylvania Power Co. of Springdale, Pa.; the St. Joseph Lead Co., Rivermines, Mo.; the Lima Locomotive Co., Ohio; and the Allegheny Steel Co. of Breckenridge, Pa. Also, the well-known River Rouge plant of the Ford Motor Co. at Detroit has boilers of 26 470 sq. ft. heating surface, fired with mixed pulverized coal and blast-furnace gas, having a normal evaporation of about 220 000 lb. of water per hour from and at 212° F. with 275 000 lb. reasonable overload.

About the middle of this year (1923) the number of large boiler plants in operation in America on the Lopulco system was nine, comprising 43 boilers with a total heating surface of approximately 360 000 sq. ft. Probably about 300 000 sq. ft. of this is in operation at one time, which at the very moderate figure (low-capacity plant) of 0·75 lb. of coal burnt per sq. ft. of heating surface per hour (6·50 lb. of water evaporated) corresponds to, say, 120·5 tons per hour or something like 850 000–1 000 000 tons per annum, equal to, say, 47 standard 50 000-lb. boilers in constant operation. Probably over 2 000 000 tons of pulverized coal have so far been burnt on the Lopulco system.

The position in this respect will, however, be entirely altered almost within the next few months. At the present time (October 1923) 29 different plants are being equipped. In addition to the doubling of the River Rouge plant (four more boilers each of 26 470 sq. ft. heating surface being added), the Ford plant in Canada is in the course of conversion; the Lakeside station is also being doubled (8 more boilers each of 17 500 sq. ft. being added); the first section of 8 boilers of 17 800 sq. ft. each are being erected for the Union Electric Co.'s new Cahokia power station for St. Louis (to be eventually 300 000 kW); the Cleveland Electric Co. are installing 4 boilers each of 30 600 sq. ft. heating surface (the largest boilers in the world, with a normal evaporation of 300 000 lb. per hour); the Union d'Électricité are equipping 4 boilers each of 16 678 sq. ft. heating surface at Vitry (Paris); and the United Electric Railways plant at Rhode Island is also being fitted with 3 boilers each of 12 600 sq. ft., whilst most recently the Duquesne Light Co. are installing five 26 500-sq. ft. boilers at their Colfax station, and the Detroit Edison Co. six 29 500-sq. ft. boilers at the New Trenton Channel station.

The total boiler heating-surface of these 29 boiler plants (comprising 91 boilers) now being equipped with Lopulco pulverized fuel is approximately 1 400 000 sq. ft., corresponding to a coal bill—calculated as before—of about 385 tons per hour, or approximately 2 695 000 tons of coal per annum, equal to, say, 142 standard 50 000-lb. boilers in constant operation. This will make a total of 3 400 000 tons of pulverized coal per annum, or nearly half the power-station capacity of the whole of the United Kingdom.

It will be agreed, therefore, that whatever may be the advantages and disadvantages of pulverized fuel for steam generation, it has long since passed the experimental stage, and what may be termed all the main problems and difficulties have already been solved in America. Obviously the simplest method, therefore, for a British power station engineer is not to experiment himself, but to save time by visiting the United States and inspecting the position on the spot so as to take advantage of all the accumulated experience that is to be had for the asking.

The General Principles of Pulverized Fuel.

The general principles of pulverized-fuel practice are already fairly well known, so that it will only be necessary to give the briefest outline of them.

The coal is first crushed and then passed over a magnetic separator to get rid of any accidental particles of iron which would cause damage to the pulverizers. The crushed coal is then dried, first of all to enable the pulverizers to work efficiently, but also because the pulverized fuel in a very dry state is perfectly "fluid," and the ease with which the material may be conveyed, controlled, and mixed with air is increased, whilst the speed and temperature of ignition of the pulverized material are greatly increased. The degree of drying is a matter of opinion and will be discussed later in the paper, but the modern practice with pulverized fuel is to dry it so that it contains not more than 2 per cent of moisture, and preferably 1–2 per cent. The "unit" system of pulverizing, however, is stated to handle undried coal so long as the moisture content does not exceed 10 per cent.

In general, damp coal "packs" in the pulverizer and greatly increases the horse-power required, whilst reducing the output. Thus, in an example mentioned by Mr. Cecil F. Herrington of a pulverized-coal plant of the Bethlehem Steel Co. of a capacity of 135 tons of coal per 24 hours, the coal contained 5 per cent of moisture, but if used in this condition the output of the pulverizers was reduced 20 per cent as compared with dried coal with 1–2 per cent of moisture. Dried coal also has the advantage that it is less liable to spontaneous combustion and there is no tendency to stick in the conveying pipes or pulverized-fuel bunkers, so that drying to less than 2 per cent of moisture is altogether a paying proposition.

The dried coal is then pulverized in ball mills, and here again the exact degree of treatment to which the coal is subjected is a matter of opinion. To-day, however, rough average practice as regards the fineness of the material is that about 90 per cent of an average sample must pass through a 100-mesh screen (100 holes to the linear inch, 10 000 holes per sq. in.) and 65 per cent through a 200-mesh screen, but much depends on the quality of the coal. Excessively fine

grinding, however, such as 85 per cent through a 200-mesh screen, is not now as a rule necessary under modern conditions.* The pulverized coal is then mixed with a certain amount of air and burnt in burners. These are of three general types which may be defined roughly as follows :—

(1) Natural-draught burners, in which the pulverized coal is taken into the furnace by this means only.
(2) Mechanical coal-feed burners, using revolving fans or brushes.
(3) Compressed-air burners, using air under pressure to blow the fuel into the furnace.

The modern burner is also so arranged that the air is only mixed in any quantity with the pulverized fuel very near to the burner itself, partly because the mixture is explosive, and also so as not to cause any separation of the heavier fuel from the air and give a mixture of uneven strata for combustion, as would be the case if the mixed fuel and air had to travel a long distance. A good type of burner gives less than 3 per cent variation in the air-fuel mixture at any portion of the travel.

Advantages (up to 1920) of Pulverized Fuel for Steam Generation.

As already stated, the position with regard to pulverized fuel has entirely changed since 1920, from which date the experience gained by the burning of several million tons of pulverized coal, mostly in large plants and under the latest conditions, has considerably altered many of our previous ideas on the subject. The general opinions up to 1920 in Great Britain as to the advantages and disadvantages of pulverized fuel as compared with mechanical stoking, some of which contradict one another, can be summarized as follows, and it may be stated also that Great Britain has not been very well informed on the matter during the past few years.

(1) *High boiler-plant efficiency.*—It has long been admitted that pulverized fuel, from the point of view of efficiency of steam generation, gives results far superior to any method using coal in the ordinary way, whether crushed or in the lump condition, and with either hand or mechanical firing. The chief reason for this was known to be the extremely intimate mixture of the air and the finely divided fuel, so that a very much reduced amount of excess air over the theoretical is required. It was contended by some advocates of pulverized fuel that the figure for excess air was only about 20 per cent above that required by theoretical conditions, as compared with 50 per cent for very good plants with mechanical stoking. Consequently, fuel in a pulverized condition burns smokelessly with about 17–18 per cent of CO_2, no CO, and such an intense heat, with maximum radiation, that one of the problems has long been to get the brickwork to withstand it. In a general way it was stated also that 82½–85 per cent boiler-plant efficiency was to be obtained, with a saving of 20–25 per cent in the coal bill as compared with mechanical stoking, always provided that various other difficulties could be surmounted. As examples of individual opinions, Mr. N. C. Harrison of the Atlantic Steel Co. stated that the boiler-plant efficiency obtained was 85·22 per cent with a very large plant of 100 tons of coal per 24 hours, as against 78·04 per cent for mechanical stokers, without deducting the auxiliary power used in either case, and Scheffler and Barnhurst, in their paper read in 1919 before the American Society of Mechanical Engineers, gave a list of 18 ordinary industrial boiler plants fired with pulverized coal, in which the efficiency obtained varied from 72·7 to 85 per cent.

(2) *Complete combustion in the ash.*—One of the reasons of the greater efficiency was also the universally recognized fact that pulverized fuel gives complete combustion, as proved by the very fine ash resulting, whereas with practically every form of mechanical stoking there is a loss due to unburnt and partially burnt fuel in the comparatively large masses of ash and clinker and to the riddlings, i.e. fuel falling between the portions of the furnace.

(3) *Absence of moisture in the coal when burnt.*—The fact that pulverized coal was burnt with only about 1 per cent of moisture, and certainly not over 2 per cent, was also agreed to be an advantage, since the temperature of the flame is not reduced, by having to evaporate a comparatively large volume of water in the fuel.

(4) *Ease and convenience of transport in the boiler house.*—Pulverized fuel has semi-liquid properties and can be blown with the greatest ease for great distances through small-bore pipes bent round corners in almost any fashion.

(5) *Great flexibility as regards the variety of coal that can be burnt.*—It was also generally agreed that pulverized-coal firing is much more flexible as regards the variety of coal that can be burnt. For example, the principle of grinding the coal extremely fine obviated clinkering difficulties, so that coals with a high ash or sulphur content could be burnt efficiently, whereas it was almost impossible to consume them in many types of mechanical stoker. The advantages in this direction were certainly not realized to the full extent, especially in the case of a very large power station in which there is almost always quite a considerable variation in the quality of the coals used, often within a few hours. Finally, an important advantage recognized was that pulverized fuel works perfectly in conjunction with oil fuel and any gaseous fuel such as blast-furnace gas or coke-oven gas.

(6) *Greater flexibility in steam output.*—Another advantage claimed was greatly increased flexibility of the steam output of the plant, it being possible to take an enormous overload, often as much as 100 per cent in an emergency, whilst the firing could be started up or shut down in a remarkably short space of time. Another very important point is that, in contra-distinction to the case of mechanical stoking, these fluctuations result in comparatively little difference in efficiency.

(7) *Reduced stand-by and banking losses.*—In consequence of this greater flexibility in steam output,

* This point is dealt with in detail in a paper (No. 1780) entitled "Boiler Tests with Pulverized Coal," by H. Kreisinger and J. Blizard, read at the Spring Meeting of the American Society of Mechanical Engineers, Chicago, 21–26 May, 1921.

banking and stand-by losses, a serious item in many mechanically-fired plants with erratic steam demand, are automatically eliminated to a very great extent.

(8) *Much greater ease of scientific control.*—It was regarded as a minor advantage of pulverized fuel that it lent itself to a much more efficient control of the working of the plant, since a current of air and pulverized fuel through pipes is obviously much more simple to adjust, control and measure than is the fuel in the case of mechanical stoking. The real advantages in this direction were, however, hardly realized.

(9) *Reduced labour costs.*—Another advantage generally claimed was a net saving in labour as compared with mechanical stoking, although in the majority of cases this does not seem to have been based on any very conclusive data. Mr. N. C. Harrison, however, in the case of the Atlantic Steel Co. already mentioned, gave the pre-war labour costs, at the rate of $0·365 per hour, as approximately $0·195 per ton at 90 tons per 24 hours, or $0·176 at the full output per 24 hours—a very low rate.

Disadvantages (up to 1920) of Pulverized Fuel for Steam Generation.

It may be stated in the first place that the disadvantages given are in some instances exaggerated, and were in many cases due to defective plant and lack of knowledge.

(1) *Power consumption in the preparation of the fuel.*—It was considered that one of the chief disadvantages of pulverized fuel was the excessive cost of preparing the fuel, that is in handling, crushing, drying and pulverizing, particularly the power required by the pulverizers. Great differences of opinion, however, existed on this point. For example, R. Trautschold in 1917, for a 50-ton plant per 24 hours, with coal at $3 per ton, stated that the figure was 43 per cent of the cost of the coal, including 13·25 per cent for equipment, 5·75 per cent for drying, 20 per cent for pulverizing, and 4 per cent for conveying.

Some figures in Mr. L. C. Harvey's report in 1918 gave for this particular year a total average cost of pulverizing per ton for a 50-ton plant per 24 hours of $0·58 (2s. 5d.), for a 100-ton plant $0·51 (2s. 1½d.), for a 150-ton plant $0·48 (2s.), and for a 200-ton plant $0·45 (1s. 10½d.). These figures do not include interest and depreciation or the cost of conveying the coal to the furnaces, and have been converted to English rates of wages, 10d. to 1s. 3d. per hour, being based also on coal containing 7 per cent of moisture at $5 (£1 0s. 10d.) per ton delivered, 6 lb. evaporation per lb. of coal burned, repairs at 7 cents per ton, and power 12·7 cents (6·35d.) per ton pulverized. The figure of " 6 lb. evaporation " is, however, presumably a misprint.

In the same report are given, however, some specimen examples of plants with American prices, including interest and depreciation during the 1918 period (when prices were high), as follows: A plant of 80 tons per day in which the total cost of pulverizing was $2·21 (9s. 2½d.) per ton, the cost of another similar plant being $2·34 (9s. 9d.), whilst a plant of 30 tons averaged $1·489 (6s. 2·45d.) per ton, and a large 150-ton plant $0·772 (3s. 2½d.) per ton. It is also stated in the report that the average cost of drying the coal was equivalent to the cost of 20–30 lb. of coal per ton, or 0·90–1·30 per cent of the amount dried under average conditions, the final exit temperature of the coal being not over 250° F.

Mr. Harrison, in regard to the plant already mentioned as giving 85·22 per cent efficiency with pulverized coal, states that the total cost of preparation of the fuel was equivalent to 6 per cent of the cost of coal consumed.

Obviously the amount of moisture in the coal, which may be anything from 1 to 20 per cent, and the size of the installation play an important part, but in general it was maintained that this figure of the cost of preparation of the fuel from the lump coal to the burners, and including the cost of the fine ash disposal, was far greater than that of mechanical stoking, the crushing and handling of the coal, the driving of the stoker, the mechanical draught and the working of the mechanical ash conveyers.

(2) *Cost of wear and tear and breakdowns.*—Another disadvantage regarded by many engineers as inherent in pulverized fuel, although usually on scanty grounds as regards actual data and experience, was excessive wear and tear on the preparation plant generally, together with risk of breakdowns, not only in the pulverizers but also in the pipe circuits and at the burners. It was a general opinion that coal could not be pulverized continuously in huge quantities without incurring an extensive repair bill, and the wear and tear and the risk of breakdowns were regarded as being far in excess of those obtaining with mechanical stokers, even including the mechanical handling and (if necessary) crushing of the ash and clinker.

As a typical individual opinion, N. C. Harrison gives the total cost of repairs on the Atlantic City steel plant, dealing with 100 tons per day, as $1 002·47 for 2 months' running, 5 275 tons of coal being pulverized, corresponding to $0·190 per ton.

(3) *Deterioration of the furnace linings.*—Another of the chief objections to pulverized fuel was stated to be the excessive wear and tear and deterioration of the firebrick linings as compared with those in the case of mechanical stoking, due to the intense heat of the combustion, so that in many cases it was impossible to work the burners at their maximum efficiency, i.e. 17 to 18 per cent of CO_2, because the brickwork would not withstand the conditions, although obviously the higher the temperature the more efficient was the combustion. A minor defect in this connection was also stated to be the sand-blast action of the fine hot ash on the brickwork.

(4) *Damage to the boiler.*—Some engineers also claimed that pulverized-fuel firing was apt to cause damage to the boiler because of what they regarded as intense local heat.

(5) *Dusty and dirty nature of the operations.*—A common idea was that the pulverizing of dry coal was an extremely dirty, dusty and objectionable job, whilst it was impossible to keep the boiler plant in a clean condition.

(6) *Absence of proper temperature control.*—In spite of the general agreement as to the ease of control in the

working of pulverized fuel, a number of engineers were of the opinion that another disadvantage of such fuel was the lack of proper methods of controlling the temperature of the flame, so that the amount of coal burnt could not easily be adjusted to suit fluctuating evaporations. This undoubtedly was the case in one or two systems of pulverized-fuel firing.

(7) *Danger of explosions.*—A very common objection to pulverized coal was the fact that it was regarded as being much more dangerous than the ordinary methods of firing, especially from the point of view of greatly increased liability to serious explosions. Coal in an extremely fine state of division, particularly if the volatile content is high, is a very explosive material, as we know for example from the historical coal-dust explosion experiments inaugurated by the late Sir William Garforth at Altofts Collieries and since carried on by the Government at Eskmeals.

(8) *Danger of spontaneous combustion.*—In this connection an analogous disadvantage of pulverized fuel was the greatly increased liability of the coal to spontaneous combustion, especially when containing over 1 per cent of moisture. For these reasons special precautions had to be taken to keep down the temperature and prevent re-absorption of moisture, whilst not more than 5 to 6 ft. depth of coal was allowed in the bunkers. On this account also, generally not more than 10–15 hours' supply is stored at any one time, and the period of storage in any case should not exceed three days, whilst the bunkers have to be designed so that the material cannot accumulate in the corners. Further, when fires do start they are extremely difficult to put out and flooding has to be resorted to.

(9) *Ash troubles.*—Another series of objections to pulverized fuel centred round the ash, which is of course in an extremely fine state of division. In the first place it was stated that much of this fine ash, at least 50–75 per cent of the total ash in the coal, was discharged from the top of the chimney, causing a nuisance in the neighbourhood. Secondly, the ash becomes molten because of the intense heat, and is blown all over the inside of the boiler plant, not only on the boiler tubes and the superheater, but also in the economizer tubes and flues. Another serious difficulty that was not generally realized until large installations were set to work, was "slagging." That is to say, the large amount of ash accumulating at the bottom of the furnace chambers becomes molten and forms an incandescent, sticky mass, which corrodes and "fluxes" the brickwork. It is also very difficult to handle, particularly as the viscosity varies with the quality of the coal. Slagging was found to be particularly objectionable in the case of low-grade coals, such as Illinois and Indiana qualities, high in sulphur, with a low-melting-point ash, and the difficulty is accentuated at high rating.

(10) *Capital costs.*—Naturally it is in any case difficult to give data on this point, but, whether justifiably or not, the capital cost of a pulverized-coal installation was regarded as being considerably higher than that of mechanical stoking for the same net duty, which was said to be partially due to the fact that it was necessary for nearly all the pulverized-fuel plant required to be in duplicate because of the liability to breakdowns. Further, the space required by the preparation equipment was thought to be excessive, necessitating increased cost in land and buildings.

In the United States the pre-war cost of a 100-ton-per-24-hour pulverized-coal plant (5 000 kW) was stated to be very roughly about \$45 000 to \$50 000, although F. A. Scheffler and H. O. Barnhurst in their publications take the cost of a 100-ton plant (5 000 kW) as \$64 000, or \$12·80 per kW, and of a 1 000-ton plant as \$240 000, or \$4·80 per kW.

Mr. L. C. Harvey in his report of 1918 gives the cost of typical pulverized-coal plants complete (including buildings), calculated on the basis of British conditions in 1918 (when prices were high), as follows:—

Tons per day	Cost of plant	
	\$	£
10	46 500	9 687
50	55 500	11 562
100	67 500	14 062
150	75 000	15 625
200	93 000	19 375
250	93 000	19 375

TABLE 1.

Figures given by N. C. Harrison in regard to the Atlantic Steel plant.

	Costs per ton at outputs per day of		
	80 tons	90 tons	100 tons
	\$	\$	\$
Labour at \$0·365 per hour	0·2200	0·1950	0·1760
Repairs	0·1900	0·1900	0·1900
Power for handling, crushing and pulverizing	0·1340	0·1340	0·1340
Drying 2·62 per cent moisture coal at \$5.0 per ton (0·40 per cent)	0·0218	0·0218	0·0218
Total cost per ton	0·5658	0·5408	0·5218

In the United States it has been customary for the past few years to take for depreciation in connection with pulverized fuel, a life of 40 years for the buildings, 15 years for the old-fashioned rotary driers, and 20 years for the rest of the plant. Thus on a 100-ton-per-24-hour plant the depreciation figure is 12 cents net per ton, which seems a small amount. Taxes and insurance were regarded as constituting 2 per cent of the total capital expenditure.

(11) *Total costs of preparation.*—Finally, as regards the total inclusive costs of pulverized fuel, some makers of the plant in America are said to have estimated this as $0·35 per ton, although exactly what this includes is not clear.

Figures given by N. C. Harrison in regard to the Atlantic Steel plant are given in Table 1. Taking the average figure as $0·54 per ton, this corresponds to about 11 per cent of the coal burnt, excluding capital charges.

F. A. Scheffler and H. O. Barnhurst give the total cost per ton of coal handled as $0·3975 per ton at 100 tons per 24 hours, and $0·2975 per ton at 1 000 tons in 24 hours, and they estimate the total costs as $0·6575 and $0·3895 per ton including interest on capital, rates and taxes, and depreciation, taking the capital cost of the two plants as $64 000 and $240 000, as already stated.

The Lakeside Plant of the Milwaukee Electric Railway and Light Co.

Before describing this installation, it will be as well to state in a few words the essentials of the Lopulco system of pulverized fuel. These include the use of the water screen, an arrangement of steel tubes in the bottom of the furnace chamber, which has done more than anything else to solve the practical problems of very large-scale pulverized-fuel burning, and through which the boiler water circulates so as to cool the accumulated ash and prevent slagging, combined with hollow furnace walls. The latter are kept cool by a current of cold air, and the heated air is then passed as secondary air to the burners, which are of the air-pressure design, with a special type of automatic coal feeder, and on the "triplex" principle, the flame being directed downwards into a very large combustion chamber. Finally the latest type of drier, invented since the Lakeside installation, is of a simple vertical design through which the coal passes continuously by gravity, being dried by the waste hot gases in the chimney base, no coal at all being required.

In 1915 the Milwaukee Electric Railway and Light Co. found it necessary to make extensive additions to their power plant and finally planned a new 200 000-kW station, the site for which was purchased in 1916 at Lakeside, 1 mile south of the southern limits of the city of Milwaukee, with 6 000 feet frontage on Lake Michigan. It was decided to equip this huge plant entirely with the Lopulco system of pulverized fuel, because of the very satisfactory experience with this system at the old power station of the company at Oneida-street, Michigan. This latter plant, which is still running, consists of 5 Edgemoor water-tube boilers each of 468 (nominal) American horse-power, and, on the advice of the chief engineer of the company (Mr. Anderson), was equipped with pulverized-coal firing in 1918, after previous tests on one boiler. The result was a great success, although the plant was not built for pulverized fuel and the working of the system was handicapped in various ways, for instance by the absence of economizers.

A very extensive series of tests, each of 17–25 hours' duration and spread over 10 months, was carried out by Mr. Anderson and also by Mr. H. Kreisinger, then of the United States Bureau of Mines, to determine the performance of pulverized Illinois and other low-quality coal under every possible condition, but particularly as regards the fineness of grinding necessary and absence of moisture required for the most efficient working. The net result of the many months' running and almost continual testing on the Oneida-street plant was to show that with the inferior Illinois coal results of 80·20–82·70 per cent efficiency were obtained on long tests with boiler and superheater only, and the average efficiency from month to month was 80 per cent and over.* It was also discovered, as a result of this experience, that it is not necessary to pulverize the coal as finely as was previously thought, the average figure to-day being—as already stated—equivalent to about 90 per cent through a 100-mesh screen and 65 per cent through a 200-mesh screen. What is really required is *uniform* grinding, i.e. not so much 85 per cent through a 200 mesh and a residue of large particles, but, if possible, 100 per cent through a 100 mesh, when 65 per cent through a 200 mesh is ample as a rule. Further, it was early discovered that it was not essential to dry the coal down to 1 per cent of moisture or less, and that in most cases 2 per cent was quite satisfactory, provided the drying was even.

Because of difficulties due to the war, a start was not made with the Lakeside plant until December 1919, but the whole of the present installation was completed and running in December 1920, with a duty of 40 000 kW (50 000 kW at full output), together with much of the buildings, foundations and cooling-water plant for 200 000 kW, whilst at the present time a further 40 000 kW is being installed. The whole plant was designed entirely by Mr. Anderson and the engineering staff of the Milwaukee Electric Railway and Light Co., the Combustion Engineering Co. being responsible for the pulverized-coal section of the plant.

The complete installation is divided into four main parts, the switch-house, the turbine room, the boiler house, and the pulverizing section, the latter being 108 ft. by 125 ft. and at present equipped for pulverizing coal for 80 000 kW. As giving some idea of the size of this station, the full 200 000-kW plant will require 360 000 gallons of cooling water a minute, or 518 000 000 gallons per 24 hours, which will be obtained from the adjoining Lake Michigan.

The present boiler plant for 40 000 kW consists of eight 1 306-h.p. (American) Edgemoor four-pass water-tube boilers, working at 300 lb. pressure and arranged in two sections of four each, one section (with one boiler as a stand-by) supplying one 20 000-kW turbo-generator.

* See also H. D. Savage: "The Use of Powdered Coal under Steam Boilers." Paper read in New York before the American Iron and Steel Institute, 27th May, 1921.

For the full output of 200 000 kW, or 160 000 kW normal running, there will thus be 24 of these boilers, all fired with pulverized fuel.

The principal dimensions of each boiler, normally evaporating 90 000 lb. from and at 212° F. per hour and 115 000 lb. overload, are as follows :—

Number of tubes high	15
Number of tubes wide	38 and 37
Total number of tubes	563
Length of tubes	20 feet
Diameter of tubes	4 inches
Number of steam drums	5
Total heating surface of boiler	13 060 sq. ft.

The boilers are fitted with Foster superheaters of such a capacity as to heat 90 000 lb. of steam per hour from 411° F. (300 lb. pressure) to a superheat of 200 degrees F., i.e. a temperature of about 611° F. Each boiler is also fitted with a Sturtevant cast-iron economizer installation of 7 603 sq. ft. heating surface, with by-pass connection to the chimney, the feed water entering the economizers at 140° F. and leaving at 253° F., i.e. being raised through 113 degrees F. and saving about 10 per cent in the coal bill. The principal dimensions of the economizer installation are as follows :—

Number of tubes wide	12
Number of tubes long	44
Total number of tubes	528
Length of tubes	12 feet
Outside diameter of tubes ..	4½ inches

It is interesting to note that this very modern high-pressure American boiler plant retains the use of the cast-iron economizer. In the author's opinion, the tendency in power station design, especially in Great Britain, to use steel-tube economizers for over 200 lb. pressure is a fundamental mistake. Steel will not withstand for long the corrosive action of the flue gases, and the author is convinced that the resulting excessive wear and tear, breakdowns, and stoppage for replacements are not worth the slight advantages of the steel-tube economizer as regards lightness, convenience, and the somewhat less space occupied, especially since cast-iron economizers can be arranged to work at any given boiler pressure by installing an extra turbine feed pump between the economizer and the boiler.

The plant is fitted with a steam-turbine-driven induced-draught fan for each boiler, discharging into concrete flues 8 ft. 0 in. high and 11 ft. 6 in. to 18 ft. 0 in. wide, leading to two reinforced concrete chimneys 220 ft. high, the diameter at the bottom being 16 ft. 6 in. and at the top 15 ft. 0 in., the main shell being 5 in. thick at the top and 24 in. thick at the bottom, and having also a 4-in. concrete lining for a height of 60 ft.

As regards boiler feed-pumps, the maximum evaporation of the 8-boiler installation is approximately 920 000 lb. per hour, the normal figure being, as already stated, 90 000 lb. per boiler with 6 boilers in operation.

The feed pumps consist of two 6-in centrifugal pumps, driven by 250-h.p. steam turbines and each delivering 39 000 gallons per hour, and two 4-in. centrifugal pumps driven by 150-h.p. motors and delivering 24 000 gallons per hour, so that there is the ample reserve of one steam-driven pump or two motor-driven pumps. The condenser water (at about 80° F.) from the turbine condensers is pumped to an overhead hot-well tank, and falls by gravity through two feed-water heaters, which raise its temperature to approximately 140° F. It then passes through a Lea V-notch feed-water meter of 800 000 lb. per hour capacity, situated above the feed pumps, giving a 15-ft. suction head. It may be stated that the whole plant is so arranged that part of the auxiliaries, e.g. boiler feed-pumps, induced-draught fans, circulating pumps, etc., are steam-driven, the exhaust steam being used to heat the feed water so that it enters the economizers at a temperature well over 100° F. At the same time no latent heat is lost, the balance of the steam required being provided by the house turbine.
